Dennis Gabor, Principal Contributor: Dr. Atkinson, phase coherence is a statement about an established relationship among the phases of physical or reconstructed waves, not merely about two records having the same declared sampling rate. A sampled complex waveform may be represented as $z_k(t)=a_k(t)\exp\{j[\varphi_s(t)-\varphi_{LO,k}(t)+\varphi_{path,k}(t)]\}+n_k(t)$ during measurement interval k. Here a_k is an amplitude, φ_s is the source phase at the receiver reference plane, $\varphi_{LO,k}$ is the effective local-oscillator phase, $\varphi_{path,k}$ accounts for signal-path phase and processing conventions, and n_k denotes noise and modelling residual. The sampled phase is a difference. If the receiver retunes and its oscillator reacquires lock at an arbitrary phase, the first complex sample after the retune does not announce which portion of the new phase belongs to the emitter and which

Copyright 2026, James M. Atkinson

belongs to the instrument. The ambiguity can remain even if frequency accuracy is excellent. A calibrated mapping is required to transfer phase from one acquisition epoch into another.

For coherent summation one ordinarily needs a phase law over both observation windows, including a reference for the interval that was not directly observed. If two signal snippets are $x_1(t)$ and $x_2(t)$, and the second has an unknown constant phase offset α, the sum $x_1(t)+x_2(t)\exp(-j\alpha)$ is an arbitrary family until α is measured or otherwise constrained. One cannot choose α solely to maximise the final coherent amplitude and then use that very amplitude as independent evidence that the signal remained coherent. Such optimisation may be useful as exploratory signal processing, but it does not establish physical phase continuity. Even a single correctly measured sample at each end of a gap leaves the accumulated integer number of carrier cycles ambiguous when the intervening phase trajectory is unconstrained. This is why phase unwrapping, despite its elegance, is not a substitute for information that the receiver did not collect.

A common frequency reference constrains an oscillator's rate and perhaps its slow phase evolution, but it does not necessarily determine a synthesiser divider's startup state. A receiver may restart a phase-locked loop at a different relative phase on each retune. Some hardware permits deterministic phase synchronisation; other implementations require calibration following every frequency change. The apparatus must therefore be characterised in its actual configuration. The operator should not infer deterministic reacquisition from a 'lock' flag, a successful frequency command, or identical numerical carrier settings. Where the architecture supports timed commands, synchronised triggering alone may still leave a

Copyright 2026, James M. Atkinson

stable but unknown phase rotation. A reproducible constant offset is more useful than an unrepeatable one, yet even a constant offset needs a measured value before interferometric or coherent spectral conclusions can rely upon it.

The appropriate bridge is an independently maintained observable. A calibrated pilot signal may be delivered into the receiver chain at a declared reference plane, measured both before and after retuning, and related to a phase-continuous external standard. Alternatively, an uninterrupted parallel channel can observe a common signal component throughout the gap. The pilot or witness must itself possess adequate spectral purity and be measured in a manner that does not create the very discontinuity under examination. It must also be relevant to the frequency band and path being corrected. A calibration performed at one tone may identify a constant complex rotation at that tone, but it may not identify frequency-dependent group delay or an arbitrary phase slope across a wideband channel. Multi-frequency calibration can be needed when the application reconstructs a broad or stepped-frequency aperture.

Consider a receiver which measures a stable test tone at a first tuning frequency, visits another band and returns. In the hypothetical absence of a phase-preserving retune architecture, measured phase after the return may differ from the phase extrapolated from the first interval by an unknown offset of, say, 70 degrees. The number is illustrative; it is not the measured behaviour of any specific product. If the investigator forces the two records into alignment by subtracting 70 degrees, the resulting trace can look continuous, but the adjustment is a calibration only if the 70-degree offset was estimated from an independent reference, not chosen to make the

Copyright 2026, James M. Atkinson

questioned signal match. Where the pilot's phase estimate has standard uncertainty u_α radians, that uncertainty propagates into the coherent sum and into every derived phase-sensitive quantity. The analyst should disclose the phase estimate, the frequency to which it applies, the reference plane, and the uncertainty budget.

A missing interval imposes a further limitation that cannot be fixed by oscillator calibration alone. An emitter may change phase discontinuously or cease transmitting and resume while the receiver is tuned elsewhere. Even a perfectly coherent local oscillator does not establish continuity of the remote source. A phase-preserving receiver and a phase-continuous emitter are separate propositions. To claim continuity of the emitted waveform, the experiment must monitor a persistent correlated reference, establish an emitter model with justified bounds on its phase innovation, or state clearly that continuity is assumed rather than observed. In a forensic report the distinction matters because a reconstructed continuous trajectory can conceal a genuine change in transmitter state, and the resulting error may be far larger than the calibration uncertainty of the receiver itself.

An acceptance test should be deliberately adversarial. Use a laboratory source with a known phase programme, record an uninterrupted witness channel, retune the test channel repeatedly across different frequencies and hold times, and compare post-retune residuals against the witness under varying temperature and input power. Include sudden phase changes confined to the unobserved interval; the reconstruction must not be permitted to pass merely because its smoothing algorithm makes them disappear. Log exact sample counters, tune-command timing, synthesiser lock transitions, calibration signals, gain and filter settings, and any rejected

Copyright 2026, James M. Atkinson

epochs. Test the distribution of residual phase, not only the mean, and repeat across the intended signal bandwidth. If residuals exhibit an uncontrolled mode ambiguity, a reliable coherent aperture has not been demonstrated. My criterion is bounded and physical: coherence may be asserted only for those intervals, bands and signal classes for which the reference transfer and the unobserved source evolution have been independently constrained.

Andrey N. Kolmogorov, Peer Question: Professor Gabor, you distinguish a phase alignment obtained from the observed signal from one independently measured by a calibration channel. Suppose the receiver records only two short bursts of a carrier whose source phase is said to be stable but whose physical oscillator is not accessible. A processor searches many integer-cycle continuations and retains the one giving greatest coherence. What is the statistical population with respect to which the reported alignment should be assessed? How can we quantify the consequence of searching many phase hypotheses when the investigator's strongest-looking solution was selected after inspecting the same data? I also wonder whether a repeatable alignment in one laboratory test proves stability under field conditions where temperature, retune order and the source modulation are uncontrolled. Please distinguish the effect of random calibration error from a discrete phase reset that has several plausible modes, and identify observations that would justify calling one mode physically established rather than merely numerically attractive. A court may otherwise mistake the largest fitted correlation for an independent observation of continuity.

Copyright 2026, James M. Atkinson

Dennis Gabor, Response: Professor Kolmogorov, the observation cannot be interpreted without the selection rule. If the processor chooses the largest of many candidate coherent sums, its distribution under the hypothesis of no persistent phase relation differs from that of a sum formed with a correction fixed in advance. A defensible null experiment must reproduce the entire search, including the permitted phase grid, event-selection rules and quality thresholds. One could process noise-only or deliberately phase-randomised records under the same code, measuring how often a convincing apparent bridge is found. The reported false-alarm rate belongs to that full procedure rather than to one preselected hypothesis. This is particularly important when candidate integer-cycle continuations multiply with gap duration.

I would treat a phase reset with several plausible modes as a mixture problem. If the synthesiser's divider can produce two phase states, for example, an independent pilot may be capable of discriminating them. Without the pilot, selecting the mode that best aligns the questioned carrier is a fitted model, not proof of a unique hardware state. A repeatable laboratory result on one tune path establishes only that path under the tested conditions. It does not automatically transfer to a different divider ratio, temperature or power cycle. Repeated trials should record the distribution of post-retune phase residuals after the correction procedure is frozen, including the frequency of outlying modes and outright lock failures.

A test of generalisation should hold back complete retune sequences, not merely individual samples taken from the same sequence. Build the correction rule from one group of frequencies, temperatures and dwell intervals, then challenge it on a predeclared independent group. Use a

Copyright 2026, James M. Atkinson

continuous witness receiver to record any genuine source phase change during each gap. If the fitted method succeeds only when allowed to inspect the witness or the questioned carrier before choosing its phase, its success is conditional on information that may not exist in the intended field application. The investigator should distinguish measured phase transfer, model-supported extrapolation, and unresolved source continuity. Only the first, accompanied by its uncertainty, can be described as independently established.

The same discipline is required for confidence intervals: optimisation of the correction must be incorporated into the null and alternative procedures, including their stopping and selection rules, rather than omitted from the reported uncertainty.

Maurice S. Bartlett, Peer Question: Professor Gabor, the pilot you propose may be injected at a receiver connector, whereas the questioned radio emission has propagated through an antenna, room, cable assembly and perhaps a frequency-selective preamplifier. If both paths share the digitiser but not the entire analogue transfer function, the pilot may remove a local-oscillator phase reset while leaving source-dependent changes uncorrected. What conditions make the pilot informative for the actual measurand? Would a pilot at one frequency be sufficient for a wideband synthesis, or could a correct phase at that frequency conceal an erroneous group-delay slope elsewhere? Please also examine a pilot whose own distribution path drifts with temperature and a case in which the pilot is present only after the retune. What independent observations would discriminate receiver phase reset, pilot phase movement and changes in the external propagation channel? I ask because a calibration that tracks the wrong pathway may

Copyright 2026, James M. Atkinson

improve the appearance of the data while making the forensic interpretation less reliable.

Dennis Gabor, Response: Dr. Bartlett, the pilot's relevance follows from the transfer function it actually samples. Injection at the receiver connector can characterise the electronic receive chain downstream of that connector, including local oscillator and much of the analogue filtering. It does not measure antenna geometry, mutual coupling, a moving propagation path or phase variation in upstream components excluded from the injection. Therefore the report should identify its reference plane, the signal path shared with the questioned observation, and the uncalibrated elements. A secondary radiated calibration can exercise more of the path, provided its source phase and physical geometry are independently controlled. The two measurements answer related but different questions, and their residuals should not be silently conflated.

A one-tone pilot identifies a phase difference at its own frequency. To infer broad-band coherent synthesis, one may need the phase as a function of frequency. A delay τ in the signal path contributes a phase slope approximately $-2\pi f\tau$ under a specified complex Fourier convention. If the path delay changes by a nanosecond, the phase variation across 100 MHz is $2\pi(100\ \text{MHz})(1\ \text{ns})$, about 0.628 radians or 36 degrees. A calibration at one spot frequency can perfectly remove a constant rotation yet leave this frequency-dependent error. The calculation is illustrative, but it demonstrates why phase and group-delay calibration should be distinguished. Multiple independent tones or a characterised wideband calibration stimulus may be necessary to estimate the slope and its uncertainty.

Copyright 2026, James M. Atkinson

To separate pilot movement from receiver movement, independently observe the pilot before it enters the suspect distribution branch, then compare its phase with a second stable reference at the receiver input. Repeat after cable swaps, thermal changes and return-to-frequency trials. If the pilot was absent during the gap, its post-retune value can identify the current phase offset but may not reveal every event during the absence. An uninterrupted witness channel provides stronger information about the source itself. I would allow the calibration to transfer only across components physically observed or previously characterised, and would declare the remaining source and propagation phase uncertainty separately.

An apparent phase agreement that vanishes when the pilot is moved to a different frequency is evidence of an incomplete transfer function, not proof that the emitter changed its phase.

Dennis Gabor, Cross-Peer Question to Harry Nyquist: Harry Nyquist, your account of the sample clock and local oscillator clarifies that identical timestamps do not guarantee continuous phase. Yet many engineers claim that a deterministic numerical oscillator running against one never-reset sample counter solves the retune problem. Would you examine the exact boundary of that claim when the RF front end also has an independently settling synthesiser and frequency-dependent filters? In particular, can a numerical phase accumulator be continuous while the analogue input-to-baseband transfer acquires a new unknown phase? Would your conclusion change if the receiver performed direct RF sampling without an analogue mixer, or if an FPGA adjusted its digital frequency without interrupting samples? Please give a falsifiable test rather than an architectural slogan. I

Copyright 2026, James M. Atkinson

am asking whether digital determinism should be treated as an end-to-end coherence guarantee or as one verified component of a larger measurement chain whose remaining phase terms still require independent observations.

The proposed experiment must also show which calibration quantities are retained before the retune rather than estimated opportunistically from the later target.

Harry Nyquist, Cross-Peer Answer to Dennis Gabor: Professor Gabor, the numerical oscillator is one state variable, not the whole receive chain. If a digitally generated phase is computed from an uninterrupted absolute counter, its phase at each sample can be determined mathematically, even when the programmed frequency changes. That property is valuable and testable. But if the physical input is first mixed by an analogue synthesiser which reacquires lock at an unknown phase, a deterministic post-ADC numerical oscillator cannot reconstruct the lost analogue phase merely by maintaining its own accumulator. The output is the composition of both operations, and the unknown analogue term survives. Likewise an analogue filter's group delay may change when a preselector or gain state is switched, leaving frequency-dependent phase errors after an otherwise perfect digital rotation.

Direct RF sampling can remove one analogue mixer and its phase-reset ambiguity, but it does not remove every source of discontinuity. Clock multipliers and dividers, switched sampling paths, ADC calibration, digital downconverter resets, and sample loss can still alter phase or chronology. A particularly clean case would be continuous raw RF sampling with an

Copyright 2026, James M. Atkinson

unbroken sample counter and a digital channeliser which visits different analysed bands without changing the analogue acquisition. There, retrospective digital retuning may preserve the same physical time series, subject to filter and representation conventions. But the engineer must demonstrate that the original wideband samples really remained continuous and that none were discarded. A display that hops between channels is not evidence that the underlying capture was wideband and gapless.

The falsifiable test is a phase-continuous injected two-tone or phase-coded stimulus recorded by an independently monitored witness. Execute the complete set of retune commands, including any analogue front-end changes, while measuring input and output phase at defined reference planes. Perform one trial using purely digital post-acquisition retuning and another requiring the analogue synthesiser to reacquire. A genuine end-to-end deterministic phase model should predict the post-retune residual in withheld trials without selecting a correction from the questioned signal. Record any divider-mode dependence, settling, counter gap or recalibration event. Digital determinism is therefore a valuable component of a coherent system only when the remaining physical phases are either preserved or measured.

Dr. James M. Atkinson, Moderator: Mr. Nyquist, Professor Gabor has separated numerical alignment from measured phase continuity. Please take the token to examine how sampling frequency, integer sample counts and oscillator phase are related, and to identify the particular loss of information that follows retuning even where the digitiser never changes its clock rate.

Copyright 2026, James M. Atkinson

Harry Nyquist, Principal Contributor: Dr. Atkinson, it is necessary first to avoid an attractive but false equivalence: an accurately timed sequence of samples does not by itself determine the carrier phase that those samples ought to possess after a frequency change. The sampling clock defines the instants at which a sampled signal is measured. The local oscillator defines the phase of frequency conversion in a heterodyne or complex downconversion path. Both can derive their average rates from a common standard without possessing a reproducible absolute phase relation after a synthesiser retune. In a digital receiver, the numerically controlled oscillator may likewise be restarted at zero phase, allowed to run freely, or recalculated from an absolute sample counter. Those three policies yield different output phase histories despite their identical nominal tuning frequency. The exact policy must be established from implementation and a physical test rather than guessed from the front-panel display.

Suppose that an RF input has instantaneous phase $\varphi_{RF}(t)$ and that a mixing oscillator has phase $\varphi_{LO}(t)$. In an ideal complex downconversion, the observed baseband phase is $\varphi_{BB}(t)=\varphi_{RF}(t)-\varphi_{LO}(t)+\varphi_{H}(t)$, with φ_{H} representing the complex filter and reference-plane contribution. Across a retune, the sample index n may advance monotonically, yet φ_{LO} can gain an unknown offset $\Delta\varphi_{LO}$. If φ_{RF} and φ_{H} remain otherwise unchanged, the baseband phase jumps by approximately $-\Delta\varphi_{LO}$. The result is not corrected merely by writing the same timestamp into both records. It is also not corrected by replacing the sample rate in a software metadata field, since the missing variable is a phase state. A common low-frequency reference, such as a nominal ten-megahertz source, cannot uniquely

Copyright 2026, James M. Atkinson

prescribe the phase of an independently divided gigahertz oscillator without a suitable phase-synchronisation architecture.

The phase of a digital oscillator can be made deterministic when its accumulator state is defined as a function of a shared absolute sample counter and the frequency command, but only if the implementation actually preserves that relation across state changes. If a new command resets the accumulator, the phase is discontinuous even if its phase increment is exact. If an accumulator runs through the retune, there may be a mathematically continuous numerical carrier whose slope changes; however, the analogue path might still switch a synthesiser divider, move a filter, alter automatic gain, or introduce a calibration reset. An auditor should therefore examine both the digitally generated phase and the analogue conversion chain. Verification at the software phase accumulator alone does not cover phase motion that occurs before the ADC.

A particularly important case is synthesis across multiple subbands. Suppose an investigator records three overlapping frequency windows, each with its own unknown phase rotation α_k. Where overlaps contain a sufficiently strong common calibration feature, one may estimate relative rotations. But the graph of overlaps must be connected: a subband with no overlap and no common witness cannot be placed on the same phase reference by algebra alone. With noisy overlaps the estimation becomes a weighted network problem, whose gauge freedom must be fixed by choosing a reference phase. A small residual after fitting may result from a flexible model. The model should be challenged on withheld calibration tones and by returning to a previously observed frequency after visiting unrelated settings.

Copyright 2026, James M. Atkinson

A useful test involves an injected pilot of frequency f_p and a continuous physical reference source. Let θ_{before} be the estimated pilot phase before retuning, θ_{after} the estimated phase following it, and $2\pi f_p \Delta t$ the phase advanced by an ideal stable pilot during elapsed time Δt, all expressed relative to a continuously known clock. A phase residual may be written $r=\mathrm{wrap}[\theta_{after}-\theta_{before}-2\pi f_p \Delta t]$, where wrap returns an angle modulo 2π. The observable r identifies a residual phase modulo complete cycles. It does not alone tell how many integer cycles were accumulated during the gap, nor does it establish the RF source phase at other frequencies without calibration of the transfer function. If the pilot and signal occupy different paths, additional uncertainty belongs in the model; if they share a path, the pilot may still fail to detect signal-specific propagation changes.

One sometimes hears that oversampling or higher ADC bit depth can restore coherence. Those techniques may improve estimation accuracy within the observed intervals, but neither recreates an unmeasured oscillator phase after an uncontrolled reset. At high signal-to-noise ratio an estimator can measure a phase offset to a small fraction of a radian; it remains perfectly capable of estimating the wrong physical object if the chosen reference is itself interrupted. Conversely a modest sampling system with a stable, well-calibrated phase witness may provide defensible relative phase information. The distinction is between measurement resolution and identifiability. A count of digital samples supplies chronology; it does not guarantee that all relevant phase states are observable.

The evidence ledger should therefore include at least the original complex samples, hardware sample counter, local-oscillator control commands, reference-clock identity, synthesiser reset behaviour, filter configuration,

Copyright 2026, James M. Atkinson

phase corrections and their estimated uncertainty, and the independent measurements by which each correction was justified. The investigator should repeat short and long retunes, measure worst-case reacquisition residuals, and test whether transitions behave differently between particular frequency settings. A deterministic mode may exist over a small range even where a different divider boundary causes an arbitrary phase reversal. Consequently it is unsound to certify a receiver as 'phase coherent across retuning' without specifying its permitted retune paths and the conditions under which calibration is repeated. The correct conclusion is conditional: continuous sample time and a common reference can support a coherent reconstruction only when the phase-state transfer is characterised and the signal's own unobserved evolution is separately accounted for.

William Feller, Peer Question: Mr. Nyquist, suppose the receiver is absent from the carrier for a short interval but its sample counter runs without interruption and an external oscillator supplies an excellent frequency standard. The analyst assigns an integer number of cycles to the gap and concludes that the later burst belongs to the same phase trajectory. How should the uncertainty of that integer assignment be evaluated when the carrier frequency estimate itself has statistical error and the emitter may possess random-walk phase fluctuations? Is there a point at which several cycle counts become equally compatible with the observations? I should also like to know whether simply increasing the sample rate before and after the gap makes the integer choice more reliable. Finally, distinguish a calibrated local-oscillator reset from an actual phase change at the transmitter, because the post-gap observations may be identical under those two

Copyright 2026, James M. Atkinson

mechanisms. Please give a rigorous interpretation of an unresolved integer ambiguity.

Harry Nyquist, Response: Professor Feller, the number of accumulated cycles during an unobserved interval depends on the integral of the true instantaneous frequency. If the gap length is Δt and the frequency error is $\delta f(t)$, the uncertain phase advance contributed by that error is $2\pi\int\delta f(t)dt$. With a constant uncertain frequency error δf, the scale is $2\pi\delta f\Delta t$; if δf is stochastic, the uncertainty depends on its covariance over the gap. At sufficiently large uncertainty, several integer-cycle continuations may be compatible with the observed endpoints. A phase measured modulo 2π cannot distinguish them without additional information. Reporting one selected integer as though the instrument observed it would replace an inference with an invented event history.

Higher sample rate improves the temporal density of the observations that exist, and can improve phase estimation under appropriate signal and noise conditions. It does not directly observe the carrier while the receiver is tuned elsewhere. If the pre-gap phase is measured accurately, and the post-gap phase is measured equally accurately, an unknown cumulative phase advance may still have multiple possible cycle counts. An independent pilot or uninterrupted witness can constrain that advance; alternatively a validated bound on frequency drift and modulation may limit the admissible integers. The bound must include the emitter dynamics as well as receiver-clock uncertainty. An arbitrary claim of source stability, adopted solely to force unique unwrapping, is insufficient.

Copyright 2026, James M. Atkinson

A local-oscillator phase reset and a transmitter phase step can create the same difference in observed baseband phase at one receiver. To distinguish them one may compare an independently clocked receiver observing the transmitter continuously with a local calibration signal injected into the retuned receiver. If the independent receiver shows source continuity while the pilot shows a receiver reset, the ambiguity can be narrowed. If both independent observations are absent, the cause may remain fundamentally nonidentifiable. The proper result is then a set of compatible hypotheses or an interval for phase advance, not a fabricated exact count. This is a limitation of available evidence, not a defect cured by more decorative decimal places.

The uncertainty budget should record the time interval and spectral model used to establish the bound, not merely a numerical guess at the number of missed cycles.

Harry Nyquist, Cross-Peer Question to Rudolf E. Kálmán: Professor Kálmán, the sample-count discussion yields an ambiguity which a dynamic estimator might try to eliminate by predicting through the retune. What state representation would you require when the local oscillator can restart in one of several phase modes and the emitter may independently step phase? Can a single linear Gaussian filter preserve the true range of possibilities, or must the reconstruction maintain distinct hypotheses until a calibration observation discriminates among them? Please also examine what happens when the filter's covariance shrinks after reacquisition because it has absorbed post-gap samples of the questioned signal. Does that narrow covariance establish an objectively correct phase bridge, or only internal consistency under the model? I would value a criterion for when

Copyright 2026, James M. Atkinson

such a filter may support coherent integration and when the engineer must return to noncoherent processing.

Please state whether the model is falsified if a withheld retune gives residuals outside its claimed phase interval.

Rudolf E. Kálmán, Cross-Peer Answer to Harry Nyquist: Mr. Nyquist, a single linear-Gaussian filter is an approximation whose adequacy depends on the shape of the posterior uncertainty. If a divider reset allows phase states separated by π radians, for example, the posterior may be bimodal. A single mean located between the modes can describe neither physically plausible state. One should retain a mixture representation, an explicit discrete-mode variable, or parallel estimators conditioned on the alternative reset hypotheses. The emitter's possible phase step is another latent variable; unless an independent witness constrains it, the system can confuse emitter and receiver changes. A clever filter does not create an observation that the sensing arrangement failed to make.

Covariance contraction after reacquisition may be entirely legitimate for the state actually observed. But if the update uses only the questioned signal, and the selected mode was chosen to make that same signal continuous, the covariance is conditional on the mode assumption and the fitted source model. The engineer should report mode probabilities or alternative trajectories where justified, not conceal model uncertainty in a small conditional standard deviation. There is also a distinction between estimating post-gap phase accurately and establishing the integer-cycle history through the gap. A tight estimate at the endpoint does not automatically determine that history.

Copyright 2026, James M. Atkinson

A coherence acceptance criterion should be tied to withheld predictions. Use calibration runs with known oscillator resets and programmed source phase steps; estimate correction parameters from the allowed calibration stream, then evaluate residual phases in independent test intervals. If the procedure correctly identifies the mode with a declared error rate over the relevant tune paths, it may support coherent integration within those boundaries. If multiple modes remain or the source dynamics can invalidate the bridge, separate the windows or combine them noncoherently. The analyst should publish the state assumptions, transition model, observation matrix, process-noise treatment and every excluded interval. What matters is whether the reconstruction predicts an independent observable, not whether its own smoothed display appears persuasive.

The withheld trial supplies an external challenge to the model, which internal covariance reduction cannot provide on its own. The appropriate validation must include the full family of retune paths anticipated in the field, including those not used to estimate transition parameters. Otherwise apparent predictive confidence can be an artefact of a narrow experimental design.

Dr. James M. Atkinson, Moderator: Professor Kálmán, I should like you to distinguish a measured post-retune phase from a state inferred by prediction. How does an estimator carry uncertainty through a period when the receiver has not observed the carrier, and when should the correct result be a family of possible phases rather than one elegant but unjustifiably precise curve?

Copyright 2026, James M. Atkinson

Rudolf E. Kálmán, Principal Contributor: Dr. Atkinson, the central issue is observability. A dynamic model may predict how a phase state would have evolved during an interval without measurements, yet it cannot establish that a physical system obeyed the model when the relevant disturbances are unknown. Let the state vector x_k contain carrier phase, frequency offset and perhaps frequency drift at discrete epoch k. A simple model is $x_{k+1} =F_k x_k+w_k$, where F_k propagates the state and w_k describes process disturbances, with covariance Q_k. Measurements take the form $y_k=H_k x_k+v_k$, with measurement noise covariance R_k. These equations are useful only if their state definitions, linearisation, and disturbance statistics represent the physical receiver and source. Across a retune the observation matrix may be absent or rank-deficient; the estimator then predicts but does not receive new phase evidence from the unobserved carrier.

For a linear-Gaussian model the predicted covariance is $P_{k+1|k}=F_k P_{k|k}F_k^T+Q_k$. During a gap, that covariance ordinarily grows because process uncertainty accumulates. If the filter reports a narrowing phase uncertainty solely because it has imposed a smoothness assumption, the engineer should inspect whether Q_k has been unrealistically reduced. Oscillator phase noise, frequency drift, sudden re-lock errors and source modulation may not share a convenient stationary Gaussian law. A discrete random phase reset calls for a mixture or multiple-hypothesis model, not for the continuation of one Gaussian phase state across a transition that the instrument did not record. The phase variable is circular as well; ordinary linear covariance in radians can misrepresent a distribution that wraps around ±π or contains separated phase modes.

Copyright 2026, James M. Atkinson

Consider a hypothetical carrier with initial frequency error uncertainty of one hertz and a retune gap of 0.25 seconds. Even neglecting all other disturbances, the resulting uncertain phase advance has a scale $2\pi(1\ \text{Hz})(0.25\ \text{s})=\pi/2$ radians, or 90 degrees. The number is a simplified sensitivity scale, not a complete standard uncertainty calculation, because the frequency error may change during the gap and its distribution matters. The example nevertheless shows why a small frequency uncertainty can become a material phase ambiguity after enough unobserved time. Extending the gap by a factor of four multiplies this simple phase sensitivity by four, whereas a fresh independent pilot measurement could reduce it if that measurement truly bridges the required phase state. This is a dynamical observability question, not a count of digits on the clock display.

A retuned receiver introduces at least two additional latent states. The first is the initial phase of its re-acquired local oscillator, possibly with a discrete ambiguity due to synthesiser division. The second is the phase transfer of the selected analogue and digital filters. They need not share one distribution, and their errors may be correlated with temperature or gain settings. An estimator that collapses both into a free scalar rotation can align a single calibration tone, but it may fail to correct frequency-dependent dispersion across the measurement band. A properly designed state model distinguishes constant phase offset, group delay and higher-order phase variation. To estimate all three, the calibration signals must span sufficient frequency diversity and the measurement geometry must make the parameters distinguishable. Adding parameters without independent observations makes the fitted record look adaptable, not necessarily accurate.

Copyright 2026, James M. Atkinson

The relation between phase measurement and source behaviour is especially hazardous. Suppose a legal defensive receiver observes a periodic burst before retuning and again afterwards. A state estimator predicts the phase of the burst carrier through the gap using the measured pre-retune frequency. But the emitter could have changed synthesiser state, stopped and restarted, or employed intentional modulation. If those possibilities are not excluded by a reference channel, the estimator's continuity is a statement about its imposed source model, not the actual transmitter. The appropriate evidence report may give multiple candidate trajectories, with their assumptions and probabilities only where justified. It may also declare the inter-window phase relation unidentifiable. Such a result is scientifically stronger than presenting one curve supported by an untested prior.

One useful experiment would produce a programmed calibration waveform through a controlled test source. Include known phase steps at unpredictable times within the receiver's retune gaps, while a separate uninterrupted measurement instrument records the true programme. Fit the estimator without access to the hidden phase-step schedule and evaluate whether its confidence intervals cover the withheld truth under each test condition. Repeat with different signal-to-noise ratios, retune delays, and oscillator holdover periods. Where the estimator systematically assigns undue confidence to incorrect phase continuity, revise its transition model or reject coherence claims for that mode. A second experiment should return to the initial tuning frequency and compare predicted phase to an independently measured pilot, detecting calibration hysteresis.

The audit should store prediction and update states separately, with the covariance and innovation sequence at every stage. Record the time of each

Copyright 2026, James M. Atkinson

tune command, the instant the hardware actually resumes valid samples, the model version, any calibration data used to set the phase offset, and any samples excluded as transient. An engineer may perform coherent combination over calibrated windows while allowing a discontinuity in the model at each retune. This is preferable to silently bridging the gap in the raw waveform. Coherence is an experimentally limited property of the reconstruction, not a perpetual attribute conferred by a single disciplined reference clock. A defensible statement is therefore narrower: within measured calibration uncertainty and an explicitly bounded source-dynamics model, selected windows are consistent with one phase reference. Beyond that boundary the result is prediction, not observation.

Sir David R. Cox, Peer Question: Professor Kálmán, your state estimator can carry a distribution of predicted phase across a retuning interval, but the observing instrument may switch preselectors, reset a synthesiser, and enter a settling state that is neither stationary nor characterised by a single Gaussian perturbation. How would you design a validation experiment that identifies which part of the apparently coherent post-retune record comes from measurements and which part comes from an imposed dynamic model? Consider both a continuous injected pilot and a genuine intermittent RF source whose phase trajectory is not known. Would a narrow confidence band around a model-predicted phase be meaningful if the hardware transfer function has changed without entering the model? In particular, how would you test for bias that appears only after several sequential retunes, rather than in the customary single return-to-frequency trial? I ask for a criterion by which the instrument operator could reject the

Copyright 2026, James M. Atkinson

reconstruction even when its plotted phase trace looks smooth and its software reports normal lock.

Rudolf E. Kálmán, Response: Sir David, validation must separate the physical observations, the assumed state transitions and the state that the filter predicts. I would first write an explicit transition equation with a mode variable for each retune path. In one mode the analogue oscillator might preserve an established phase relationship, in another it might reacquire at one of several possible divider phases, and in a third a change of preselector could introduce an unknown frequency-dependent phase shift. The estimator cannot assign small uncertainty to an unmeasured switch state merely because its ordinary locked-mode noise is small. Either the transition parameters must be calibrated independently or the posterior distribution must retain the unresolved alternatives.

A proper experiment therefore requires a continuous phase witness at a declared reference plane, hardware sample counters and timestamping, together with a separate pilot which experiences the relevant receiver signal path. Randomise the order of retunes and include paths not used for fitting. Assess whether predicted phase residuals for withheld transitions fall within the claimed coverage interval. A model predicting nominal 95 percent coverage should be examined across enough independently repeated trials to test that assertion, whilst recording dependence between trials and environmental changes. It is insufficient to fit the filter on the first fifty retunes and then quote its internal covariance as the error estimate for those same fifty. Such a statistic describes consistency with its assumptions, not an independent measurement of phase continuity.

Copyright 2026, James M. Atkinson

For an intermittent source the more difficult problem is identifiability. A continuous pilot can identify instrument phase only over the range of phase-transfer behaviour it actually probes. It cannot independently establish the signal phase accrued while the transmitter was silent. If the source model is uncertain, the estimator must propagate that uncertainty separately. A controlled pilot at two frequencies may expose a filter-delay error hidden by a single-frequency correction; a sequence of retunes over temperature may reveal drift or hysteresis not present in short trials. Failure on any withheld condition should suspend the global coherence claim until the transition model has been revised and independently tested. A smooth line is a possible numerical consequence of interpolation and filtering. It is not itself a datum proving continuity.

Rudolf E. Kálmán, Cross-Peer Question to Martin Ryle: Sir Martin Ryle, in your account of multichannel direction finding a small phase offset can change the inferred bearing. Suppose an estimator assigns a sharply peaked posterior phase correction after retuning because several receiver channels agree. Would that agreement constitute independent calibration if all channels derive their oscillator phase from one distribution network, or if a common path-model error affects every antenna? Please distinguish error cancellation in a differential phase estimate from the evidence required to justify an absolute phase bridge across missing observations. I would also ask how a practical laboratory trial should expose a fault that preserves pairwise receiver differences yet corrupts the phase of the entire array relative to an independently observed transmitter. The experimental criterion needs to survive changes of antenna baseline, pilot placement and retune sequence, otherwise a narrow covariance may simply be a product of

Copyright 2026, James M. Atkinson

a shared and untested assumption. Please specify whether an independent phase monitor would distinguish these explanations when pairwise errors cancel.

Martin Ryle, Cross-Peer Answer to Rudolf E. Kálmán: Professor Kálmán, multichannel agreement is strong only to the extent that the channels possess relevant independence and their phase differences are observable at the reference planes used by the inference. An error shared identically by all channels can cancel from pairwise phase differences; the array may therefore retain good relative bearing capability while lacking evidence of absolute phase continuity through a retune. The converse also matters. A reference distribution fault that changes one branch but not the others can alter measured baselines and produce a biased bearing despite a well behaved central oscillator. The array's covariance model must reflect these distinctions instead of assigning independence by counting receiver boxes.

I would conduct a geographically and electrically controlled trial with an emitter or injected wavefront at known phase and location. Observe it through a separate continuously recording reference receiver whose clock and signal path do not share the questioned reset mechanism. Then execute the array retune sequence under test and compare the recovered pairwise phase, absolute transfer phase and resulting bearing against the independent witness. Repeat after changing antenna baseline, rotating the apparatus, exchanging reference branches and moving the calibration feed to alternate points in the receiver chain. A phase model that predicts one reference plane but not another should be described as limited to the former. One successful baseline is not proof of an end-to-end calibration generalising to every field geometry.

Copyright 2026, James M. Atkinson

Where a common-mode phase disturbance cancels in the differential result, that cancellation is a useful design property, but it is not an observation of the omitted absolute information. Where retuning interrupts sample collection, an estimator may bridge the gap using a physical model and constrained source dynamics; any location estimate relying on that bridge must disclose the bridge's uncertainty. If the model fails an independent test, a noncoherent or separately epoch-calibrated analysis may remain valid. The scientific aim is not to insist that every retune destroys all useful inference, but to identify precisely which inference survives the retune and what measurements warrant it. The experiment must retain the underlying calibration files and branch settings so that a later reviewer can independently compute the reported residuals and challenge any common-error assumption.

Dr. James M. Atkinson, Moderator: Sir Martin, please consider the practical receiver and antenna array. If separated spectral windows are to form a synthetic aperture or a coherent direction-finding observation, what controls must transfer phase through the actual RF paths rather than just through the software that displays the records?

Martin Ryle, Principal Contributor: Dr. Atkinson, the construction of a coherent array begins with the physical signal path. A shared sampling standard, common timing pulse and frequency plan are useful, but each receiving branch also includes an antenna, feed, cable, amplifier, mixer, filter and digitiser whose complex transfer function may change with tuning, temperature and time. In an array the measurable quantity is often a phase difference between stations or antenna elements, not the absolute phase of one source. Retuning can alter that difference even if the clock remains

Copyright 2026, James M. Atkinson

disciplined. The instrument must therefore demonstrate reproducible relative calibration at each selected tuning state, and any interpolation between states must be independently tested rather than accepted from a nominal phase plot.

A simple two-channel model makes the distinction evident. Let the desired electric field at antenna i be $E_i(f)$, and let its complete receiver transfer function be $H_i(f,t)$. The recorded complex value is $y_i(f,t)=H_i(f,t)E_i(f)+n_i(f,t)$. A comparison y_1/y_2 depends on the ratio H_1/H_2 as well as the actual field ratio. If retuning changes the phase of H_1 by 40 degrees but H_2 by 10 degrees, the measured relative phase shifts by 30 degrees even though the external wavefront is unchanged. The values are hypothetical. A stable common reference does not make the two H_i phases equal; it provides a framework on which calibration may be built. The relative transfer needs measurement at the relevant frequency and time.

The geometry and the retune schedule can produce a more subtle error. When two antenna channels sample one emitter simultaneously, the relative carrier phase contains information about path-length difference. If they instead sample at different moments, any emitter drift, movement or propagation variation can be mistaken for a spatial phase difference. The analyst must distinguish simultaneous coherence from time-interleaved coherence. A synthetic wideband measurement can be assembled from sequential subbands only if the target remains sufficiently stationary, or its evolution is measured and corrected. The more rapidly the scene changes, the less defensible it becomes to combine widely separated observation epochs into one instantaneous aperture. The burden is not removed by excellent local oscillator stability.

Copyright 2026, James M. Atkinson

A calibration arrangement should inject a common phase-known test signal at a set of clearly defined reference planes. Input calibration at each receiver connector characterises much of the electronics but not the antenna, mutual coupling or propagation. A radiated calibration source incorporates more of the external path but introduces its own geometric and environmental uncertainty. A robust programme uses both where justified. One should test phase offsets after cold start, repeated short retunes, extended dwell at other frequencies, return to an earlier frequency, and changes in gain or filter state. A multi-tone or swept calibration may be needed to characterise group delay and frequency dependence. The investigator should retain the calibration raw observations, not only the final compensation coefficient.

Where subbands overlap, the overlap provides a self-consistency check but not necessarily an absolute calibration. A least-squares fit can estimate phase offsets that make neighbouring bands agree. Yet if all bands share an incorrect propagation model or a receiver-induced spur, agreement may be physically misleading. The overlap should therefore be challenged with an independent calibration source and repeated after a change expected to alter a known component of the system. I would particularly test for a frequency-dependent linear phase term: an uncorrected group delay τ produces phase variation $-2\pi f\tau$ under a declared Fourier convention. A constant phase offset calibrated at one f cannot remove that slope at all frequencies. The resulting wideband impulse response can be distorted even though a narrow calibration tone aligns perfectly.

In direction finding the consequences can be quantified. For a two-element baseline of length d, an incoming plane wave at wavelength λ has an ideal

Copyright 2026, James M. Atkinson

relative phase related to $2\pi d \sin \theta/\lambda$ under a chosen geometry and angle convention. An error in the instrument phase is therefore liable to bias the inferred angle, especially where the derivative of phase with respect to θ is small or the baseline yields ambiguities. The engineer should propagate uncertainty through the actual geometry instead of converting degrees of phase directly into a universal angular error. Multipath and polarisation mismatch may create additional phase changes that no instrument-only correction can remove. One must not label all residuals 'clock errors' merely because the model contains a clock parameter.

The practical acceptance protocol must include measured timing alignment, lock-state supervision, repeated phase-transfer calibration, sample-loss detection, independent reference monitoring and demonstrations on test emitters at known positions. Review the performance immediately before and after retuning and exclude unsettled acquisition intervals from coherent processing unless those transients are themselves modelled and verified. Record actual rather than nominal tune-completion times. Use distinct test angles and frequencies to reveal a compensation method that works only at one calibration point. A negative result should be stated plainly: if the calibration connection disappears or the source evolution cannot be bounded, the separated observations may still be analysed noncoherently but must not be represented as one fully phase-continuous aperture. That restriction protects the investigator against false precision and false attribution.

William Sealy Gosset, Peer Question: Sir Martin Ryle, a calibration campaign may repeat one return-to-frequency operation many times, yielding a very small measured spread of phase corrections. An author then

Copyright 2026, James M. Atkinson

claims that the system will maintain coherence under any frequency-hopping survey. How would you evaluate the relevance of that experimental sample to an operational collection of retune paths, including different frequency separations, synthesiser-divider boundaries, temperature changes and waiting times? In particular, could a large number of highly correlated repetitions provide less information than a smaller collection that explores the actual instrument operating envelope? Please explain how an investigator ought to state an uncertainty bound for a particular retune sequence without either exaggerating the device's universality or dismissing the genuinely useful repeatability demonstrated under controlled conditions. How could the final calibration record be structured so that a later reviewer distinguishes repeated trials from genuinely independent challenges of the instrument model? I ask also how confidence limits should be modified when thermal drift creates correlation between successive experimental observations.

Martin Ryle, Response: Mr. Gosset, the measurement sample must represent the configurations to which its conclusion will apply. One thousand consecutive returns between the same two synthesiser settings at constant temperature may estimate short-term repeatability under those conditions with considerable numerical precision. It need not characterise the phase after switching a preselector, crossing a divider boundary, changing input frequency by an octave, or restarting a PLL after prolonged inactivity. The apparent sample size is also misleading if the trials share one slow oscillator drift or calibration reference error. Treating all trials as independent merely because the measurement file contains a thousand rows would understate uncertainty.

Copyright 2026, James M. Atkinson

I would stratify the testing by actual retune path, frequency separation, dwell time, temperature, receiver configuration and reference-source state. Randomise the order within practical constraints, then reserve complete classes of transitions as withheld verification cases. Repetition within each class measures conditional scatter, whilst comparisons between classes expose systematic phase offsets and interactions. A statistical model can be useful, but it should include shared reference effects and any observed hysteresis. If a rare retune mode is operationally possible but scarcely tested, the report should not award it the same phase-transfer confidence as the well measured modes. The proper result may be a lookup table of validated transitions with separate uncertainty intervals and explicitly unqualified combinations.

The instrument's physical behaviour must be documented with the statistics. Record the exact frequency commands, observed lock times, raw phase witness, calibration input, hardware counters, branch configuration and environmental state. The record should identify the number of independent runs, not only the number of numerical samples. If the receiver returns to frequency while a continuous reference pilot remains visible, that proves a more narrowly defined calibration property than a system that lacks any continuous witness during the operational gap. An engineer can honour excellent repeatability under tested conditions while refusing to extrapolate that repeatability beyond the evidence. Such limits make the acceptance claim more useful to an investigator who needs to know whether a specific retune path is defensibly phase-coherent. The final uncertainty should therefore distinguish repeatability conditional on one

Copyright 2026, James M. Atkinson

configuration from uncertainty associated with extrapolation to an untested configuration.

Martin Ryle, Cross-Peer Question to Norbert Wiener: Professor Wiener, suppose the array uses an adaptive coherent combiner whose phase corrections are selected to maximise a receiver signal while the emitter is intermittent and the array has been retuned repeatedly. The result may show a convincing beam at one bearing, but the same algorithm could perhaps fabricate a directional preference from correlated channel noise and shared clock transients. How would you design the negative controls and model comparisons to keep that possibility visible? Please address whether maximising phase agreement should be regarded as an inference about the signal's source, as an instrumental calibration, or merely as a data-dependent detection statistic. I would also value your view on the evidential consequences when the operator has never measured the post-retune response of the actual antenna-plus-receiver chain at the relevant frequency. Could a low residual still coexist with a wrong bearing because all channels share an incorrect phase-transfer model? I am particularly concerned about whether a visually coherent result survives independent reference substitution.

Norbert Wiener, Cross-Peer Answer to Martin Ryle: Sir Martin, the output of an adaptive combiner is a statistic of the observed samples and the permitted family of phase weights. Its interpretation depends on whether the weights were independently calibrated, fixed before seeing the questioned signal, or fitted to that same signal. If the weights are fitted, their optimisation is part of the detection test. A peak at one bearing can reflect a real incoming wave, but it can also reflect correlated noise, a

Copyright 2026, James M. Atkinson

common clock transient or an inaccurate array manifold. The beam pattern itself does not identify which explanation generated the peak. A low residual under one fitted model may coexist with substantial location bias if all channels share a calibration error that the model cannot represent.

The controls should include a physically disconnected or terminated input trial under the same retune and clock conditions, an independently generated known source at multiple bearings, and an alternate receiver configuration with a distinct reference path. Simulated null data may supplement these tests when the simulation faithfully includes correlated disturbances and filtering. Record every searched bearing, phase-correction rule, calibration parameter, and rejected interval; then derive the null distribution for the maximum search statistic, not the value at a bearing selected after inspection. Compare the algorithm's prediction on withheld calibration sources with its fit on the training sources. A model whose apparent precision collapses on withheld bearings has not demonstrated generalisable measurement accuracy.

The category of the result should be stated plainly. An independently calibrated phase transfer supports a physical phase-comparison inference within its uncertainty. A self-calibrating beamformer can be a useful adaptive detector, but does not automatically supply an independent measurement of the true phase accrued during missed time. A retrospective phase search that reports one strongest-looking emitter hypothesis can be presented as exploratory with the proper multiple-search qualification. Where the actual antenna-plus-receiver transfer function has not been measured at the operating frequency, the analyst should include a model-discrepancy term or withhold precision attribution. The proper objective is a

Copyright 2026, James M. Atkinson

bounded and reproducible finding, not an optimised diagram that looks more certain than the instruments permit. It is the empirical out-of-sample behaviour, not the smoothness of the fitted beam, that should govern a precision claim.

Dr. James M. Atkinson, Moderator: Professor Wiener, please close the principal round by addressing statistical coherence. How does one distinguish a physically stable relation across retunes from an algorithm that finds whichever phase rotations maximise correlation, and what evidential tests are needed to avoid declaring the same data both a calibration and proof of its own validity?

Norbert Wiener, Principal Contributor: Dr. Atkinson, coherent combination is often presented as a computational operation: align complex sequences and sum them. In an experimental science it is instead an inference about the phase relation that would have existed at a common reference plane. The estimated rotation between two records must therefore be regarded as a random or uncertain parameter with a provenance, not as an invisible editing convenience. When a correlation algorithm chooses a phase to maximise a statistic, the fitted statistic is subject to selection bias. It will improve even on many data sets that contain no physically continuous source phase. The strength of evidence must be assessed on independent data or with a valid null distribution that accounts for the selection procedure.

Let $x_k[n]$ denote complex samples in retune epoch k, and let α_k represent the estimated phase correction. A common processing form is $S[n]=\Sigma_k w_k x_k[n]\exp(-j\alpha_k)$, where w_k are weights and any necessary time and

Copyright 2026, James M. Atkinson

frequency alignment has already been defined. The expression is not self-justifying. If the α_k are measured from an independent calibration pilot, their uncertainty is part of the coherent sum. If they are fitted by maximising $|S|$ using the same signal being investigated, the analysis should describe an adaptive statistic and estimate its false-alarm behaviour accordingly. A result that appears far above the noise floor after maximisation may include the benefit of searching many allowed phase configurations. Its evidential weight cannot be assigned as though α_k had been specified beforehand.

The phase-correction errors can be analysed by their characteristic functions. For a hypothetical zero-mean Gaussian phase error ε of variance σ_φ^2 radians squared, the expected complex phasor $\exp(j\varepsilon)$ has magnitude $\exp(-\sigma_\varphi^2/2)$. That is one precise way to describe coherence loss under a particular distributional model. If σ_φ is 0.5 radians, the factor is exp(-0.125), approximately 0.8825. But phase-reset errors may be multimodal, wrapped or correlated across epochs, in which case this convenient Gaussian calculation does not apply. A narrow histogram obtained from repeated identical tune commands may also be unrepresentative of transitions across synthesiser divider boundaries. The correct error distribution should be measured over the intended range of frequencies and operating conditions.

A coherent gain calculation likewise needs an explicit baseline. Suppose N equal-amplitude observations contain independent noise with identical variance and a common source phase that has been correctly transferred. The coherent signal amplitude grows proportionally to N while the incoherent noise amplitude grows approximately as sqrt(N), yielding a signal-to-noise improvement proportional to N in power when the

Copyright 2026, James M. Atkinson

assumptions hold. Unknown random phase offsets can destroy that gain; deliberate fitting of the offsets to noise can create a biased estimate of gain. If measurement intervals have correlated noise, unequal sensitivity or phase corrections inferred from the same observations, the simple scaling no longer holds. The analyst should report the actual weights, covariance, selected windows and calibration uncertainty, and test performance against a source whose phase history is known independently.

A robust comparison requires three analyses of the same acquisition set. The first is noncoherent accumulation, which does not rely on a phase bridge. The second is coherently combined processing with phase corrections fixed from an independent pilot. The third, clearly labelled exploratory, permits data-driven phase search. Compare their behaviour on an authorised reference signal and on null or noise-only intervals processed with exactly the same search rules. If the exploratory method produces apparent coherent gain even in the null control, that fact must enter the false-alarm model. One may also divide the calibration data into training and test epochs: fit phase-transfer parameters on one set and evaluate their ability to predict withheld retunes. A method that only aligns the training set has not demonstrated transferable calibration.

Uncertainty must be carried forward to any downstream inference. In a correlation-based direction-finding system, a phase-calibration residual may bias the inferred bearing. In a reconstructed wideband impulse response, a frequency-dependent phase error may broaden the response and move its apparent delay peak. In an evidence statement, a gap that was filled by model prediction must not be described as an observed signal. The investigator should therefore retain raw unmodified records and a fully

Copyright 2026, James M. Atkinson

reproducible map from each sample to its source epoch, correction parameter and uncertainty. Software version, calibration-data selection, rejected samples and independent witness observations are material parts of the experiment.

Finally I would reject a universal declaration of 'coherent across retuning'. The correct quantity is a demonstrated, configuration-specific distribution of phase-transfer error and source-model uncertainty over specified retune paths, frequencies, temperatures, dwell times and observation durations. An implementation may support reliable coherence for repeated tuning between two closely spaced bands, yet fail after a long excursion or power interruption. It may align a continuous laboratory source but not an intermittent field transmitter. Where the uncertainty becomes too large, the scientifically valid option is to return to noncoherent processing or to present alternative phase hypotheses. The result remains useful, but its limitations are visible. The purpose of the experiment is not to produce the smoothest possible trace; it is to determine whether the smoothness observed is genuinely supported by physics and independent measurement.

Egon Sharpe Pearson, Peer Question: Professor Wiener, a phase-reconstruction programme may tune its regularisation settings, rejection thresholds and preferred pilot channels until the coherent output of a weak RF signal becomes strikingly strong. A report might then apply a fixed-threshold false-alarm rate estimated before those choices were made. How should the procedure account for the many opportunities the analyst had to obtain an apparently convincing result? Suppose the same processing also discards epochs whose fitted phase disagrees with the selected hypothesis, thereby creating a narrow retained residual distribution. What kind of

Copyright 2026, James M. Atkinson

independent challenge would make that reported gain meaningful rather than a consequence of fitting, selection and retrospective exclusion? I would like to know whether a test set of known signals is sufficient, or whether an explicit null-data challenge and a record of all attempted processing configurations are equally important in reaching a bounded forensic statement. Include the analyst's choice among multiple source-model families in that record of attempted comparisons.

Norbert Wiener, Response: Mr. Pearson, an adaptive decision procedure must be evaluated as the whole procedure that was actually applied. If an analyst explores many phase corrections, integration windows, pilot choices and rejection thresholds before choosing the one yielding the largest statistic, the null distribution is not the distribution of a single fixed statistic. The exploration must be included in the test, or a genuinely untouched data set must be reserved for confirmation after the method has been fixed. Merely reporting the selected run with a nominal false-alarm rate calculated for an unselected result gives the reader the wrong experiment.

I would insist on a complete processing ledger. It should retain the original data, the proposed transformations, rejected epochs and reasons for rejection, parameter searches and trial counts, and the final decision rule. Apply that recorded procedure to null or negative-control data in which the phase relation is deliberately absent, as well as to known positive-control signals captured independently of the suspected event. The null data need to preserve relevant correlations, noise structures and receiver state changes; replacing them with idealised white noise may be too easy a test if the real instrument produces correlated transients. In addition, a withheld set of genuine retune transitions should assess whether calibration

Copyright 2026, James M. Atkinson

parameters estimated elsewhere predict phase independently of the tested signal.

One must also distinguish useful data quality control from selection that is driven by the desired conclusion. A predeclared rule excluding samples during a documented receiver-overload interval is defensible if the excluded interval is still reported. A post hoc rule rejecting every epoch that weakens the coherent fit can bias the conclusion. The report should give results with and without contested exclusions when feasible, including sensitivity to alternative phase hypotheses. Where the adaptive procedure improves signal detection but cannot establish the absolute phase trajectory, it may be described as an exploratory detector. That is valuable, but a claimed physical reconstruction of continuous carrier phase demands separate calibration evidence. A correct false-alarm statement is a claim about the whole tested decision process, not merely its most pleasing output. Independent replication with a predetermined decision rule supplies a stronger test of claimed detection performance.

Karl Pearson, Peer Question: Professor Wiener, if phase corrections were estimated from a shared pilot distributed to several receiver channels, an analyst might quote a small standard error for each channel and treat all those corrections as independent in the coherent sum. But a pilot-source phase disturbance would affect every estimate, and a temperature-dependent distribution cable could create further covariance. How should the final gain or phase-confidence claim reflect shared errors, especially when several receivers are combined and the number of apparent observations is large? Would increasing the number of receiver channels overcome a systematic pilot error, or might it merely make the wrong phase

Copyright 2026, James M. Atkinson

solution appear more repeatable? Please distinguish a common-mode error that cancels from the desired differential result from one that changes the physical quantity being inferred. I also ask how an operator might measure cross-channel dependence rather than assume it negligible for convenience. The common pilot must be assessed as an actual physical component of the measurement model.

Norbert Wiener, Response: Mr. Pearson, the uncertainty of a coherent combination depends upon the covariance structure of the phase corrections and the noise, not solely on the marginal uncertainty of each channel. If the phase error in channel i is $\varepsilon_i=c+u_i$, with c a common pilot or reference error and u_i a channel-specific term, the variance of their mean under the simplest independent-component model is $\mathrm{Var}(c)+\mathrm{Var}(u_i)/N$ for N equally weighted channels. The common component does not shrink as channels are added. For a differential phase between channels i and j, however, an exactly common c cancels, leaving u_i-u_j. That cancellation can be valuable for relative array measurements whilst saying nothing about the absolute phase of the array against an independent source reference.

In real systems the common error may not enter every branch identically. Filter transfer functions, cable temperatures, clock division and pilot distribution can shape it differently, so simple cancellation is a hypothesis to test. Measure the cross-covariance of calibration residuals under repeated, independently driven reference perturbations; include trials where the pilot is substituted, its distribution cables are exchanged, and the instrument is challenged with different gain states and temperatures. Separate an externally measured phase reference from the common pilot used for

Copyright 2026, James M. Atkinson

correction, because calculating covariance solely from residuals after fitting a common phase may hide part of the error. Report the covariance matrix or a conservative bound and show how it enters the beam or coherent-sum uncertainty.

Increasing receiver count may improve signal collection and reduce independent receiver noise. It cannot by itself remove an unmeasured systematic bias that is shared across channels. An array can become remarkably repeatable in reporting the same wrong direction if its assumed phase manifold is wrong. Thus the evidential statement should distinguish relative phase calibration, absolute phase traceability, and the physical emitter model. Coherent gain is a performance claim under particular error assumptions; it is not a certificate that every source phase step, gap or clock disturbance has been observed. Where the uncertainty cannot be quantified credibly, a noncoherent summary or a bounded set of phase hypotheses remains the scientifically stronger report. Measurement correlations should be retained explicitly in the published uncertainty record, not hidden by an averaging convention.

Dr. James M. Atkinson, Moderator: The discussion has established that phase-coherent integration across receiver retuning is not guaranteed by a stable sample rate, a locked synthesiser, or an algorithmically smooth time series. It becomes defensible only where the end-to-end phase-transfer law is independently measured or sufficiently constrained, the source evolution through unobserved intervals is bounded, the effect of calibration and receiver state changes is propagated into the uncertainty, and withheld trials demonstrate the claimed performance. A direct-RF-sampling architecture with uninterrupted capture offers a stronger starting point than

Copyright 2026, James M. Atkinson

a switched analogue oscillator, but still requires preservation of sample continuity and known digital filter states. Pilot references and model-based reconstruction can help when their limitations are explicit. An adaptive fit to the questioned signal must be reported as such, and its apparent coherent gain tested under the full search and selection procedure. The panel's conversation is a modern fictional scholarly reconstruction, not authentic historical speech. The practitioner should retain every raw sample and state transition, disclose any unresolved cycle-count ambiguity, and prefer a noncoherent or qualified result where physical continuity is unproved.

QUESTION 075. TECHNICAL SOURCES AND EDITORIAL QUALIFICATIONS. Scientific and mathematical foundations for subsequent source-to-claim verification: W. J. Riley and D. A. Howe, Handbook of Frequency Stability Analysis, NIST Special Publication 1065 (2008); H. Nyquist, Certain Topics in Telegraph Transmission Theory, Transactions of the AIEE 47 (1928); D. Gabor, Theory of Communication, Journal of the Institution of Electrical Engineers, Part III, 93 (1946); R. E. Kálmán, A New Approach to Linear Filtering and Prediction Problems, ASME Journal of Basic Engineering 82 (1960); N. Wiener, Extrapolation, Interpolation, and Smoothing of Stationary Time Series (1949); M. Ryle's published work on radio interferometry and aperture synthesis. Specific quotations, edition details and applicability to the contemporary SDR experiments require independent verification before publication. All examples are hypothetical, and none is a measured performance claim concerning a deployed receiver.

Editorial qualification: Every speaker exchange is a fictional scholarly reconstruction; no reported test result is presented as a measured field result.

QUESTION 076

Copyright 2026, James M. Atkinson

What do pulse-to-pulse timing distributions establish about scheduled telemetry?

Dr. James M. Atkinson, Moderator: I invite Professor Kolmogorov to distinguish periodic telemetry from a merely repeated interval visible on the receiver display. What observable properties of a time-stamped RF event sequence justify an inference about an external transmission schedule, especially where the monitoring system has known revisit intervals, intermittently missing detections, and finite timestamp accuracy? Our concern is lawful defensive RF monitoring, not the interception of message content; the entire discussion must therefore identify the instrumentation and statistical limits of any proposed inference.

Andrey N. Kolmogorov, Principal Contributor: Dr. Atkinson, the pattern of observed events is not identical to the stochastic process producing the physical emissions. A receiver provides an observation of an underlying process through a measurement operator with its own timing, gating, detection limits and possible omissions. The analyst should define three objects before fitting a periodic model: the actual but generally unobserved emission times, the occasions on which the apparatus could have detected them, and the finally accepted event timestamps. These three objects coincide only under unusually favourable experimental assumptions. When the apparatus revisits a frequency periodically, the sampling operation can impose a lattice on the observed times. A peak in an interarrival histogram may therefore describe the operator's scan schedule rather than the clock of any transmitter.

Copyright 2026, James M. Atkinson

Let the putative emission times be T_k, for integer event index k, and let a periodic hypothesis specify $T_k=T_0+kP+E_k$, where T_0 is the epoch, P is a positive recurrence interval in seconds, and E_k is timestamp jitter or scheduling departure, also in seconds. This equation is a hypothesis about a physical emitting process. The observer instead records R_j, comprising detected events after selection, and may not know which physical index k produced each accepted j. If every nth emission is missed, successive observed differences can cluster near nP even though the underlying repetition period remains P. If the receiver is available only on windows beginning at multiples of S seconds, the detection opportunity itself has period S. Observed intervals near S are therefore not sufficient evidence that P equals S.

To put this difficulty into numbers, suppose a lawful test source emits every 0.200 second, and each physical pulse has a conditional probability p=0.70 of being detected during an observation window with continuous receiver availability. If the individual detection outcomes are independent and their probability is constant, the number K of true emission intervals between consecutive detected pulses has a geometric distribution, $Pr(K=k)=p(1-p)^{(k-1)}$ for integers $k\geq1$. The first three probabilities are 0.70, 0.21 and 0.063. Consequently accepted intervals of 0.200, 0.400 and 0.600 second arise naturally from a single underlying period, without implying three operating modes. The assumption of independent losses is important: fades and processor overload can introduce runs of missing detections and make the geometric model inappropriate.

Copyright 2026, James M. Atkinson

An investigator must look for evidence across several timescales. Plot timestamps against independent reference time; calculate interarrival intervals; analyse the phase of each observation relative to plausible cycles; inspect event-time autocorrelation; and calculate a point-process periodogram or related spectral measure with an explicit treatment of the observation window. No one of these charts should be treated as decisive. A strong candidate period should make predictions for withheld intervals and for a new instrument schedule, rather than merely provide a good fit to the data used to estimate it. Very short records support many rival periods, and large gaps create exact aliases when the association between observed and emitted pulses is ambiguous.

Now contrast periodicity with a renewal process. Under the simplest homogeneous Poisson model, independent intervals have exponential distribution with rate λ events per second; the mean interval is $1/\lambda$ and the coefficient of variation of the intervals is one. A regularly scheduled emission with small jitter has a lower coefficient of variation before missed detections; thinning and event grouping can inflate it. A renewal process with a narrow interval distribution can also appear scheduled without being governed by an absolute wall-clock phase. Thus a small coefficient of variation demonstrates regularity relative to the observation model, not necessarily an external oscillator or a deliberate scheduler. A more discriminating test asks whether a fixed epoch and period predict events far into the future, or whether timing phase wanders as intervals accumulate.

Nonstationarity is a particularly serious problem. A sensor may switch

Copyright 2026, James M. Atkinson

between sleep and wake states; another may change the reporting rate after a threshold crossing; a battery-powered device may lengthen its interval as environmental conditions change. Combining these states in one histogram can produce several peaks whose geometry mimics an emission with multiple fundamental periods. A receiver may also decimate events according to its own queue and timestamp policy. The correct description is conditional on state, observation coverage, and environmental conditions. A change-point analysis is often more honest than fitting one period to the complete record.

Consider a laboratory experiment that intentionally alternates between a periodic pulse source and a renewal-process pulse source having the same mean emission rate. The test operator should independently record every physical pulse at the generator with a traceable counter, while the monitor records its own detections, missed events, tuner position, and clock state. Repeat with controlled thinning, deterministic missed pulses, correlated fading, receiver revisit schedules and introduced timestamp steps. Some experiments should use jittered periods and burst grouping; others should alter only the receiver cadence. The object is to determine which statistics distinguish the sources when the observation layer has been varied, and where two physically different sources remain observationally indistinguishable.

I would require the final report to state the hypothesised period, its conditional uncertainty, the observation window, duty cycle, number and type of detected events, known counter gaps, rejected triggers, model-

Copyright 2026, James M. Atkinson

selection procedure and alternative explanations. The evidence might justify the phrase 'repetition compatible with a periodic source over the observed interval' while remaining insufficient to establish a sustained transmitter schedule. There is no weakness in such a bounded finding. The scientific error would be to convert a convenient periodic fit into a claim about a transmitter's internal control process when the measurements have not distinguished that process from the receiver's own timing.

William Sealy Gosset, Peer Question: Professor Kolmogorov, consider an investigator who has only twenty detected RF pulses, gathered from a monitor that visits the channel for a few milliseconds in every second. The interarrival histogram shows prominent concentrations near three and six seconds. The operator is inclined to declare a three-second source period and to put a narrow confidence interval around it. How would you separate finite-sample uncertainty from aliasing created by the measurement schedule, and what experiment would reveal whether the fundamental interval might instead be one second, one-and-a-half seconds, or an irregular event process subjected to repeated detection opportunities? I am concerned not merely by the width of the interval estimate but by the possibility that the period itself has not been identified. Would an ordinary standard error computed after selecting the best-fitting period convey anything meaningful about this ambiguity, especially when the observed pulses are not independent and the detection window is narrow?

Andrey N. Kolmogorov, Response: Mr. Gosset, your distinction between estimation and identification is decisive. A standard error presupposes that the relevant parameter describes the data-generating process and that the chosen estimation model is sufficiently accurate. Here several physical

Copyright 2026, James M. Atkinson

periods and an irregular source observed through a periodic receiver can produce the same accepted timestamps. One may obtain an extremely narrow standard error conditional on a three-second periodic model while having almost no evidence that three seconds is the true physical fundamental. Conditional precision must therefore not be conflated with model identification. The candidate periods should be retained as competing explanations, not discarded because one has marginally smaller residuals.

First, preserve the actual receiver dwell intervals as a time function W(t), including tuning and settling. Construct candidate event schedules for periods of one, one-and-a-half and three seconds, allowing physically plausible jitter and missed detections. For each candidate, calculate which expected pulses fall within the observed channel windows and what probability the instrument would have had of accepting them. If several candidates predict indistinguishable accepted event sets, the data do not identify a unique period. Where the monitor scans precisely once a second, observed events may cluster on that grid even under an irregular external source. The absence of pulses outside the visits has no discriminating value because the channel was not observed there.

Second, plan a test that breaks the alias. Use an independent receiver continuously tuned to the channel for an interval longer than several candidate periods, and record a known test marker to calibrate detection latency. If continuous capture is impossible, deliberately change the revisit interval to a value not commensurate with the candidate source periods,

Copyright 2026, James M. Atkinson

such as 0.73 second, while preserving all metadata. For an authentic three-second schedule, the inferred phase should remain stable relative to an external clock even when the receiver schedule changes; an artefact tied to the scan cadence should move with it. The exact choice of 0.73 is illustrative, not an optimal value for every instrument.

Third, report uncertainty in two layers: conditional variability around each candidate period and model uncertainty over which candidate is correct. A list of supported possibilities, a likelihood profile showing multiple peaks, or a bounded prediction statement is better evidence than a false single confidence interval. If the period search itself was tuned to these twenty observations, any confidence claim should account for that selection or be confirmed by new events. Short records make this hard; the investigator should not compensate by overstating certainty. An honest negative result is sometimes that no unique schedule can be established from the available observation windows.

Karl Pearson, Peer Question: Professor Kolmogorov, your geometric missing-pulse example assumes that the fate of each physical emission is independent of the others. In a receiver operating near its sensitivity limit, however, consecutive pulses may experience common fading, while an overloaded processor may lose an entire run of packets. Both faults could produce longer observed intervals than independent thinning predicts. What statistical signature would help distinguish such dependent loss from a genuinely changing transmitter period? Can a sequence with repeated integer multiples of one nominal period still support a periodic-source hypothesis if the mechanism of missingness is unknown? I also ask how a

Copyright 2026, James M. Atkinson

field investigator should use amplitude information and instrument fault logs without circular reasoning: the analyst must not define the pulses that were missed by assuming the periodic clock that the same observations are being used to prove. Which controlled witness measurements would resolve that logical difficulty? Would it help to repeat the trial with a fixed independent pulse witness, or is the joint distribution of fading and loss alone sufficient to identify which accepted intervals correspond to true emitted cycles?

Andrey N. Kolmogorov, Response: Mr. Pearson, the geometric distribution is a transparent benchmark, not a general description of missing data. Its predictive value depends on a constant detection probability and conditional independence. If consecutive emissions share a fading state, the chance of a miss following a miss may be much larger than the nominal unconditional miss probability. If a host packet queue overflows, losses may form a contiguous block unrelated to RF amplitude. Those mechanisms can create an excess of long observed intervals relative to the simple geometric law. A statistical discrepancy between the law and the observed sequence may therefore diagnose model inadequacy, but does not by itself tell us whether fading, overload or transmitter scheduling was responsible.

The physical records must supply the distinction. Preserve sampled amplitude and noise estimates during every confirmed receiver dwell, hardware sample counters, buffer-overrun flags, transport packet sequence, gain setting and tuning state. Use a known injected reference pulse to determine whether the receiver could still detect a stable signal during the alleged gap. An independent monitor with a different front end and

Copyright 2026, James M. Atkinson

preferably independent clock can observe the same channel. If the first recorder exhibits a block of dropped sample indices while the second retains pulses, a receiver-loss explanation is strongly supported. If both experience simultaneous amplitude fading, propagation or source behaviour remains to be distinguished by location and antenna tests.

Dependence can be analysed conditionally without presuming a source period. One may estimate runs of detector inactivity, the correlation of errors with buffer occupancy, and the variation of detection probability with observed signal strength during calibration trials. A hidden-state model distinguishing good and bad reception periods may be useful, but its state labels require physical validation. It would be circular to infer missing pulses as exact integer multiples of P and then cite those inferred pulses as independent evidence for P. Keep imputed events separate from observed ones, and make predictive comparisons on new intervals where the receiver coverage is independently known.

A repeated set of integer-multiple intervals remains compatible with a periodic source even when losses are dependent. Compatibility, however, is weaker than identification. The analyst should ask whether changing receiver configuration, moving the antenna, or acquiring continuous witness data preserves the candidate phase and period. If it does, the hypothesis gains support, though an external common driver remains possible. If the pattern follows buffer faults or scan coverage, the interpretation must be revised. It is a mark of professional discipline to retain competing

Copyright 2026, James M. Atkinson

explanations until a measurement capable of distinguishing them has actually been performed.

Andrey N. Kolmogorov, Cross-Peer Question to Sir Ronald Aylmer Fisher: Sir Ronald, your emphasis upon a test chosen before seeing the observations raises a question about periodic sources with intermittent missed pulses. An investigator might select the candidate period after fitting an integer lattice to accepted events, then confirm it on new data. Yet the detector's probability of accepting an emission may itself vary with the candidate phase because the receiver visits that channel according to a fixed schedule. Would the confirmation be independent in the relevant statistical sense if the new recording uses the same scan timetable and the same aliasing relationship? Please distinguish an independent sample of event times from an independent experiment on the physical source. What alteration to the observation schedule would provide genuine discriminatory power, and how would you express the result if several proposed source periods still predict precisely the same accepted events? Would you also distinguish a truly randomised scan-phase experiment from merely beginning a new recording at a different wall-clock time while the receiver and source continue to share one timing standard?

Sir Ronald Aylmer Fisher, Cross-Peer Answer to Andrey N. Kolmogorov: Professor Kolmogorov, an independent interval of calendar time is not necessarily an independent test of a physical hypothesis. If the observation windows remain phase-locked to the candidate source periods, the same sampling geometry can reproduce the same misleading lattice. A period found through a scanned receiver may be confirmed as a stable property of the joint source-and-receiver system, while the source's intrinsic period

Copyright 2026, James M. Atkinson

remains unidentifiable. Thus the desired independence involves a change in experimental conditions capable of separating alternative causal mechanisms, not merely a later timestamp on an otherwise identical measurement.

One useful intervention is to change the revisit period or phase while recording those changes against an external time standard. Select a scan cadence incommensurate with the candidate recurrence intervals over the duration of the trial, or use a continuously tuned witness receiver where lawful and technically feasible. The candidate schedule should then predict accepted pulses at the new observation opportunities. If the inferred period changes to follow the revisit cadence, the instrument alias hypothesis gains strength. If the same source-clock phase persists across different schedules, the external periodicity hypothesis becomes more defensible, subject to common clock dependencies and source-state changes.

Pre-register the consequence of the intervention. For each proposed period P_j, enumerate the expected event opportunities within the new observation windows and state which timing deviations count as detections. A model that predicts no observable pulses in the trial has little discriminatory power, even if it would have been compatible with the historical data. The test should maximise differences among predictions while remaining within instrument limits and preserving signal sensitivity. Where several candidate periods still make the same predictions, report a set of supported periods rather than selecting one arbitrarily. A good experiment can yield a clear conclusion of non-identifiability; that is preferable to a precise but

Copyright 2026, James M. Atkinson

unsupported number.

Finally, the receiver's actual duty cycle and accepted-event criteria must be measured, not assumed. A retune command time is not always the instant a stable usable RF measurement begins, because local oscillator settlement, filter response and gain control introduce delays. A test pulse injected at the relevant input can quantify that latency. Preserve the physical coverage map, the independent source witness and the algorithm used to compare candidates. Only then does confirmation under a changed measurement design contribute evidence about the emitter rather than merely demonstrate that the same instrument repeats its own pattern.

Dr. James M. Atkinson, Moderator: Professor Kolmogorov has distinguished physical pulse times from sampled event times. Sir Ronald Fisher, please address the design of an experiment and the inferential danger created when an analyst searches many possible periods and reports only the strongest one.

Sir Ronald Aylmer Fisher, Principal Contributor: Dr. Atkinson, a hypothesis acquires its evidential force from the experiment capable of refuting it, not from its accommodation of the observations after the fact. The analyst who has explored hundreds of candidate periods, several bin widths, multiple smoothing kernels and different cluster-merging rules has not performed one simple test. The most attractive period is a selected statistic. Its apparent significance must be judged by the complete procedure through which it was selected. This is especially consequential for a sparse sequence of radio pulses, since a few timestamps can be arranged to show numerous near-integer separations within the instrument's timing precision.

Copyright 2026, James M. Atkinson

The experimental unit is also easily mistaken. The successive spectral detections of a single pulse are not independent emission events. Several nearby threshold crossings may derive from one burst whose envelope oscillates around the decision threshold. Correlation across such detections makes a conventional independent-sample calculation overstate information. Before any goodness-of-fit analysis, define the physical event and the processing rule by which it becomes a catalogue entry. The rule might declare one event when detections are separated by less than a specified merge gap g seconds, with a separate refractory interval h seconds after acceptance. Those choices should come from calibrated receiver behaviour or a prespecified study design, not from whichever values yield the tidiest periodic pattern.

Suppose we analyse a series of twelve accepted event timestamps covering approximately four minutes. With only eleven interarrival intervals, a period search between 0.1 and 30 seconds may report an extraordinarily sharp maximum by testing enough harmonics or integer divisors. It would be inappropriate to apply a fixed-frequency p-value as though the period had been selected before the data were examined. The correct null calculation may use a realistic simulation of the entire monitoring chain, applying the same period-search algorithm and selecting the maximum over exactly the candidate set used in the actual investigation. A simpler design divides the data: choose the candidate period from the first portion, freeze the rule, and test prediction against chronologically subsequent events recorded under a documented configuration.

Copyright 2026, James M. Atkinson

The observation timetable must be part of that simulation. A scanning monitor that spends 25 milliseconds on a channel every 500 milliseconds supplies a very different experiment from a continuously tuned receiver. For brief pulses whose starts are uniformly distributed over the scan cycle and whose duration is negligible compared with dwell, an idealised overlap probability may approach the fraction 0.025/0.5=0.05, ignoring tuning settlement and threshold qualification. That simplified result must not be extrapolated to bursts of finite duration or synchronised sources without modelling interval overlap. If emissions themselves are periodic, the receiver and emission schedules can become phase-locked and produce persistently missed or persistently captured pulses. Random-arrival approximations can then be profoundly misleading.

A well-designed laboratory comparison should vary one causal factor at a time. Retain a continuous, independently referenced witness recording; program a known pulse schedule; then change only the receiver revisit period. Repeat with an independently jittered revisit schedule. If the inferred transmitter period follows the monitor's imposed cadence, that is powerful evidence of a measurement artefact. If it survives independent monitoring with a different scan policy, the external-schedule hypothesis becomes more defensible, though a common upstream control signal may still explain both records. The use of physically independent receiving clocks is important because two nominally separate applications can share timing corrections or trigger logic.

Copyright 2026, James M. Atkinson

Likelihood-based inference also requires care about missed events. For a periodic pulse sequence with independently missing observations, one may sum over possible integer cycle counts between accepted detections. The likelihood then involves the measurement jitter distribution, miss probability, and all assignments of observations to underlying cycle indices. It is unsound to identify the smallest observed interval as the period without qualification. Such an estimator is biased when the initial pulses are missed or when the timestamp filter rejects short intervals. Alternative models include a renewal process, a mixture of operating states, periodic pulses with random dropout, and pulses driven by external system events. Fit assessment should therefore compare predictive behaviour and penalise needless flexibility.

One may ask what constitutes a meaningful negative result. If an alleged schedule predicts pulses during periods when the receiver was blind, their absence from the recorded catalogue is not evidence against that schedule. If a witness receiver continuously observed the correct frequency with demonstrated detection probability, repeated predicted omissions may count against the model. However, that argument must include the conditional detection probability for amplitude, pulse width, interference and instantaneous receiver state. A diagnostic using an injected test pulse is more informative than merely observing a green software status indicator.

Finally, the analyst ought to state the inferential boundary. One might demonstrate that observed pulses share a stable phase relationship relative to a period of 1.25 seconds across an hour of recorded continuous coverage.

Copyright 2026, James M. Atkinson

Such evidence would be more substantial than a similar result obtained from one scanned channel observed for only seconds in each hour. Nevertheless, no timing-only test establishes that the signal carries telemetry, that a device has hostile purpose, or that a particular person controls it. Technical inference about recurrence must be kept separate from classification, attribution and legal authority. Evidence is strongest when the experimental design exposes rather than conceals the possible ways in which the investigator could be wrong.

Egon Sharpe Pearson, Peer Question: Sir Ronald, suppose an analyst examines many frequency channels, several event-merging rules and a broad grid of candidate recurrence periods. A striking result arises for one combination, and the team then begins a new monitoring interval at the selected frequency. How should the confirmation experiment avoid becoming another stage of selective searching? Is it sufficient to preserve the chosen period, or must the receiver settings, accepted timing tolerance, observation window, minimum count and criteria for declaring confirmation all be fixed in advance? Please distinguish nominal false-alarm probability, family-wise error from the original search, and the probability of observing enough events in the available blind-time pattern. I would also welcome a physically grounded example of a test that could falsify the chosen schedule rather than merely enlarge the dataset until another attractive coincidence appears. Please address how a failed confirmation interval should be reported when receiver coverage is only partly documented, and whether a later alteration to the acceptance threshold invalidates the originally declared test.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher, Response: Mr. Pearson, the confirmation procedure must be sufficiently specific that its outcome can be recognised as success or failure without alteration after the observations are seen. Fix the receiver channel, reference timebase, detection threshold and event-merge rule. Specify the candidate period P, initial phase tolerance, allowed drift, number of predicted opportunities, and minimum fraction of detectable opportunities that must contain a qualifying event. Record planned blind windows and a rule for excluding unusable intervals that does not depend on whether the desired pulse appeared. It is not enough to declare the period fixed while continuing to change the event definition or timestamp alignment to rescue the fit.

The exploratory search incurs selection. If an analyst chooses the largest response from numerous candidate periods and channels, the distribution of that maximum under a no-schedule hypothesis differs from the distribution of a single prespecified statistic. A separate confirmation interval can reduce this problem because the chosen period and rule are held fixed before the new data arrive. But the confirmation itself should not be repeated indefinitely without adjusting the interpretation of repeated opportunities to declare success. If the result is inconclusive, the next investigation can be designed afresh, clearly identified as a new experiment rather than represented as a continuation of one fixed test.

Imagine that a candidate schedule predicts one pulse every five seconds. During a new 15-minute session, there are nominally 180 possible emission times, but the receiver's logged channel coverage includes only 60 of them

Copyright 2026, James M. Atkinson

within the calibrated timing tolerance. The test therefore has at most 60 meaningful opportunities to observe the predicted signal, not 180. If sensitivity trials indicate a conditional detection probability of 0.9 for pulses meeting the prespecified amplitude and width, a sustained schedule would yield about 54 accepted detections in those opportunities, before accounting for dependence and state changes. A result of only two detections would be difficult to reconcile with that particular conditional model. It would not, however, refute an unqualified schedule involving variable power or changed operating state.

A particularly useful falsification control is to alternate two receiver observation schedules while keeping the physical test source unchanged. If the candidate period vanishes or changes solely because the revisit cadence changes, that is evidence against interpreting the period as intrinsic to the external source. A negative control using an irregular known source can estimate how often the entire detection and selection chain produces a spurious periodic finding. Report both false-positive results and missed genuine periods, since a procedure that never declares a false schedule may simply be incapable of recognising any weak schedule at all.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Maurice S. Bartlett: Dr. Bartlett, suppose the analyst fits a periodic line to a point-process spectrum, then interprets the line's height as evidence for a scheduled transmitter. In your account, a periodic observation window can impose a line even when the source is irregular. How should one design a spectral comparison that incorporates the measured sampling windows and the detector's dead time? Is a conventional time-series permutation adequate if it destroys the

Copyright 2026, James M. Atkinson

very clustering or dependence that makes the real null process difficult? Please consider the danger of using a large set of surrogate event records that appear random only because their generation ignores the receiver's actual blind periods. Which aspects of the acquisition chain must be reproduced before a reported spectral confidence level has a physical meaning? If the receiver suppresses overlapping detections during a recovery interval, please explain how that dead-time rule should enter the surrogate generation before any claim of statistical significance is made.

Maurice S. Bartlett, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Sir Ronald, a point-process significance test must account for the observation operation under which the accepted events were generated. If the true null process is a stationary Poisson source but the monitor observes only during periodic windows, independent random timestamps distributed uniformly across the entire calendar interval are not an appropriate surrogate for the recorded data. Those surrogates fill blind periods with events the real receiver could never have accepted. The resulting null spectral distribution may underrepresent the strong periodic structure introduced by the measurement windows, making the observed periodogram peak seem more exceptional than it is.

Construct surrogate physical emission processes under the specified null, then pass each through the measured W(t) coverage function, a calibrated detection-probability model, and exactly the event-merging and timestamp procedures applied to the real signal. If dead time prevents a second trigger within a fixed interval after one acceptance, reproduce that state dependence. If detection probability changes with received amplitude, the

Copyright 2026, James M. Atkinson

surrogate model must include a defensible amplitude distribution or preserve relevant empirical conditions. Only after this observation process should the point-process spectrum and the maximum-period search be computed. The significance comparison then concerns the statistic the actual apparatus could have generated, not an idealised continuous observer.

A simple permutation of observed intervals can be misleading because the intervals may not be exchangeable. They may depend on scan phase, signal level, instrument overload, or clustering in the physical emissions. Permutation methods require assumptions that must be examined rather than invoked because they are computationally convenient. Block-based rearrangement preserving some local dependence may be useful for exploratory sensitivity, but it too can destroy long-range structure or invent new event-window relationships. A controlled physical null experiment using a known irregular source, observed through the actual receiver, may offer more persuasive evidence about false periodic peaks than a purely mathematical shuffle.

I would also report the spectrum of the observation opportunity process itself, not merely that of the accepted events. If both exhibit a line at the same frequency, instrument cadence becomes a concrete alternative explanation. Repeat with a changed scan policy and record whether the event-spectrum line follows it. Such interventions do not supply a universal proof, but they address causation in a way that a single p-value cannot. For the report, state the simulated or measured null, observation windows,

Copyright 2026, James M. Atkinson

detector dead time, spectral estimator, period-search range and multiplicity of comparisons. A spectral line is a descriptive fact; its physical explanation requires these further controls.

Dr. James M. Atkinson, Moderator: Sir Ronald has called attention to period selection and experimental controls. Dr. Bartlett, please distinguish regular event trains from spectral features caused by clustering, intensity variation, and observation-window structure.

Maurice S. Bartlett, Principal Contributor: Dr. Atkinson, a point process is a natural description of the observed event times, but its spectrum must not be read as though it were the ordinary power spectrum of a continuous carrier. We can represent accepted events by the counting process N(t), the number of accepted observations up to time t, and, formally, a train of impulses at event times R_j. Spectral analysis of such data can reveal recurring structure, yet it is affected by the mean intensity, event clustering, finite observation, missing detections and instrument dead time. The spectrum is an attribute of the recorded event process. It becomes an attribute of the physical emissions only after the observation mechanism has been characterised.

For a stationary process, one might compare the intensity λ, the mean number of events per second, with a second-order covariance or pair-correlation structure. A periodic point process with modest independent timing jitter produces concentrations of pairwise time differences near integer multiples of its period. An independent homogeneous Poisson process does not contain the same persistent periodic structure, although finite random samples may show incidental peaks. A clustered process can

Copyright 2026, James M. Atkinson

contain excess short-lag pairs because several accepted triggers are generated around one physical burst or because one event provokes further events. Such clusters increase low-frequency or broad-band point-process spectral components and can be confused with a genuinely periodic scheduler if the observation procedure is not made explicit.

Finite-window effects deserve more care than a simple histogram. Suppose the instrument observes a channel only during disjoint windows whose indicator is W(t), equal to one when detection is possible and zero otherwise. The observed point train is, in a simplified model, multiplied by W(t), followed by the threshold detector and event-merging algorithm. The recorded spectral structure is then influenced by the transform of W. A regular revisit timetable can impose spectral lines on a fundamentally irregular external process. Conversely, a continuous emitter with weak bursts may be selected only at particular sampling phases. One cannot remove this effect merely by subtracting the average count. A defensible analysis must measure W(t), preferably using hardware-generated tuning and sample-availability records rather than an operator's recollection.

A common simulation is instructive. Generate an independent Poisson emission process at ten pulses per second, with a fixed detection probability only during a 40-millisecond observation interval repeated every 200 milliseconds. Those windows contribute a nominal 20% duty factor before threshold losses. The accepted event times will be concentrated in repeated clusters separated by roughly 200 milliseconds, even though the underlying Poisson source has no scheduled recurrence. An interarrival histogram may

Copyright 2026, James M. Atkinson

show a strong maximum related to the monitor's cadence. An analyst unaware of the observation windows could interpret that maximum as a telemetry interval. Change the revisit period to 310 milliseconds while leaving the source unchanged; any shift of the apparent periodicity toward the new instrument cadence would reveal the observational origin.

A renewal model provides a different counterexample. Let inter-emission intervals be independent gamma-distributed variables with mean P and coefficient of variation lower than one. This process has relatively regular separations but no absolute phase lock: its cumulative timing deviation from a fixed epoch grows with the number of events. A true periodic controller with bounded jitter around an absolute schedule can retain a stable phase relationship over long observation. If every interval is formed from an independent renewal draw, accumulated timing variation grows with sequence length. Hence the variance of residuals relative to a fitted clock, evaluated on held-out data and with correct uncertainty for estimated parameters, can help distinguish the two classes. One should not infer an exact mechanism from this statistic alone because externally driven renewal processes can also display long-range regularity.

An event grouping rule is not innocuous. If a burst contains ten threshold excursions separated by a few milliseconds, counting each crossing may make the accepted intensity ten times the true burst intensity. A refractory interval exceeding that gap can collapse those crossings into one event, but can also merge two separate bursts emitted close together. The researcher should use independently observed waveform envelopes to choose the rule

Copyright 2026, James M. Atkinson

and report sensitivity across plausible merge intervals. Repeated findings across settings are more compelling than a single preferred plot. Where the rule changes the inferred repetition period, the uncertainty is structural, not merely a statistical confidence interval about one chosen model.

I would preserve more than one time representation. The unaltered hardware sample index identifies chronology within one acquisition stream; a calibrated physical event timestamp permits cross-receiver comparison; a software receipt timestamp identifies delivery and may bear queueing artefacts. A detector often reports the time of the largest spectral magnitude inside its analysis window, which may occur after the physical burst onset and vary with amplitude. Cross-correlation against a local known test pulse can quantify that latency as a function of signal level and filtering. Event-time analyses lacking this calibration can overstate scheduling precision by orders of magnitude.

My final prescription is not to abandon spectral methods but to embed them in a declared observation model. One should compare the event spectrum under the original scan schedule and under a deliberately altered schedule, examine the empirical pair-correlation against surrogate data generated through the same receiver windows, and validate period estimates out of sample. Include receiver dead-time logs, event-merge decisions, measured detection probability, clock adjustment records and all rejected observations. The claim that pulses are 'consistent with a recurring external event process' may then be justified. The stronger claim that the external source deliberately follows a particular schedule requires independent

Copyright 2026, James M. Atkinson

evidence that the observed recurrence has not been imposed by the measurement system.

Claude Elwood Shannon, Peer Question: Dr. Bartlett, a point-process periodogram may reveal a prominent line at one frequency, yet the physical RF emission is a waveform containing information that the event catalogue discards. Which aspects of the signal's temporal organisation survive reduction to an impulse train, and which are lost? If a telemetry source changes modulation or packet structure while retaining the same burst times, an interval analysis might remain stable but cease to describe the same transmission process. Conversely a receiver detector might convert variations in pulse width or signal-to-noise ratio into timing shifts that appear as jitter. How should an analyst decide whether timestamp-only evidence is sufficient for the proposed inference, and what additional observations should be retained without undertaking unauthorised content interception? I am particularly concerned with the distinction between identifying timing structure and claiming knowledge of a device's internal data or protocol. Could a lawful, low-content measurement of pulse width and envelope shape expose a detector-induced timing shift without requiring access to any demodulated message, and what calibration uncertainty should accompany that comparison?

Maurice S. Bartlett, Response: Dr. Shannon, the event catalogue retains the chosen timing features and little else. A threshold-triggered event time may represent the first crossing of an amplitude criterion, the maximum of a filtered envelope, a correlator output peak, or a host-supplied packet receipt label. The catalogue generally discards the original waveform's detailed amplitude, modulation, spectrum, intra-pulse phase, and potentially its

Copyright 2026, James M. Atkinson

duration. Two very different transmissions may therefore produce the same event-time series. If the scientific question concerns timing regularity, the reduced catalogue can be useful, provided its detector origin is calibrated. If the question concerns transmitter identity or protocol structure, the timing series alone is rarely sufficient.

One should retain minimal lawful RF measurements capable of testing the event definition without indiscriminately collecting content. These may include carrier-frequency estimate, occupied bandwidth, pulse duration, received power, receiver gain and noise reference, detector statistic, time-of-arrival uncertainty and hardware sample-index range. In a controlled laboratory one can keep raw complex samples of a known benign test signal. The purpose is to establish how a changing pulse envelope influences the detector's timestamp and whether distinct physical pulses become merged into one accepted event. Any use of operational signals must remain within the investigator's actual authority and applicable legal conditions.

A simple example shows the information loss. Suppose two test emitters each produce one pulse every two seconds. One emits a narrow Gaussian-like envelope, the other a much longer asymmetric waveform with a rising edge that crosses the threshold late. If the event time is defined by first threshold crossing, the second emitter's timestamps may exhibit an amplitude-dependent delay. A periodogram of accepted event times can show the same nominal two-second recurrence for both while the measurement error distributions differ. Calibrate detection latency against

Copyright 2026, James M. Atkinson

signal amplitude and width, then test whether the inferred period persists under a different, independently justified timestamp estimator. A clock-phase claim accurate to one millisecond cannot be supported by a detector with ten milliseconds of unmeasured amplitude-dependent latency.

The full physical waveform is not always necessary for a limited conclusion. If a continuously tuned, calibrated receiver registers many well-separated burst onsets with low timestamp uncertainty, timing periodicity may be well established. But the analyst must state what was not measured. One may say that detected RF-energy events recur at a measured interval, not that a specific packet format or message type was transmitted. Additional observations should be selected to challenge instrumental alternatives and preserve reproducibility, not to magnify the conclusions beyond the evidence. Statistical compression is useful only when its effect on the inferential target is understood and disclosed.

Maurice S. Bartlett, Cross-Peer Question to David H. Blackwell: Professor Blackwell, your discussion of non-identifiability suggests that more data may not always solve the problem. Suppose two models predict the same accepted event distribution whenever the receiver is tuned according to its established scan schedule: one model has a true periodic source, while another has an irregular source repeatedly observed in short windows. Would gathering ten times as many events through the unchanged schedule necessarily improve inference about the source's clock? How should an investigator measure the expected value of changing the experiment, rather than simply increasing duration, and what stopping rule would recognise a situation in which the current apparatus cannot

Copyright 2026, James M. Atkinson

discriminate the hypotheses? I should also like you to distinguish mathematical equivalence of observed distributions from finite-sample uncertainty about models that are theoretically distinguishable but practically very similar. How would you decide, before committing to a longer observation, whether the proposed additional measurement can make those competing physical mechanisms observably different?

David H. Blackwell, Cross-Peer Answer to Maurice S. Bartlett: Dr. Bartlett, collecting more observations improves discrimination only when the competing models induce observably different distributions under the adopted measurement policy. If their distributions of accepted timestamps are exactly identical, no amount of additional recording under the same policy can separate them. The extra data may give a very precise estimate of the common observed distribution while leaving the cause unresolved. This is structural non-identifiability. A different situation occurs when the distributions differ slightly but the finite sample is too small to reveal that difference. In that case additional independent observations may help, although the required duration can be great and the practical detector model may change over the longer period.

The distinction can guide experimental design. Instead of asking only 'How long should we listen?', ask 'Which feasible measurement action makes the predicted observations under H_P and H_W most different?' Candidate actions include changing the revisit period, changing its phase, recording continuously for a short targeted interval, improving antenna sensitivity, or adding a second independently clocked receiving path. Each action has costs and may change gain, noise or event selection. Predictive simulation should

Copyright 2026, James M. Atkinson

include those changes so that apparent improvement is not merely a new calibration error. A source hypothesis that predicts events in an unobserved interval gains no support from extending that same blind interval; changing the coverage can supply new information directly.

Expected information gain may provide a formal design criterion, but its numerical value depends on chosen models and probabilities. Without validated probabilities it is better to compare qualitative predictions and choose an intervention with clear falsifying consequences. For example, if a three-second source period and a one-second scan alias predict exactly the same events at the current revisit cadence, choose a new cadence or continuous observation for which the candidate source phases imply different arrival opportunities. Before the test, write down the distinct predicted observations. After it, report both successes and failures, including events rejected by detector quality rules.

A stopping rule should separate scientific conclusion from operational fatigue. If repeated planned observations are informative and the posterior or likelihood evidence remains inconclusive, the report can give a bounded likelihood comparison or a range of periods. If the present architecture makes the hypotheses observationally equivalent, the correct stopping condition is not 'wait longer' but 'change apparatus or acknowledge non-identifiability'. An analyst should never cite the sheer number of accepted events as proof that a specific source mechanism has been established. The provenance of the events and the distinguishability of the rival mechanisms matter more than the count.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Bartlett has demonstrated that even an irregular source can acquire spectral structure through a periodic observation window. Professor Blackwell, please examine whether the schedule is identifiable from the incomplete data and what sequential decisions are justified.

David H. Blackwell, Principal Contributor: Dr. Atkinson, the practical issue is identifiability rather than the beauty of a fitted curve. Two or more distinct physical models may induce essentially the same distribution of accepted event times when only a small portion of the spectrum is observed. One model may contain a regularly transmitting source whose pulses are intermittently missed. A second may contain an irregular source sampled through a periodic scan schedule. A third may contain several emitters whose bursts happen to overlap in the selected channel. If the observations cannot distinguish these mechanisms, no statistical estimator can make the missing information appear merely by increasing computational sophistication.

Let H_P denote a periodic-emission hypothesis, H_R a renewal-process hypothesis, and H_W an irregular source combined with a periodic observation window. These are models, not moral or operational judgments. Their likelihoods for event data D should be evaluated conditional on the documented receiver availability process W, calibration and false-event model. A likelihood ratio comparing H_P with H_R is meaningless if the rival explanation H_W has been omitted despite an obvious periodic scan timetable. Model selection should be driven by physically plausible alternatives and controlled experiments, not an

Copyright 2026, James M. Atkinson

artificially narrow set of mathematical choices.

A schedule can be predicted only when its phase and rate remain stable at the relevant horizon. Suppose a candidate period P=2 seconds is fitted using accepted pulses from a ten-minute record. A useful test asks how many pulses should be expected in the next five minutes, given the planned observation windows and detector sensitivity. If the model predicts events predominantly when the receiver is not listening, the next interval has little power to discriminate it from an irregular alternative. The operator should design a new observation schedule that opens windows around competing predictions and records controls at other times. An independent continuously tuned witness channel may be the simplest improvement, although it has its own noise floor and possible overload conditions.

Sequential evidence must also be calibrated for repeated stopping. A monitor that checks a candidate pattern every minute and announces success when any one check becomes impressive has selected a favourable stopping time. A fixed sample-size significance threshold is not automatically valid for this indefinite sequence of looks. One can predefine an error-spending or sequential likelihood procedure, or reserve an independent confirmation period whose definition precedes the event inspection. In either case, the decision rule and any early stopping boundary belong in the evidential record. The goal is not mathematical ceremony but a test whose false-alarm behaviour can be reproduced in the actual monitoring configuration.

Copyright 2026, James M. Atkinson

There is a distinction between classifying whether an event occurs and predicting its timing. A scheduled telemetry source may change interval according to duty cycle, external command, internal buffer state or power management. A model that predicts a stable mean rate but not the next event's time offers only limited evidence of schedule. Conversely, a renewal process with low dispersion can predict the near-term next interval reasonably well while lacking an absolute repeating clock. The prediction target must therefore be stated: event count, interarrival distribution, clock-phase concentration, or exact next arrival window. Each target has different scoring rules and uncertainty.

The losses are often selective. A receiver with automatic gain control may detect only strong pulses. If strong pulses are systematically transmitted at one position in a repeated data frame, the accepted sample will appear more periodic than all emissions considered together. A signal's fading pattern can also correlate detection probability across successive pulses. The correct test incorporates pulse amplitude, threshold, antenna configuration and interference state. An apparent periodicity strengthened by a more aggressive detection threshold might reveal that one class of bursts is being selected, not that the transmitter changed its timing. Receiver sensitivity experiments should therefore vary thresholds without making unsupported claims about undetected content.

A careful experiment introduces known periodic, renewal and state-switching test sources, randomly assigns trials and blinds the analyst to the source type. The receiver should record both raw IQ and its detection

Copyright 2026, James M. Atkinson

ledger; an independent reference measures true pulse occurrence. Some trials should include missed pulses caused by controlled attenuation, others should include scanning blind intervals, and others deliberate timestamp offsets or dropped packets. The validation goal is a confusion matrix that reports false classification rates across realistic pulse widths, amplitudes and interference. A model successful only with generous signal-to-noise ratio and no missing events should not be presented as suitable for a difficult field survey.

I would conclude by requiring a report to preserve the alternative models that remain compatible with the evidence. A finding may properly say that accepted events are more predictable under a periodic model than under a specified renewal model over the tested interval. It must not silently expand into a claim that the transmitter's firmware deliberately schedules packets or that one particular device produced them. The analyst should state the competing models, blind-time pattern, decision horizon, detection assumptions and performance of held-out predictions. Where no independent test separates source and instrument periodicities, the correct result is non-identifiability, not an artificially precise estimate of an imaginary scheduler.

Solomon Kullback, Peer Question: Professor Blackwell, your comparison of a periodic model, a renewal model and a periodic observation-window artefact is appealing, but model comparison itself may be fragile when the likelihood of missing events is poorly constrained. What should an examiner do when the models use different numbers of hidden pulse indices, different assumptions about correlated detector loss, or different

Copyright 2026, James M. Atkinson

allowances for receiver clock drift? Does selecting the largest likelihood meaningfully resolve the physical hypothesis if those nuisance assumptions dominate the result? Please address how one might use predictive scoring or information divergence without hiding the role of the chosen model family. In particular, could a strongly preferred periodic model be an artefact of omitting an intermittent receiver state that changes acceptance probability, and which measurements would demonstrate that possibility directly? I would especially welcome a test in which the data distinguish a bad model of the receiver from a bad model of the emitter, since improved fit alone may reward unnecessary flexibility.

David H. Blackwell, Response: Professor Kullback, a ranking among imperfect models is not proof that the highest-ranked model corresponds to the physical truth. Likelihood ratios compare the conditional probability of observed data under declared hypotheses. If the observation mechanism is misspecified, the ranking can favour the wrong source model with remarkable confidence. An intermittently deaf receiver can make a random external process appear episodic or periodic. Conversely a real schedule with correlated fades can be penalised by a model that presumes independent missing events. The appropriate response is to expose sensitivity to those nuisance assumptions rather than to present a single numerical winner as a causal verdict.

I would construct at least two model families for the detection process: one with constant independent losses, and another with a time-varying reception state informed by measured front-end gain, noise floor, scanner activity and transport overflow. Within each family compare periodic and

Copyright 2026, James M. Atkinson

irregular source models using predictions on a held-out interval. Record scores on the original, unaltered event ledger and report how the rankings change with plausible detector models. If adding a measured reception-state variable eliminates an apparent periodic advantage, the original inference depended on an unmodelled instrument effect. That is a substantive scientific finding, not a failure of statistical technique.

Information measures require careful interpretation. A divergence between two fitted distributions can quantify their distinguishability under the chosen representation, but does not itself establish which generating mechanism is real. A small divergence means that the available measurements may be unable to discriminate the models, even with many events unless additional observables are acquired. A large divergence supports discrimination in that specific data representation, subject to sampling uncertainty and selection. It is reasonable to report expected predictive loss or likelihood ratios only alongside the observation model, calibration data, fitted parameter ranges and actual test protocol. The model family must remain open to realistic alternatives discovered through instrumentation challenges.

Consider an experiment with identical external test pulses emitted according to one prespecified schedule, but with the receiver deliberately alternating between normal operation and a state that drops most short pulses. Record the state independently, including when it changes. A model unaware of the state may infer that the transmitter entered a slower scheduling mode; a model conditioned on the state should recover the

Copyright 2026, James M. Atkinson

unchanged emission process. Reverse the experiment by changing only the generator schedule while keeping the receiver fixed. Correct attribution requires the analysis to respond differently to these two interventions. That is a more convincing examination of the physics than fitting ever more elaborate hidden variables to an unchallenged observation. The report must disclose when competing explanations remain observationally equivalent.

David H. Blackwell, Cross-Peer Question to David G. Kendall: Professor Kendall, your queueing model separates physical emission bursts from host-delivered event clusters, but the two mechanisms can be highly similar in a record containing only console timestamps. What would be an efficient controlled experiment to distinguish them without assuming access to the transmitter's internal firmware or packet content? Suppose the receiver's host periodically empties a buffer, while a lawful test source itself emits packets in regular batches. Which time-domain measurements must be made before the analyst can tell whether a burst family began at the antenna or in the software pipeline? Please describe the case in which both source-side batching and receiver buffering are present simultaneously, and explain how an evidence ledger should allocate observed timing uncertainty to each stage rather than burying all delays inside a single timestamp correction. Would a traceable hardware pulse marker at the ADC input establish enough chronological independence to identify the receiver queue, or are further boundary measurements required?

David G. Kendall, Cross-Peer Answer to David H. Blackwell: Professor Blackwell, the experiment should instrument the boundaries between the source and the receiving software. Use a calibrated laboratory transmitter with a known pulse programme and an independent RF witness near the

Copyright 2026, James M. Atkinson

receiving input. The witness produces an acquisition timestamp tied to a hardware sample counter before the disputed host queue. In the test receiver, retain its own sample indices and device-time tags, transport sequence information, application ingestion times, and display publication times. The result is not one event-time stream but a chain of related time observations. A difference emerging only after transport or application buffering belongs to the receiving system rather than the external RF field.

First, hold the source's emission schedule fixed and impose a safe measured host workload that delays packet processing. If the display begins to show regularly spaced groups while device-index and witness times remain unchanged, the imposed clustering arises downstream. Second, hold the receiver configuration fixed and change the generator from individual pulses to programmed three-pulse batches. The witness and device-time stream should both reflect the new physical grouping. Third, combine the two disturbances. The witness then records true source-side batching, the device preserves the same physical order, and the host display may impose a further set of clusters. This combined trial is important: real investigations seldom enjoy only one mechanism at a time.

Where exact latency cannot be measured at every processing stage, the report should present bounded intervals rather than an unjustified point estimate. A hardware capture marker can calibrate the analogue and device timestamp offset; packet sequence and monotonic host receipt logs can characterise transport delay; application and display logs can characterise later queueing. A wall-clock correction or network synchronisation state

Copyright 2026, James M. Atkinson

change must be separately retained because it can alter external-time labels without altering physical sample order. If the host clock was stepped backwards, one should not sort events solely on its printed timestamps. Device sample sequence is generally more trustworthy for local chronology when its continuity has been independently verified.

The evidential product should retain original timestamps, derived corrected timestamps, known gaps, stage-specific uncertainties and the software versions used to calculate each. It should distinguish a measured emission pulse from a detected feature, an accepted event from an inferred missing event, and a displayed group from a physical burst family. If the independent witness is absent, certain source and receiver grouping explanations may remain observationally indistinguishable. State that limitation. One can reasonably conclude that the console reported periodic clusters without asserting that the emitter's firmware created them. The entire purpose of the boundary experiment is to make the final causal statement proportional to what was actually observed.

Dr. James M. Atkinson, Moderator: Professor Blackwell has described how physically distinct mechanisms may remain observationally indistinguishable. Professor Kendall, please close the principal series by considering queues, burst families, renewal timing and the interpretation of detected clusters.

David G. Kendall, Principal Contributor: Dr. Atkinson, a telemetry-like emission process can be affected by queues in the device, queues in the measurement apparatus, or both. The first may determine when physical pulses are transmitted; the second may determine when the operator sees

Copyright 2026, James M. Atkinson

them. One must be careful not to infer the former from the latter. A transmitter that collects sensor reports in memory and sends them in short batches can produce strong clustering and repeated long gaps even without a periodic transmission clock. A monitoring computer that accumulates receive packets and releases them after filesystem delays can produce a superficially similar event log. These possibilities become distinguishable only when the raw acquisition chronology is preserved independently of host delivery times.

An elementary queueing model may represent reports arriving into a source buffer at rate λ and being served in batches or individually at rate μ, both in events per second. In a stable single-server model one ordinarily requires a mean service capacity exceeding the mean arrival rate, but real telemetry may have a duty-cycled radio, finite buffer, priority traffic, and a scheduled service window. The transmitter's observed burst interval can reflect the service policy rather than the sensor's report-generation interval. Conversely, a receiver process may delay and group detections into one display update. Consequently a repeated gap among accepted events need not measure the sampling interval of the underlying sensor or the recurrence period of a transmitter controller.

A useful distinction is between a renewal process and a clustered or self-exciting process. Independent renewal intervals are conditionally described by their interarrival distribution. A clustered process may instead show elevated probability of an additional event shortly after one has occurred, even when its overall rate varies little. The statistics of short gaps and long

Copyright 2026, James M. Atkinson

gaps should be assessed together, with a declared grouping interval and evidence of true event separations. A burst containing several packets can yield a mixture of very short within-burst intervals and much longer between-burst intervals; fitting a single smooth interarrival law conceals the hierarchical organisation. A credible analysis may model bursts as cluster centres with their own recurrence and packets within each cluster with another spacing law.

Take a hypothetical lawful test device that transmits a group of three RF pulses every 10 seconds, separated internally by 20 milliseconds. A detector that counts every pulse gives intervals near 0.020, 0.020 and 9.960 seconds in each cycle. If an event-merge rule joins triggers separated by less than 50 milliseconds, the same physical record becomes one accepted event every 10 seconds. Both catalogues are correct under their respective rules, but only the second describes burst families. The test has not established whether the grouping originates in a transmitter data frame, a local radio repeater, multipath replicas, or the detector's own recovery; raw waveform examination and receiver challenges must resolve those competing explanations.

The observation apparatus may introduce a queue with random delays D_j after physical acquisition. If the display timestamp is $R_j=T_j+D_j$ rather than a hardware time-tag of T_j, differences $R_{(j+1)}-R_j$ include $D_{(j+1)}-D_j$. Delivery delays can increase interarrival variability, cause out-of-order apparent events, or create bursts when many queued packets are flushed together. The queue may even emit at a fixed software refresh interval,

Copyright 2026, James M. Atkinson

imposing periodicity unrelated to the incoming RF process. Hardware sample counters and pre-queue device timestamps are therefore indispensable. A smooth GUI clock or nominal network synchronisation cannot replace evidence of the actual sample-to-time mapping.

Missed pulses introduce further mixture behaviour. A periodic source with independent detection losses creates integer multiples of its true period among accepted intervals, as Professor Kolmogorov has explained. A clustered process with missing within-cluster detections can instead alter both cluster size and inferred burst duration. Suppose a three-pulse test burst has per-pulse detection probability 0.8 under an independent-loss model. The probability all three are accepted is 0.8 cubed, or 0.512; the probability none is accepted is 0.2 cubed, or 0.008. Between those extremes lie partially observed clusters that may look like one-pulse or two-pulse source emissions. These figures are conditional on independent detection and cannot be transferred to burst-wide fading where the failures are correlated.

The experiment should compare an independently recorded source-event ledger with the receiver's raw samples, packet counters and displayed event file. Vary the transmitter's batch schedule while holding the measurement configuration fixed; then vary only the receiver buffering and event-merge settings. Include deliberately introduced host backlog, known scan blind intervals and controlled amplitude fades. Estimate within-cluster and between-cluster distributions separately and test whether conclusions remain stable across reasonable changes in the event definition. An

Copyright 2026, James M. Atkinson

apparent source period that shifts with the GUI refresh interval has been attributed to the wrong system. Likewise, a burst grouping that disappears when the detector threshold is altered deserves qualification before it is described as a source protocol.

A report should distinguish physical emission pulses, received waveform features, accepted detector triggers, reconstructed burst families and displayed event summaries. It should disclose counts and timing for each layer, including any data that were deliberately rejected. The purpose of this separation is not pedantry. Each layer answers a different question, and each may be required to explain the observed timing. A warranted conclusion might identify statistically repeatable burst families in the measured RF energy while leaving their internal scheduler and source identity unresolved. The analyst's obligation is to retain the timing evidence and its uncertainties in a form that a later examiner can challenge, not to assign an exact transmitter mechanism because one interval histogram appears pleasingly regular.

Norbert Wiener, Peer Question: Professor Kendall, an analyst may see several apparently independent RF events arrive at the console simultaneously, although the actual acquisition occurred at different times. Suppose the device and host form a layered queue: an RF detector produces hardware time tags, USB transfers packets, a background application writes records, and a graphical display refreshes at a fixed rate. Which portions of that chain could impose periodic arrival patterns or artificial clustering, and how could the operator reconstruct the original chronological order? I also ask how one should distinguish the actual transmitter's queueing behaviour

Copyright 2026, James M. Atkinson

from a receiver's packet backlog without relying on unobserved assumptions about the source's internal design. Would a correlation between display update times and burst detections ever be enough to infer a source schedule? If the hardware time tags remain monotonic while software receipt times reverse order, is the inversion itself evidence of delivery reordering, or must one first exclude a clock adjustment or timestamp conversion defect?

David G. Kendall, Response: Professor Wiener, the ordinary display-time record is downstream of several stochastic and deterministic stages. The RF source may generate a physical pulse at T_k. The device records a hardware timestamp H_k, ideally related to T_k by a calibrated constant and small error. The packet enters a transport queue, accumulates a variable delay Q_k, reaches the application, and is finally published at a display refresh D_j. If the software assigns the event time at D_j, several distinct physical arrivals may appear simultaneous at each refresh. A histogram constructed from those display times can show an impressive period equal to the GUI refresh cadence even when the RF source is irregular. Such regularity is evidence about the graphical interface until its relation to hardware acquisition has been demonstrated.

Reconstruction should begin with immutable sample counters or device timestamps, not with host wall-clock ordering. Preserve packet sequence identifiers, counter resets, overrun and dropped-sample flags, transport receipt times, queue depths and the conversion that maps hardware time to externally referenced time. Sort on the physically meaningful acquisition index where possible, noting any ambiguity introduced by missing packets

Copyright 2026, James M. Atkinson

or counter wraparound. A time estimate reconstructed from a new calibration is a derived result, not an original observation; retain both. If the acquisition hardware did not record its own chronology, some reorderings may be impossible to determine after the fact, and that limitation cannot be repaired by a confident spreadsheet sort.

To distinguish source queueing from receiver backlog, employ an independent continuous witness receiver that records the waveform before the disputed host transport path. If the witness shows physical pulses separated by milliseconds but the console reports them together every second, the receiver system has imposed the visible grouping. If both independent acquisition streams show actual over-the-air bursts with the same physical clustering, that supports a source-side phenomenon, although common external triggers or relays may still explain it. The experiment should also challenge the receiver transport deliberately: impose controlled processing load or adjust the display refresh without altering the test generator. A pattern that follows this manipulation originates at least partly in the measurement chain.

Correlation between display updates and reported detections cannot by itself establish a transmitter schedule. The application may process and publish events only when the display refreshes, ensuring correlation by design. A useful log identifies the physical sample time, event-detector decision time, application ingestion time and display time as separate columns with uncertainties. Event counts should be reported by acquisition interval, not by display frame, unless the latter is the explicit estimand. A

Copyright 2026, James M. Atkinson

disciplined investigator distinguishes a source emitting clusters from a host delivering clusters; both can be described by queueing mathematics, but the forensic conclusion depends upon measurements showing which queue is being observed.

Richard W. Hamming, Peer Question: Professor Kendall, consider a software engineer who has correctly recorded the beginning and ending hardware sample counters for each block but uses a convenience function to fill missing event timestamps by interpolation. If a short block was actually dropped during an RF burst, the resulting catalogue may show a smooth succession of evenly spaced pulses. What software tests would reveal this synthetic regularity, and which provenance fields should make it impossible for a later reviewer to mistake interpolated events for measured ones? I am also concerned about overflow recovery. An SDR driver may reconnect a stream after losing samples, while the application reinitialises its counter and continues writing a valid file. What invariant should the capture software enforce to prevent that discontinuity from being concealed behind an apparently continuous timeline? How would you design an automated acceptance test that fails the build when missing-sample intervals are hidden, even if the recovered event timeline looks periodic and every output file can be opened?

David G. Kendall, Response: Professor Hamming, the distinction is between samples observed and events predicted. A missing acquisition block cannot be reconstructed by interpolation as if the physical waveform had been measured. An analysis programme may produce estimated pulse times under a periodic model, but those estimates must be recorded in a separate layer with their assumptions and uncertainty. The raw ledger should

Copyright 2026, James M. Atkinson

preserve hardware counter ranges, whether each range was actually captured, and any device error flags. It should never insert an inferred event into the same category as an observed threshold crossing without a conspicuous provenance field. A later investigator must be able to discard every inferred event and reproduce the original catalogue unchanged.

A suitable acquisition invariant is that each accepted data block has a unique device identity and epoch, an explicit first and last sample index, and a documented relationship to the preceding block. If a counter resets during reconnection, the software must create a new epoch rather than silently continuing the old numbering. Missing ranges are identified as gaps; overlaps and duplicates are flagged; and the mapping from device ticks to calibrated time is versioned separately. Where a device cannot provide trustworthy counters, the programme should document that limitation and use an independent known marker to test continuity. A monotonic host clock alone does not prove that RF acquisition remained continuous during the interruption.

Fault-injection testing should make every failure mode observable. Under controlled laboratory conditions, block packet delivery, force a buffer overrun, restart the driver, step the host wall clock, and introduce a known pause in the generator while an independent recorder preserves the physical source timeline. The resulting audit file must distinguish each cause: transport delay without loss, dropped samples, clock discontinuity and actual silence. Run the event detector on the raw samples and compare its output with a catalogue reconstructed from the recorded device

Copyright 2026, James M. Atkinson

counters. If an interpolation stage creates apparent equal intervals across a gap, the audit should identify the generated entries automatically and the publication statistics should exclude them from evidence of observed periodicity.

The final recording should include a checksum of the raw acquisition, the detector software version and settings, a list of every transformation and its inputs, the error log, and a stable link from each accepted event to its underlying sample range. These controls do not prevent all scientific mistakes, but they prevent a particularly serious one: replacing missing physical measurements with a convenient model and then citing the model's regularity as evidence that the transmitter behaved regularly. Quality assurance should test not only whether the software continues running after an error, but whether it tells the truth about what was lost.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel distinguishes physical emission times from receiver observation windows, detector triggers, buffer-delivered events and software-displayed clusters. A prominent interarrival peak can arise from an external scheduled source, a narrow renewal interval distribution, state-dependent burst grouping, missed periodic emissions or the receiver's own revisit cadence. A defensible inference begins with hardware event provenance, calibrated receiver availability, a declared model-selection rule, and independent attempts to break the possible alias through altered scan timing or continuous witness observation. Integer-multiple intervals and a clean point-process spectrum are evidential clues rather than proof of an emitter's internal scheduler. Where multiple physical models explain the accepted timestamps equally

Copyright 2026, James M. Atkinson

well, the conclusion is non-identifiability. No inference about message contents, purpose or source ownership follows from timing statistics alone. The exchange is a fictional pedagogical reconstruction, and all example figures are hypothetical.

QUESTION 076. TECHNICAL SOURCES AND EDITORIAL QUALIFICATIONS

1. M. S. Bartlett, “The Spectral Analysis of Point Processes,” Journal of the Royal Statistical Society, Series B, vol. 25, no. 2 (1963), pp. 264–281, DOI: 10.1111/j.2517-6161.1963.tb00508.x. Publisher catalogue confirms the work and its focus on renewal and clustered point processes. https://academic.oup.com/jrsssb/article/25/2/264/7035255

2. International Telecommunication Union, Handbook on Spectrum Monitoring, 2026 edition, https://www.itu.int/pub/R-HDB-23. This handbook supplies the general spectrum-monitoring context; specific equations in this question are editorial derivations and are not attributed to an unspecified page of the handbook.

3. ITU-R Report SM.2256-2 (06/2026), Spectrum occupancy measurements and evaluation. The published contents distinguish duration of monitoring, sample time, observation time, revisit time, transmission length and thresholds. https://www.itu.int/dms_pub/itu-r/opb/rep/R-REP-SM.2256-2-2026-TOC-HTM-E.htm

4. Additional historical bibliography, contributor expertise and individual mathematical assumptions require independent source-to-claim verification. The statistical examples are hypothetical; their assumptions, including independence and stationarity, are explicitly limited within the discussion.

QUESTION 077

Copyright 2026, James M. Atkinson

When can inter-arrival statistics identify a class of intermittent control links?

Dr. James M. Atkinson, Moderator: Professor Feller, our question concerns what inter-arrival statistics might establish about a class of intermittent control links. Please separate renewal behaviour from scheduled signalling, and distinguish the transmitted waveform, the receiver's observations and the analyst's inference. The floor is yours.

William Feller, Principal Contributor: The first necessity, Dr. Atkinson, is to prevent three clocks from being mistaken for one another. There is the physical transmitter's clock, if a physical clock governs its emissions; there is the measurement clock that assigns timestamps to acquired events; and there is the statistical clock defined by the waiting time from one observed occurrence to the next. The third does not disclose the first merely because its intervals have an attractive numerical shape. A simple renewal process is one in which the successive waiting times, X_1, X_2 and so forth, are independent and identically distributed with a common distribution function $F(x)=P(X<=x)$, where x is elapsed time. Its survival function $S(x)=1-F(x)$ is the probability that an interval has not yet ended at elapsed age x. Where F admits a density f, the hazard $h(x)=f(x)/S(x)$ measures an instantaneous conditional propensity to observe the next event given that it has not already occurred. These are properties of the selected event process. They do not, by themselves, identify whether the source is a remote-control transmitter, a thermostat, a laboratory oscillator or a detector reporting the same pulse twice. A claim about device class must bring additional observations and a defensible reference population into evidence.

Copyright 2026, James M. Atkinson

For an exponential waiting law with mean m seconds, F(x)=1-exp(-x/m), h(x)=1/m, and the event intensity is constant. Such a model is memoryless in event age, although it need not imply that an engineer built a memoryless signalling device. For a nearly regular renewal law, the interval variance may be small compared with the squared mean; yet a source scheduled every ten seconds whose every second transmission is intermittently missed may exhibit a multiple-spaced distribution unlike the nearly regular physical emissions. Conversely, a truly irregular source watched through a receiver that revisits a frequency at regular times can appear more periodic than it is. In the field notebook I should require a record of antenna position, dwell window, threshold rule, timestamp origin and event-merging convention. The statistical sequence without that observation description resembles an instrument panel photographed after its legends have been stripped away. It can still be measured, but its causes are ambiguous.

Consider a first hypothetical experiment. A receiver observes 121 intervals, their summed duration being 605 seconds. The naive sample mean is 605/121=5.00 seconds. Under an independently observed exponential renewal model the maximum-likelihood rate is lambda_hat=n/T=121/605=0.200 events per second, and its reciprocal is five seconds. That numerical calculation is sound within the model, but it does not classify the link. The same count can be generated by scheduled events with missed detections, a superposition of two controlled sources, or a nonstationary intensity chosen to have the same total integral. The sampling uncertainty is also conditional on the specified observation scheme. One must not import the usual independent-exponential standard error when interval values have been rounded, when the receiver falls blind after

Copyright 2026, James M. Atkinson

detections, or when the recording interval is deliberately terminated following an unusually long silence.

A second experiment demonstrates the danger of confusing a physical period with a detected interval. Suppose an authorised training transmitter emits a beacon every 2.0 seconds, and an independently calibrated detector records each beacon with probability p=0.60, independently across emission opportunities. Let K be the number of physical periods between successive detections. Then P(K=k)=p(1-p)^(k-1), for integer k>=1. The probabilities at 2, 4 and 6 seconds are 0.60, 0.24 and 0.096. The mean observed separation is 2/p=3.333 seconds; an investigator who describes a roughly 3.3-second clock from the sample average has invented a timing mechanism that does not exist. The characteristic lattice of two-second multiples may nevertheless survive in the interval histogram, but only if timestamp resolution and oscillator stability are good enough to resolve it. For practical classification, we should ask whether the hypothesised renewal law predicts the entire observed gap distribution rather than interpreting its mean alone.

The question of class is thus a question of distinguishability under interventions. A receiver using one gain level can confuse a low-duty intermittent source with a weak continuous source that crosses the threshold sporadically. Repeating the measurement at a controlled second sensitivity, with identical live-time accounting, may reveal whether supposed events multiply in a manner attributable to the instrument. A second simultaneously tuned independent receiver can discover acquisition gaps that a single scanner conceals. A deliberately transmitted, known reference sequence can test whether the timestamp pipeline preserves a sequence of one-second and ten-second gaps without merging, deletion or re-ordering.

Copyright 2026, James M. Atkinson

All these controls convert an otherwise decorative fit into a testable model of observation.

We should also say what independence means. An interval process may be stationary in its marginal histogram while retaining correlation between adjacent gaps. If a transmitter emits three short packets in a burst, then waits before the next burst, the pooled histogram may display two characteristic lengths. There may be no single interval distribution under which successive gaps are independent. A renewal diagnostic can compare conditional gap distributions after a short versus a long preceding gap, or evaluate the lag-one correlation with uncertainty adjusted for finite samples. If the next interval changes with the previous one, simple independent renewal modelling is falsified, but that finding does not automatically prove intelligent command traffic. Thermal state, battery voltage, channel contention, an overloaded recorder and intentional retransmission protocols may all generate dependence. We require a candidate mechanism and a control able to make it fail.

Nor may an analyst identify a particular apparatus from the apparent rarity of a pattern. A device family might be described by a prespecified set of timing characteristics validated on known exemplars, such as burst length, recovery-time distribution, diurnal exposure and probability of simultaneous activation with environmental stimuli. A finding that an unknown trace falls within that distribution may rationally support a cautious family-level comparison, perhaps as a likelihood ratio under two explicitly described reference populations. It does not give licence to turn that ratio into a probability of guilt or identity without prior odds, selection procedures and competing explanations. I would record the class hypothesis separately

Copyright 2026, James M. Atkinson

from the event detector, document every change to classification thresholds and retain the raw timestamps along with the intervals. In the quiet of an electronics laboratory, the temptation is to hear an orderly mechanism whenever a display blinks rhythmically; sound discipline consists in testing the order before naming its source.

Jerzy Neyman, Peer Question: Professor Feller, I am concerned by the way a classifier might be judged after an analyst has chosen which spectral channel and which apparent interval deserves attention. Suppose the instrument records 120 candidate frequencies during an evening survey, each frequency offering perhaps several event thresholds, and the analyst ultimately reports the most regular inter-arrival sequence. The apparent event rate, coefficient of variation and lattice spacing are then not products of an experiment fixed in advance but of a selection procedure driven by the same data under examination. Even a correct likelihood for an isolated renewal sequence would fail to reflect the probability of having found that sequence among all the alternatives. Would you define a test that includes the search procedure itself, and would you separate statistical confidence about a class from a mere decision to inspect a frequency more carefully? I also ask how you would handle a class whose genuine exemplars range from battery-powered short bursts to mains-driven periodic control frames, because a convenient single distribution might be too narrow to represent its true diversity.

William Feller, Response: Dr. Neyman, the correct experimental unit is the complete selection procedure, not the single attractive channel recovered at its end. If a laboratory wishes to estimate how frequently an intermittent control-like pattern arises in benign background activity, it must repeat the

Copyright 2026, James M. Atkinson

complete search over disjoint, prospectively defined periods and count how often its final selection rule declares a candidate. The null distribution therefore includes antenna selection, frequency scanning, threshold adaptation, the number of interval tests and the rule for stopping. One can use resampling or simulation only if the surrogate observations preserve the real temporal dependencies and the receiver's missing-data structure. Randomly shuffling all timestamps would destroy clustering and could create a dishonest reference distribution.

The distinction between discovery and confirmation is indispensable. The initial survey can be labelled exploratory and used to formulate a specific, falsifiable observation protocol. The confirmation period then freezes channel definitions, minimum event energy, timebase calibration, burst-merging rules and the decision boundary before data are collected. A class label should not be issued unless the predictor is calibrated on independent known examples and known counterexamples. The richer the class, the greater the danger of treating its definition as elastic. A collection of carefully stratified reference distributions, with prespecified weights for the relevant environments, may be more faithful than a single nominal curve. The result should state its coverage: for example, measurements obtained with a particular receiver family, signal-to-noise range and lawful test-site protocol. Anything outside that range remains extrapolation. The final decision may reasonably be to gather further evidence rather than to pretend that a weak inference has become strong merely because the statistic carries several decimal places.

For a numerical illustration, suppose that a frozen detector was exercised against 200 independent negative test recordings, including its complete

Copyright 2026, James M. Atkinson

multi-channel search, and generated 12 alerts. Its observed false-alert fraction is 12/200=0.06, not the nominal single-channel p-value that happened to motivate the detector. The precision of 0.06 is itself limited by the number and heterogeneity of test records; an interval estimate should accompany it. A classifier trained on the very same 200 records would give an optimistic figure because it has used the labels for parameter selection. This is not an obscure philosophical concern. It determines whether an investigator gives a magistrate a defensible statement about a method's performance or merely a retrospective account of a conspicuous flashing indicator. I should require the test archive, its frozen software version, its receiver configurations and the full set of negative outcomes, including those in which nothing of interest appeared.

Claude Shannon, Peer Question: Professor Feller, your renewal law compresses a continuous radio waveform into one timestamp per accepted event. In a communications channel the physically consequential distinction might lie in pulse width, modulation alphabet, packet coding or occupancy, none of which necessarily survives an onset detector. Two dissimilar transmitters can produce the same set of onset times while carrying utterly different information, and a matched filter tuned to one waveform may systematically discard another at identical radiated power. What mathematical criterion would tell a field investigator when the timestamp catalogue is sufficient for the particular hypothesis and when a second feature stream is indispensable? I ask especially about purported control-link classification. The word control implies a relationship between a command and a response, whereas a temporal sequence may arise from telemetry, synchronisation, channel contention or the scanning instrument

Copyright 2026, James M. Atkinson

itself. How should an analyst refrain from putting semantic information into the model that no measurement channel actually acquired?

William Feller, Response: Dr. Shannon, a statistic is sufficient only relative to a specified family of probability models and the parameter whose information we seek to retain. A list of onset times may be adequate to estimate an event-rate parameter under a correctly specified point-process model, yet wholly insufficient to establish that one emission addressed a receiver, encoded an instruction or caused an actuator to change state. That distinction should appear in the title of the recorded inference. We may write 'timing compatible with a recurrent burst process' where the evidence permits, but not 'command link identified' merely because an intervalogram shows concentration near a preferred lag.

A forensic acquisition system should preserve the original spectral or complex-baseband record when lawfully and practicably obtainable, and should store the detection decisions as derived annotations rather than as the sole surviving evidence. Additional independent features may include bandwidth, pulse energy, waveform similarity across bursts, frequency agility, synchronised response in a permitted test apparatus, and changes under controlled attenuation. They must be linked to their acquisition conditions. If a waveform's duty factor determines whether a swept analyser captures it at all, then a refined interval classifier cannot recover missing signal semantics from timestamps alone. One must also distinguish uncertainty in observed pulse onset from uncertainty in internal timebase state, since those errors enter different parts of the likelihood.

Copyright 2026, James M. Atkinson

A careful investigator might adopt nested hypotheses: H0 describes background detections under the known sensor, H1 describes a nonstationary stochastic emission process, and H2 describes a particular family of lawful reference devices. Showing that H0 predicts poorly is not sufficient to establish H2. The likelihood of the actual data under H2 must be compared with the best substantive alternatives and tested out of sample. If all competing device classes predict the same onset distribution, then the timing channel has zero discriminatory power between them, whatever the beauty of its display. This is an instance of information absent from the observation, not of a clever algorithm waiting to be found. I would pass that limitation with the token rather than conceal it beneath a dramatic label. The absence of a waveform record is an information loss, not a merely inconvenient processing choice; it must be documented as such in the evidentiary limitations.

William Feller, Cross-Peer Question to Sir David R. Cox: Sir David, I should like you to distinguish two cases that a renewal histogram cannot separate. A source might possess a rate that changes deterministically as the laboratory ventilation fan starts and stops; alternatively, the rate itself might vary randomly because of an unobserved state of the equipment. Over a short observation the two could produce similar clustering and identical pooled waiting-time distributions. I ask whether a conditional-intensity formulation can identify which covariates are genuinely informative, and whether such covariates may be included when the analyst notices them only after the events have been plotted. How would you define exposure time when the receiver is blind during retuning, and how would you use a prospective holdout interval to distinguish a model of the emission process

Copyright 2026, James M. Atkinson

from a model of the instrument's attendance at the channel? Kindly also consider whether improved fit is any evidence of purpose, as opposed merely to a reduction in predictive error.

Sir David R. Cox, Cross-Peer Answer to William Feller: Professor Feller, the essential separation is between the mechanism creating physical events and the observation mechanism by which some of those events enter our catalogue. A conditional intensity lambda(t|H_t,z_t) is a local event rate at time t, conditional upon the recorded history H_t and relevant covariates z_t. It does not imply that time has become a cause. A deterministic intensity might depend on a logged environmental state, such as temperature or fan operating status; a stochastic-intensity model allows unrecorded variation in that underlying rate. In either case we must explicitly account for an exposure indicator e(t), which is one when the receiver is eligible to record the nominated source and zero when it cannot. The effective observable intensity is not simply lambda(t), but is modified by e(t), detection efficiency and any dead-time or pulse-merging process. Their effects should be estimated in separate calibration experiments wherever possible.

A prospective test must commit to its covariates before confirmation. If a fan event is discovered only after an interesting pattern appears, we should treat the correspondence as a hypothesis and schedule a new experiment in which fan state is varied deliberately and recorded synchronously with receiver live time. The model can then ask whether an increase in conditional intensity replicates under preassigned conditions. A random-intensity model may capture clustering that remains after known covariates have been accounted for, but its extra flexibility must be penalised and evaluated by predictive scoring on independent segments. One does not

Copyright 2026, James M. Atkinson

obtain a causal interpretation merely by naming a fitted latent process 'control'.

Suppose a 600-second experiment contains 300 seconds in which the receiver is truly available, with 30 accepted events in that live interval. The uncorrected rate of 30/600=0.05 events per second is the rate per elapsed calendar time, whereas the exposure-normalised observed rate is 30/300=0.10 events per live second. Neither is necessarily the physical transmission rate unless detection efficiency and the censoring model are known. If availability depends on the event history, a naïve division by live time can be biased. The output should carry a live-time ledger, and predictions should be evaluated conditional upon the same observation schedule. I thank you for drawing attention to the problem, and return the floor to the moderator for the distinction between rate modelling and physical attribution.

Dr. James M. Atkinson, Moderator: Sir David, Professor Feller has established the necessity of distinguishing physical generation from the receiver's sampling. Please explain conditional intensity, covariate-dependent clustering and the danger of treating a suitable statistical model as a diagnosis of an apparatus.

Sir David R. Cox, Principal Contributor: Dr. Atkinson, the decisive move is to replace the seductive label 'intermittent control link' with an explicit set of competing mechanisms. Consider first an intensity that is constant within a test interval. If event counts N(t) follow a homogeneous Poisson model with rate lambda events per second, counts in disjoint intervals are independent, and the number of events in an interval of length T has mean and variance

Copyright 2026, James M. Atkinson

lambda T. A second model permits lambda to be a known function of time, perhaps conditioned on the recorded state of laboratory machinery. A third, a doubly stochastic Poisson model, allows that intensity to be itself random. The observable counts in this third arrangement can exhibit greater variance than the mean because periods of high latent intensity gather events into clusters. The same visual impression might also be produced by a transmitter emitting deterministic bursts while a receiver randomly omits some bursts. Statistical form must be attached to the actual observation operation or it has no secure engineering interpretation.

My first practical requirement would be a timeline with distinct fields. The physical event times are latent unless an independently monitored reference transmitter supplies the ground truth. The receiver has a sample clock; the scheduler has dwell and revisit intervals; the detection algorithm declares a pulse onset when a defined decision variable crosses a defined threshold; finally, the software may merge nearby declarations into a single event. Each transformation can change the observed interval process. A digital recorder whose buffering occasionally delays or batches timestamps may produce the appearance of a scheduled transmission even while receiving an unstructured sequence of test pulses. Its clock drift can lead an analyst to mistake apparent rate modulation for behaviour in the source. We should therefore archive a continuous timebase calibration record, any packet or frame counter exposed by the instrument, the distribution of processing latency, and the explicit live-time mask. In a sensitive inquiry, every unmeasured transformation is an alternative explanation, not a footnote.

Copyright 2026, James M. Atkinson

A conditional-intensity model can express these issues without pretending to know the hidden hardware. Let H_t denote the accepted event history strictly before time t; let z(t) be a vector of logged environmental covariates; and let e(t) be a live-time indicator. An illustrative model is $\lambda_{obs}(t|H_t,z)=e(t)\,q(t)\exp(\beta_0+\beta_1 z_1(t)+\beta_2 z_2(t))$, where q(t) is a calibrated probability of acceptance under the relevant signal conditions, β_0 is the baseline log-intensity, and the beta coefficients represent specified covariate associations. This equation is a simplified thinning model. It does not apply without qualification when the detector has history-dependent dead time or merges close events. A candidate conditional intensity may fit beautifully yet be an artefact of a covariate sampled with the same periodicity as the receiver's revisit schedule. We should repeat the experiment with an independent sampling schedule before we attribute a coefficient to the source.

A worked calculation will show how a seemingly large association may be nothing of the sort. Suppose a lawful test records 12 events during 240 seconds of live time while an air-handling relay is off, and 36 events during another 240 seconds of live time while it is on. The observed rates are 12/240=0.05 and 36/240=0.15 per second; the raw rate ratio is 3.0. But the relay may alter broadband background amplitude, which changes q(t), or the receiver's scanning sequence may be synchronised to the relay. If acceptance probability is independently measured to be 0.5 in the first condition and 0.9 in the second, a simple corrected comparison under independent thinning gives estimated source event rates 0.05/0.5=0.10 and 0.15/0.9 approximately 0.1667 per second. The corrected ratio is about 1.667, not three. Such correction remains model-dependent; it is not a

Copyright 2026, James M. Atkinson

causal finding. The decision to randomise relay status, within safe laboratory constraints, is more important than the apparent confidence conveyed by the decimal.

One should prefer a prediction test where the physical hypothesis and the alternative models disagree. A renewal process with independent waiting times might predict that the next interval depends only on the elapsed age of the current gap. A self-exciting event model might predict a temporary increase in the likelihood of another event immediately after the last one. A varying environment may predict fluctuations that track a measured external covariate. A scheduled controller may predict a response to an authorised stimulus within a reproducible latency window. If the models give almost indistinguishable timing predictions, no classifier can recover certainty by extending the numerical precision of its coefficients. Data of another kind are required, and those data should be obtained with a lawful, non-invasive observation protocol or a controlled exemplar, not by inferring sensitive semantics from opaque RF bursts.

The event history can be tested through the time-rescaling principle. Under a correct, continuous conditional-intensity model, successive integrated intensity increments Delta_i = integral from t_(i-1) to t_i of lambda(s|H_s,z_s) ds should behave as independent unit-mean exponential variables, subject to regularity conditions and the correct handling of censoring. A departure suggests model inadequacy; apparent agreement is not proof of a unique causal mechanism. If live-time gaps cut across intervals, the integral must follow observable exposure rather than pretend every calendar second could contain an accepted event. Likewise, a hardware timestamp wrap or repeated processing delay may create a sharply peaked feature that a

Copyright 2026, James M. Atkinson

flexible intensity model can accommodate while the field engineer should instead repair the clock. The mathematical residual diagnostic and the engineering configuration log belong together.

A classification report ought therefore to state what was held fixed, what was allowed to vary and what claim would have been rejected by the opposite result. 'The observed burst timing resembles that of our laboratory's intermittent-controller exemplar under this receiver and environment' can be meaningful if the exemplars, selection rule and error rates are documented. 'The unknown emitter is an intermittent controller' ordinarily asserts more than a timestamp-only test can establish. One cannot summon the missing evidence from the posterior by selecting an obliging prior, nor from a conventional significance threshold by ignoring untested alternatives. The point of model building is to clarify the sources of uncertainty so that a decision-maker knows what can and cannot be established, not to conceal ambiguity beneath a polished likelihood plot. I pass the matter to colleagues who can challenge the choice of observation window and the conditional assumptions.

Maurice S. Bartlett, Peer Question: Sir David, your conditional-intensity proposal is attractive, but a scanner's sampling schedule may introduce a periodic zero pattern into the opportunity for any event to be detected. In the simplest presentation one multiplies the source intensity by an exposure indicator, yet a real analyser contains filter settling, video averaging, asynchronous buffering, overload recovery and trigger hold-off. It can report nothing during one interval, a delayed trigger during the next and several merged pulses after that, so the observation error itself may be temporally correlated. If an analyst measures environmental covariates only

Copyright 2026, James M. Atkinson

every minute, while physical bursts have millisecond durations, the apparent relationship to those covariates may also result from time aggregation. What residual test would reveal a mis-specified observation mechanism rather than a mis-specified emitter model? Would you insist upon an independent clocked reference channel to establish live time and timestamp stability, even where doing so reduces available receiver channels for surveillance?

Sir David R. Cox, Response: Dr. Bartlett, an exposure indicator is a beginning, not the completion of the observation model. It accurately describes an ideal receiver that is either eligible or ineligible to detect an event and whose probability of acceptance is otherwise independent of past events. A real receiver may have a response kernel, a delay distribution, frequency-dependent gain and a dead-time rule. The inferential target must then be a joint model of latent event generation and the observation transformation. For high-integrity field work, I would recommend a separate laboratory calibration trace made with known pulses that vary systematically in spacing and amplitude, followed by a small number of independent reference injections during the actual survey where permitted. The aim is not to interfere with unknown devices but to characterise the instrument with an authorised signal path.

The residual analysis should be diagnostic at several levels. First compare the accepted-event timestamps with the receiver's actual active-tune mask rather than its nominal programme. Then examine the distribution of timestamp offsets relative to dwell boundaries, processor batches and reference clock edges. If the measured event rate spikes immediately after each retune or dips after each trigger, there is evidence that the

Copyright 2026, James M. Atkinson

instrument's state affects acceptance. Next fit a physical candidate model while incorporating the empirically measured observation kernel. If the time-rescaled residuals still show correlation concentrated at revisit harmonics, that suggests the observation description is inadequate or that a process synchronised with the scan remains unmodelled. It does not unambiguously distinguish the two. An independent receiver with a deliberately different revisit schedule can help because genuine source times should not be tied to both schedules in the same way.

The aggregation issue is equally serious. A minute-sampled temperature may act as a crude proxy for a relay's short-cycle operation; a fitted temperature coefficient might actually represent an unobserved intermittent load. One can analyse its sensitivity by shifting or coarsening the covariate series, by introducing independent logging or by explicitly acknowledging that there is insufficient temporal resolution for a mechanistic inference. If a 30-minute data set contains only six episodes of equipment state change, treating its thousands of individual pulse detections as thousands of independent demonstrations of a state association produces severely underestimated uncertainty. Episodes or independently assigned state changes, not the raw event count, may form the appropriate unit for a causal experiment.

The expense of an independent reference channel is justified when the intended conclusion is consequential and the timebase is not otherwise demonstrated. If resource constraints prevent it, the conclusion should remain qualified. An engineering report can retain a plausible classification hypothesis while clearly marking timebase validation and live-time metrology as incomplete. This is preferable to granting the instrument an

Copyright 2026, James M. Atkinson

accuracy which was never measured. The result should be reproducible in principle by another investigator given the same raw trace, calibration records and software rules, and not depend upon an analyst's memory of what the waterfall happened to resemble during an event.

Sir David R. Cox, Cross-Peer Question to George E. P. Box: Professor Box, a maximally flexible Cox-process description may follow every cluster in a training record, especially when the analyst can introduce arbitrary smooth functions of time and environmental covariates. I should be grateful for an account of how an experimentalist should distinguish that sort of statistical accommodation from a genuinely predictive classification. What diagnostic would you require before the words 'intermittent control-like behaviour' entered a forensic report? Consider specifically that the investigator may have chosen the event detector by viewing the same records, and that an apparently successful model can simply reproduce the receiver's revisit schedule. How would you design a separate confirmation campaign, and which aspects of the modelling exercise ought to be deliberately frozen? Please address the practical trade-off between a rigid but wrong model and an excessively adaptive model that explains away every contradiction. In particular, would you specify a preassigned negative-control experiment whose result would invalidate the class interpretation even if its initial training likelihood remained exceptionally high?

George E. P. Box, Cross-Peer Answer to Sir David R. Cox: Sir David, modelling becomes an evasion when nothing can happen that would cause the model to be rejected. A useful statistical design begins with a clearly described engineering question, a hierarchy of predictions and a list of measurements capable of exposing model failure. For the proposed

Copyright 2026, James M. Atkinson

classification I would require a training set drawn from known lawful exemplars and a separate collection of negative controls, including background sources that are not controllers but create superficially similar bursts. The analyst must freeze event detection, channel selection, interval censoring, the vector of features, model complexity, the numerical decision rule and the form of uncertainty report before opening the prospective confirmation data. Any post hoc alteration is a new experiment and needs another holdout.

I would not insist that the simplest possible model be true. A renewal model can be an informative baseline even when the real source has clustered, covariate-dependent emission. The relevant question is whether complexity improves held-out prediction under a scoring method chosen in advance. With a point process, the likelihood of withheld event times and the integrated intensity over exposed time provide one such scoring method, but both can be subverted if live-time and dead-time behaviour are inaccurately described. Calibration plots for predicted probability of one or more events in prespecified windows, together with residual analysis against receiver state, are often more informative to the reviewer than a single classification percentage.

An experimentalist must also randomise what can be randomised. If the purported source changes when a fan relay changes, vary relay state independently of the receiver scan if permitted. If the source-like pattern follows scan timing, alter dwell and revisit schedules while monitoring the same controlled environment. If the model predicts a class-specific latency after an authorised control stimulus, specify a latency band before the experiment and record how often unrelated background devices produce an

Copyright 2026, James M. Atkinson

indistinguishable response. A classifier that survives several orthogonal perturbations is more credible than one which gives a vivid account of a single night's trace. Even then, discrimination among classes is not identification of a particular device.

Suppose a complex model gives an average negative log-predictive score of 1.18 per held-out observation and a simpler model 1.22 under a specified proper scoring rule. The difference is 0.04 per observation, but its uncertainty must account for dependence between adjacent events and repeated conditions. If there are only five independent recording sessions, five thousand pulse timestamps do not magically create five thousand independent experimental replicates. State the practical size of the improvement and an interval derived from independent sessions or defensible block resampling. I should prefer the simpler model if the complex one gains little under independent test, and I should seek better measurements if both models fail. The proper output is a tested inference with explicit conditions, not an ornamented description of an ambiguous spectral line.

Dr. James M. Atkinson, Moderator: Professor Box, Sir David has passed you the question of statistical accommodation versus genuine predictive discrimination. Please consider the workshop practice of dividing records into development and confirmation sets, and explain how to prevent the instrument and the analyst from manufacturing a purported control-link signature.

George E. P. Box, Principal Contributor: Dr. Atkinson, a detector can be a wonderfully efficient manufacturer of facts which are true only of its own

Copyright 2026, James M. Atkinson

settings. There is nothing dishonest about acquiring a timestamp when an amplitude crosses a threshold, provided that the analyst remembers that it is a threshold-crossing timestamp. The mistake arises when an event created by the analysis procedure is treated as an independently existing packet with a known purpose. In an industrial experiment I should begin with a process map: the lawful test source, the antenna and propagation path, the analogue filter, any amplification, the sampled data, the detection statistic, the threshold, the event-merging software and the final classification. Every node introduces variation or selection. The map should identify variables controlled by the investigator, variables observed but not controlled, and variables that were never recorded. Without such a map it is easy to mistake the variability of the measurement process for variability of the object measured.

There is a profound distinction between explaining the existing data and predicting another observation. Imagine a development record in which an intermittent background source appears to produce a burst every 24 to 28 seconds, except when the laboratory ventilation fan is running. An analyst can fit an elegant mixture distribution, introduce a term for the fan and add a latent state for the occasional missing burst. The curve may track the historical data almost perfectly. But perhaps the receiver visited the channel every 26 seconds, lingered for 200 milliseconds and happened to do so at a different processor load when the fan-controller network was active. Another receiver, continuously tuned, could reveal that the source generated many events during the supposed silences. Unless the observation schedule is recorded and tested, the analyst has estimated characteristics of a combined system rather than of the emitter alone. I

Copyright 2026, James M. Atkinson

would therefore insist on comparing at least a continuous-monitor reference with the time-sliced survey where authorised, before the record acquired any class label.

Model choice should be guided by the technical purpose of the decision. If the purpose is to nominate a few frequencies for further lawful observation, a relatively permissive detector with an explicitly measured false-alert rate may be sensible. If the purpose is to state that a particular class of command apparatus was present, the same method is inadequate without calibration on real devices, controls representing alternative source classes and proof that the claimed features survive changes of instrument. Sensitivity and specificity are conditional on the population of tests; neither is a timeless property of a mathematical formula. The composition of the negative set matters greatly. If all negatives are benign laboratory noise while all positives are strong, neatly timed reference beacons, a classifier can learn signal strength and acquisition time rather than any signature of control traffic. The experimental record must disclose that problem.

Here is a worked classification example. Let the positive reference set contain 80 independent controlled sessions, of which a frozen detector correctly flags 68, and let the negative set contain 120 independent sessions, of which it incorrectly flags 18. On these test populations the observed sensitivity is 68/80=0.85, and observed specificity is (120-18)/120=0.85. Equal numerical values do not imply that a positive detection has an 85 percent probability of being a control link. With a hypothetical prevalence pi=0.02 in the intended survey population, Bayes' rule gives P(class|alert)=[0.85*0.02]/[0.85*0.02+0.15*0.98], approximately 0.104. That 10.4 percent is not a measured field prevalence; it illustrates why

Copyright 2026, James M. Atkinson

the proportion of positives among all candidate events matters. Replace the prior 2 percent with a different defensible value and the posterior changes. Where prevalence is unknown, report the likelihood ratio and its uncertainty rather than silently assuming an attractive prior.

The same attention must be given to serial correlation and sample splitting. An engineer could record a thousand pulses from the same five devices and then randomly assign individual pulses to training and test files. Such a division creates severe leakage. The test file contains the timing quirks of the very devices already used for training. A more credible design assigns whole recording sessions, days, device exemplars or sites to separate partitions. If the model is to generalise to a new type of instrument, withhold entire instrument types during validation. If it is intended only for repeated surveys with the same instrument, test it on new operating conditions with independently checked calibration. The relevant independence unit depends upon the intended claim. An impressive accuracy produced by resampling correlated pulses is not an estimate of generalisable field accuracy.

Our descriptive calculations should also distinguish static and dynamic features. A histogram of gap lengths is static in the sense that it discards their order. It may still be useful as a first account of what happened. But a control-like signal may exhibit a recurring cycle of several short events followed by a long interval, and a histogram of those same durations cannot show whether the long gap always follows three short ones or occurs at random positions. An ordered transition table, a renewal-age diagnostic or a conditional model might reveal the dependence. In designing a confirmation experiment, I would specify at least one feature sensitive to

Copyright 2026, James M. Atkinson

order and one deliberately insensitive feature, and compare their out-of-sample predictive value. Failure of the order-sensitive model can be valuable: it says that the attractive cyclic story did not survive the next recording.

There is an engineering reason to prefer several simpler experiments rather than one encyclopaedic classifier. Changing the receiver's dwell schedule tests scan alias; changing authorised source power tests the threshold artefact; introducing a known timestamp reference tests clock and buffering behaviour; varying harmless environmental covariates tests conditional associations. Each intervention should carry a predicted direction of change. The strongest conclusion comes when a mechanism predicts not only the original observation but also what should happen when one cause is altered while other relevant conditions are held fixed. If no safe intervention is possible, the report must acknowledge an observational result with unresolved confounding. The limitation is not a failure of mathematical sophistication, but evidence of disciplined restraint.

Finally, I should require a visible audit trail of model development, including rejected candidates. An analyst who tests twenty interval features and reports only the one giving a favourable result has not presented the full selection process. A frozen classifier, versioned calibration files, test population descriptions, false-positive examples and clear limits of applicability form part of the evidence. The reader should be able to reconstruct why one signature was nominated and another discarded. This is a question as much of scientific governance as of radio engineering. Statistical analysis cannot transform a set of missing measurements into a historical fact about what a clandestine device intended to do. It can, under

Copyright 2026, James M. Atkinson

disciplined conditions, show that a temporal process is incompatible with some explanations and consistent with others, and thereby guide the next responsible observation.

Richard W. Hamming, Peer Question: Professor Box, I should like to test your experimental philosophy against a practical constraint. Suppose a field analyst has an established event detector and can preserve only a few channels of complex samples, while hundreds of other frequencies are represented by threshold-triggered onset times. Changing the detector mid-survey may increase sensitivity but destroys comparability between earlier and later timestamps. Meanwhile, a classifier built with large numbers of features appears to discriminate authorised reference control links from benign bursts, though its most important features are difficult to interpret physically. Would you favour a simpler, weaker model whose features have defensible measurement meanings, or should the apparent improvement in held-out accuracy suffice? How would you evaluate an engineering decision in which the costs of missing a relevant event are asymmetric to the costs of classifying a harmless signal as suspicious? Please distinguish a decision rule for collecting more evidence from a claim that the emitter's nature has already been established.

George E. P. Box, Response: Dr. Hamming, I should begin by asking what decision the numerical analysis is intended to support. If a low-cost alert merely assigns the receiver to collect a longer lawful observation, one can rationally choose a high-sensitivity detector and tolerate more false alarms. A detection intended to support a categorical assertion about the nature of an emitter requires a much higher standard. These decisions have different loss functions, and I would refuse to hide the distinction in an arbitrary

Copyright 2026, James M. Atkinson

threshold. An operational loss matrix might assign a cost of 1 to an additional harmless inspection, 10 to a missed opportunity for further lawful measurement, and a much larger cost to an unsupported allegation. The numbers would have to be fixed by responsible stakeholders before the analysis, and the resulting decision policy would remain separate from the scientific likelihood.

As to model complexity, the right comparison is not 'interpretable' versus 'accurate' in the abstract. It is whether the better-performing model demonstrates reliable improvement on independent data drawn from the intended operating conditions and whether that improvement withstands reasonable perturbations. A complex model that uses detector version, receiver-revisit phase or an unrecorded laboratory day as a shortcut may have exquisite apparent accuracy and no transportability. An interpretable model based on calibrated gap distributions, burst length, energy and live-time condition may be easier to diagnose when a field instrument is retuned or replaced. Where the complex model materially outperforms it, retain both as candidates and collect further independent validation, rather than declaring the winner on the basis of a small retrospective advantage.

Preservation should not be sacrificed to classifier convenience. The earlier timestamp record must remain linked to the original threshold and software version. A later, improved detector can be applied to retained raw data where such data exist, with derived events clearly distinguished from those recorded contemporaneously. Otherwise it is better to stratify the observation into epochs governed by different observation kernels, then assess consistency within rather than across incompatible epochs. An alert's meaning is conditional upon the acquisition process that produced it. If one

Copyright 2026, James M. Atkinson

half of a survey used threshold A and the other threshold B, the analyst cannot combine the event streams as if they were measured on one unchanging scale.

For the decision-theoretic calculation, assume a candidate source has a 0.10 probability of belonging to the nominated reference class under a declared prior; a further non-invasive monitoring session costs one unit; and missing a true candidate costs ten units. Under this deliberately simplified utility model, the expected loss of doing nothing is 10*0.10=1, equal to the cost of monitoring. The apparent equality illustrates that the decision is sensitive to the stipulated costs and prior. It does not prove the device is a controller. If independent investigation shows that the monitoring session is inexpensive and yields strong new evidence, the expected value of information may favour monitoring even when current classification remains weak. A thoughtful experiment is not a confession that the earlier model failed; it is what responsible evidence gathering looks like when a consequential conclusion demands more than a waveform's rhythm.

Harold Hotelling, Peer Question: Professor Box, your example of Bayesian predictive value is persuasive, but a false-alarm estimate obtained at one laboratory may not remain valid at another where the density of incidental wireless signals, the screening geometry and the availability of the receiver are quite different. The negative population can change faster than the positive signature. Suppose a classifier has been validated against a narrow set of electrically quiet rooms yet is deployed in a hospital engineering wing containing many intermittent medical and building-management transmissions. Even without any change to the unknown source, its posterior probability and false-alert burden will alter. What experimental

Copyright 2026, James M. Atkinson

design would allow an investigator to quantify this domain shift, and when should an instrument's classification algorithm cease to issue class labels at all? I also ask whether the classification should explicitly include an 'unknown or out-of-distribution' result rather than force every event into one of the classes observed during training.

George E. P. Box, Response: Professor Hotelling, I agree that a closed set of categories is often an invention of the classifier rather than a truth about the world. A forensic survey encounters devices and interference conditions that its training laboratory has never seen. The classification procedure should therefore contain a rejection option which states 'not reliably assigned within the validated reference classes'. That outcome is not a technical embarrassment. It is the rational response when evidence is insufficient, when a candidate falls outside training support or when competing models provide nearly identical predictions. The confidence attached to a forced label is worthless if the true source lies outside the model's vocabulary.

To measure domain shift, I would construct a validation programme that stratifies sites by objectively described electromagnetic conditions, receiver models, scanning schedules, background occupancy and environmental variation. Whole sites or sessions would be held out so that the assessment does not borrow the distinctive fingerprints of a room already present in training. For each stratum the report would give the number of independent trials, detection and classification results, and an interval of uncertainty. It might be appropriate to recalibrate alert thresholds locally using negative-control observations, but this must occur without peeking at the outcomes used for the final claim. When local negative controls show a false-alert rate

Copyright 2026, James M. Atkinson

significantly above the validated range, freeze class labelling and revert to descriptive acquisition pending recalibration.

An explicit out-of-distribution indicator could depend upon feature support, distance from validated combinations of acquisition conditions and instability under modest perturbations. But distance alone is not a universal probability of novelty, and a high-dimensional method can be confidently wrong when training data are incomplete. The simplest practical control is often a known signal run through the same receiver at the start and end of a visit, together with background records acquired under the same schedule. A change in accepted event counts under that control indicates that measurement behaviour has altered. The investigator should then distinguish instrument drift from changing ambient traffic instead of silently transferring the earlier classification rate.

Consider a negative-control comparison: a classifier produced 3 false alerts in 100 independent quiet-room sessions and 27 in 100 independent hospital-wing sessions. Those empirical rates are 3 percent and 27 percent. Pooling them into 15 percent without site qualification conceals the central fact that the environment strongly conditions performance. Moreover, each percentage has sampling uncertainty, and the sessions may not be independent if a single transmitter operates throughout several recordings. A report should present them separately, state its sampling unit and avoid transporting the first rate to the second environment. As you suggest, an explicit 'unknown' category is often a greater contribution to forensic integrity than a fractional improvement in a closed-set accuracy table.

George E. P. Box, Cross-Peer Question to Walter Laws Smith: Dr. Smith, we have discussed a series of timestamps as if the interval law could be fitted once and then carried from one inspection to the next. But a practical controller may operate in bursts, with short intervals within a burst and long intervals between bursts. It may also be observed by a scanner that independently misses some bursts, or by a triggered recorder that fuses consecutive pulses into one. Could you explain when a regenerative or renewal-reward description is preferable to a simplistic model of independent gaps? I would like a worked example which shows how a mixture of within-burst and between-burst intervals can mislead the analyst about event rate and duty cycle. Please address the boundary problem: in a finite recording, the first and last bursts may be truncated, and the resulting likelihood changes if one forgets that the censoring depends upon the measurement window. A reproducible definition of complete cycles should also state how the analyst handles source state changes occurring within the recording interval.

Walter Laws Smith, Cross-Peer Answer to George E. P. Box: Professor Box, the distinction between ordinary renewal gaps and complete cycles is decisive. A burst source can be represented in terms of cycles that begin at a defined regeneration event, such as an observed start-of-burst marker under controlled recording. Within each cycle a number of pulses may occur with short gaps, followed by a longer waiting period before the next cycle. If the cycles are independent and identically distributed under a particular experimental condition, a renewal-reward calculation relates the long-run average event rate to expected events per cycle divided by expected cycle duration. Yet the individual inter-pulse gaps need not be independent, nor

Copyright 2026, James M. Atkinson

need they share one simple distribution. The chosen cycle boundary must correspond to an observable, operationally defined feature, not to the analyst's preferred division of a plot.

For example, suppose a test controller emits exactly three pulses separated by 0.1 seconds, then waits until the next burst start at a period of 20 seconds. Each complete cycle has three pulses and duration 20 seconds, so the long-run pulse rate is 3/20=0.15 per second and the burst-start rate is 1/20=0.05 per second. The observed inter-pulse intervals within a complete cycle are 0.1, 0.1 and 19.8 seconds, yielding a mean interval of (0.1+0.1+19.8)/3=6.667 seconds. That mean correctly corresponds to 0.15 pulses per second in the long run but describes neither the intra-burst spacing nor the burst recurrence interval. An analyst calling 6.667 seconds the device's 'period' would confound three distinct quantities. If the instrument merges all pulses within 0.5 seconds, however, only burst starts remain; the observed rate becomes 0.05 per second and the interval histogram concentrates near 20 seconds.

Finite-window censoring matters. If recording begins halfway through a burst, the first accepted interval is not a complete cycle. If it stops during a long silent period, treating the last partial observation as a completed short interval biases the mean downward. Likelihood methods can include right-censored waiting time and left truncation, provided the observation boundary and the initial state are properly described. A scanner's off-channel periods create further censoring, potentially dependent on scheduling, and should be handled with a live-time mask rather than repaired by arbitrary interpolation. The model may need a hidden-state component if burst boundaries cannot be observed reliably. We should not

Copyright 2026, James M. Atkinson

state that the data identify a unique hidden state when several mechanisms lead to the same accepted timestamp sequence.

The renewal-reward model offers a useful decomposition, not a magic classifier. If the laboratory knows an authorised device emits clusters following scheduled sensor measurements, a comparable burst-cycle distribution may support a limited class-level similarity finding. Without waveform, response or environmental evidence, the same pattern could come from monitoring equipment, telemetry, interference or capture logic. I would retain raw pulse and merged-burst catalogues as separate derived records, documenting how each was produced. Comparisons across rooms and dates should use one clearly defined event unit. A pulse rate from one survey cannot legitimately be compared with a burst-start rate from another as if they measured the same physical phenomenon.

Dr. James M. Atkinson, Moderator: Dr. Smith, Professor Box has requested a distinction between elementary inter-arrival distributions and the renewal structure of whole bursts. Please consider regenerative cycles, missed events, incomplete observation and the danger of giving a numerical 'period' a mechanical significance it does not possess.

Walter Laws Smith, Principal Contributor: Dr. Atkinson, an observer can fail at the very first step by choosing the wrong event unit. A physical emission might contain many symbol transitions, one packet envelope, several retransmissions or a complete burst of exchange with another apparatus. If the analyst counts each threshold crossing as an event, an overloaded digitiser may create multiple apparent events from a single physical pulse. If the analyst applies a hold-off interval, it may convert a

Copyright 2026, James M. Atkinson

sequence of genuine emissions into one merged burst. One should therefore state whether the interval is measured between symbol transitions, detected pulse onsets, packet envelopes, burst starts or inferred session starts. These are not interchangeable units. They yield different distributions, and a frequency table cannot tell which unit was originally meant after the acquisition metadata have been discarded.

The renewal-reward relation provides a disciplined way to understand clustered sequences. Suppose complete, independent operating cycles have durations C_i seconds and contain R_i accepted events under a stable receiver configuration, with finite positive mean cycle duration E[C] and finite mean reward E[R]. Under suitable regenerative assumptions the long-run accepted-event rate approaches E[R]/E[C]. This is not the reciprocal of the mean within-burst gap unless the event definition and the cycle boundaries make it so. For an authorised controller whose output contains four transmissions per 30-second cycle, the mean nominal pulse rate is four divided by thirty, approximately 0.1333 per second. If a detector accepts only three of those four transmissions per cycle, the rate becomes 3/30=0.10 accepted events per second under that observation condition. The law does not tell us which pulse was omitted. The catalogue of accepted gaps could still suggest a different periodicity. This example introduces an observation-specific reward, not an assertion about some unmeasured clandestine device.

A practical complication is dependence between cycle length and the number of pulses. Suppose an authorised battery controller emits extra retries when the channel is congested. The physical retry count may increase precisely during unusually long cycles. The long-run rate formula

Copyright 2026, James M. Atkinson

E[R]/E[C] can still apply under suitable regenerative conditions, but it does not justify multiplying E[R] by 1/E[C] to obtain conditional rates in arbitrary subgroups or treating reward and cycle duration as independent. For diagnostic work one should inspect their joint distribution. Plot R_i against C_i, examine whether longer cycles contain more retransmissions and compare the resulting behaviour with a candidate channel-contention model. A pooled interval histogram loses that relationship; a well-kept experiment need not. The acquisition plan should also distinguish a missing burst from a burst whose pulses all fall below threshold, because the two omissions lead to different interpretations of a cycle.

Now consider the event-missing process. Let each true pulse be detected independently with probability p in an idealised model. If a controller produces four pulses per cycle, the number K of accepted pulses in that cycle has a binomial distribution with parameters 4 and p, and E[K]=4p. With p=0.75, the expected accepted pulse count is 3, which gives the nominal accepted rate of 0.10 per second in our 30-second example. The probability of missing all four is (1-p)^4=(0.25)^4=0.00390625. That is a small but nonzero probability of losing the entire cycle even under independent acceptance. If attenuation or a common receiver outage makes pulse detection correlated, the chance of losing the whole burst can be much larger. One must not borrow this binomial calculation without verifying the independence premise. A receiving antenna in a pattern null creates correlated non-detections across a burst, and a processor that hangs for a second may suppress all pulses arriving during that period.

The boundary of observation is another source of error. Consider a finite experiment that starts halfway between physical bursts and ends while the

Copyright 2026, James M. Atkinson

final burst is incomplete. A simple average of completed intervals excludes the last, possibly long, unobserved residual interval. That procedure can bias the estimate of the waiting-time distribution and of the recurrence law, depending on the stopping rule. In some settings a forward-recurrence time has a different distribution from an ordinary renewal interval because a randomly chosen moment is more likely to fall inside a long interval than inside a short one. A field investigator who starts a recording when an interesting indicator first flashes is not sampling the process at a randomly chosen time. The resulting initial interval is selected by the trigger, and assumptions of unbiased stationarity require justification. The acquisition should specify the temporal origin, the policy for ending the recording and whether long silences were recorded or simply left unobserved.

A test can be strengthened by measuring the same reference process with two independently configured but synchronised receivers. One may record continuously while the other uses a scheduled dwell that resembles the field survey. We can calculate accepted intervals for each, retain the observation masks and compare the inferred burst-cycle lengths. If the scan-based instrument reports a conspicuous 30-second period but the continuous reference reveals irregular physical bursts, the supposed schedule was introduced or exaggerated by the observation system. If both record consistent burst starts, the recurrence hypothesis gains support, although the device's role remains unresolved. A third test alters the threshold while preserving waveform acquisition. A pattern of additional short intervals at a lower threshold may indicate previously missed physical pulses or may represent newly accepted noise. The distinction requires waveform checks and negative controls, not wishful thinking.

Copyright 2026, James M. Atkinson

Another aspect of regenerative structure concerns equipment states. A controller may have a dormant period, a wake-up handshake, a brief exchange and a recovery phase, so that each cycle contains mechanistically different intervals. A two-state or multi-state model may summarise this sequence, but the states need not be identifiable from timestamps alone. For example, a four-pulse burst could be interpreted as one request and three acknowledgments, or as four periodic telemetry frames, or as repeated threshold crossings of one long modulated emission. Only a lawful controlled exemplar, waveform features or an observed response can discriminate those narratives. The state names in a mathematical model should therefore remain neutral, such as state A and state B, until independent physical evidence supports the claimed function.

I would also insist upon reproducibility across event definitions. A method that labels a source 'intermittent command class' only when the merger window is 80 milliseconds but reverses its conclusion when the window changes to 100 milliseconds is reporting instability in its processing rule, not a robust property of the source. One can prespecify a reasonable range of thresholds and merger windows from calibration, then test whether principal conclusions remain stable. Sensitivity analysis should reveal which steps are responsible for a class decision. If a small defensible change produces a different class, decline the label and retain the timed event observations as evidence of an as-yet-undetermined process. The objective of renewal theory in this setting is to expose the assumptions beneath a claimed recurrence, not to convert uncertainty into certainty by introducing a sophisticated term.

Copyright 2026, James M. Atkinson

Solomon Kullback, Peer Question: Dr. Smith, I should like to press the distinction between comparing two candidate renewal models and identifying a radio-link class. Suppose one proposed model is a burst-cycle renewal law with a sharply concentrated 30-second recurrence, and another is a mixture of background Poisson activity and scan-induced deletions. The analyst computes an information divergence between their fitted interval distributions and declares the larger divergence decisive. But both distributions were fitted on the same data, the reference instrument was used in both model constructions, and the intervals overlap through shared burst boundaries. Under those circumstances, the conventional independent-sample interpretation of a divergence estimate seems questionable. What would you count as a genuinely new observation? Could a likelihood ratio remain useful if the two models yield the same marginal gap histogram but different ordering of short and long gaps? How would you prevent the very construction of the burst boundaries from determining the result that is supposedly being tested?

Walter Laws Smith, Response: Professor Kullback, a divergence quantifies a distinction between specified probability distributions; it does not provide independence, identify a source or validate the estimated model family. If the two candidates are fitted on the same record, the apparent separation is vulnerable to overfitting, especially when the burst boundaries are selected to make one model look orderly. An honest comparison should fix the event-merging and cycle-definition rules on a training set or in a calibration experiment, then apply the frozen rules to independent recording sessions. The likelihood should be based on whatever stochastic structure the model actually asserts. If it predicts the ordered sequence of complete cycles, the

Copyright 2026, James M. Atkinson

likelihood of ordered cycle observations is relevant; a histogram-only likelihood may discard the very dependence that separates the models.

The significance of temporal order can be demonstrated simply. Imagine a record with six inter-arrival gaps, three of 0.2 seconds and three of 12 seconds. One arrangement alternates short and long gaps. Another places three short gaps together and three long gaps together. The marginal histogram is identical, yet their transition structure differs sharply. A model of paired exchanges or short bursts might make a specific prediction about that order; a simple independently sampled mixture would not. An ordering-sensitive test must be defined before the validation sequence is inspected and must include measurement uncertainty in event boundaries. If the source has been observed through gaps, even the true order may be partially unknown because unrecorded events can lie between accepted timestamps.

One can formulate a comparison using a likelihood ratio on complete, well-defined cycle observations under two frozen models, or a predictive log-score difference on withheld sessions. In either case, uncertainty should respect the dependence within cycles and between repeated sessions from the same apparatus. Repeatedly slicing one record into many overlapping windows does not multiply the number of independent devices or operating conditions represented. If independent field sessions are scarce, a hierarchical model can acknowledge common session effects, but its inferential limits should be reported. The weight of evidence then applies to the tested alternative models, not to the entire universe of possible RF sources.

Copyright 2026, James M. Atkinson

As for boundary selection, I would anchor the rule to an observable marker established by a controlled physical test, such as a known waveform envelope or a documented trigger from the reference apparatus. Where no marker exists, repeat the analysis across a prespecified range of merger windows and show how inference changes. A conclusion that depends critically upon an arbitrary interval cut-off should remain provisional. An attractive measure of information can never compensate for an ill-defined unit of observation. That is precisely why the definition of an event belongs in the methods section ahead of the first histogram, and why a forensic reviewer must be able to run the complete pipeline from preserved source data to the reported interval sequence.

Walter Laws Smith, Cross-Peer Question to Peter Whittle: Professor Whittle, let us suppose that an investigator observes intermittent detections at a succession of frequencies and notices that intervals within each frequency contain apparent cycles near 20, 40 and 60 seconds. Some analysts might call these harmonics of a scheduling clock, but others would recognise the receiver's own 20-second revisit cycle. I should like you to address the relationship between spectral analysis of event counts and the time-domain laws we have discussed. How can a point-process spectrum or a sampled count series acquire lines that did not originate in a transmitter's internal oscillator? What test would discriminate the physical periodicity from an alias created by regular observation gaps? If the receiver cannot collect all channels continuously, what bounds should be placed on a negative result at an unobserved frequency, and what role can an altered, incommensurate revisit schedule play in an independent confirmation?

Copyright 2026, James M. Atkinson

Please include the effect of pulse thinning on the spectral shape, since uniform event loss is not equivalent to systematic censoring by the receiver.

Peter Whittle, Cross-Peer Answer to Walter Laws Smith: Dr. Smith, a line in the spectrum of accepted-event counts is not necessarily a line in the spectrum of the physical emission process. The observed event train is shaped by the instrument's sampling and detection operations. Under a simple idealisation, a periodic exposure mask multiplies a time-varying event intensity. Multiplication in time creates convolution of spectral content, and periodic components of the mask can shift or mix energy into the observed spectrum. A low-frequency pattern in a binned count series may therefore be an alias of sampling, a property of a nonstationary event rate, or a genuine recurrent source feature. Its presence alone does not distinguish among these origins. A purported scheduling frequency should be tested against independently logged receiver revisit phases and a controlled, differently timed acquisition schedule.

Consider a source whose physical event process has no preferred 20-second rhythm and a receiver that can detect the nominated channel only for one second in each 20-second cycle. The observed event opportunities cluster into one-second windows at times approximately 0,20,40 and 60 seconds, even if physical events arrive independently at constant intensity. A histogram of accepted events can then exhibit peaks related to the scan schedule, and an event-time periodogram may show a line or modulation at the scan repetition frequency. If the receiver next uses a 23-second revisit cycle while other conditions are stable, an artefact induced by its attendance can move towards the new schedule; a genuine physical schedule should not simply follow the instrument's chosen period. This is a controlled

Copyright 2026, James M. Atkinson

discrimination strategy, not an unqualified proof, because source behaviour and the observation environment may change between tests.

A frequency-domain calculation can help expose the problem. A nominal 20-second revisit has a fundamental frequency 1/20=0.05 hertz. A 23-second revisit has a fundamental frequency 1/23 approximately 0.043478 hertz. An apparent 0.05-hertz feature that follows the instrument to about 0.043478 hertz supports an observation-mask explanation. A feature that remains near 0.05 hertz under continuous observation or under several independent schedules more strongly supports physical recurrence, provided the event-detection pipeline and clock calibration are comparable. The comparison must be accompanied by the spectral resolution available from the observation duration. For a 200-second record the nominal Fourier spacing is 1/200=0.005 hertz; that is small enough to separate these particular idealised frequencies in principle, but finite-window leakage and sparse event counts may prevent reliable discrimination in practice.

Negative evidence deserves similar restraint. When the receiver is off-channel it does not observe silence. It observes nothing at that frequency. We can state a probability of missing events under a calibrated model of duty cycle, detection efficiency and burst timing; we cannot assert their physical absence merely because no accepted timestamp appears. If the source's scheduling phase is nearly locked to the receiver's off-channel windows, even a substantial total observation time may offer little effective exposure. A defensible report therefore gives the live-time mask, the relevant model assumptions and the uncertainty surrounding any upper bound on event rate. I thank you for the question; I would return to the

Copyright 2026, James M. Atkinson

moderator the larger issue of how our spectral and temporal diagnostics can be tested together rather than elevated into competing slogans.

Dr. James M. Atkinson, Moderator: Professor Whittle, the panel has now examined renewal assumptions, doubly stochastic intensity, experimental selection, burst-cycle structure and spectral aliasing. Please bring these matters together in a practical identification protocol for an intermittent radio source, with explicit attention to what the evidence does not establish.

Peter Whittle, Principal Contributor: Dr. Atkinson, the useful mathematical object is not a single histogram but a collection of observations related by an explicit dynamic model. We may regard the underlying emitter as producing a point process, the receiver as applying a time-dependent observation operation and the analyst as computing summaries from the resulting catalogue. An observed event train can be represented symbolically as Y(t)=sum_i delta(t-t_i), where t_i are accepted event times and delta denotes an idealised point mass, but the engineering system has finite timestamp precision, filter settling, threshold latency and dead-time limitations. We should therefore distinguish this mathematical abstraction from the digitised instrument output. If an engineer bins accepted events into intervals of width Delta, the resulting count series can be analysed as a stochastic time series, but its autocorrelation and spectrum depend upon Delta and on the live-time process. A class label should not be attached to any single peak without asking what else would make that peak appear.

There are several distinct frequencies in the problem. A device may contain a master reference oscillator at megahertz frequencies; its message

Copyright 2026, James M. Atkinson

scheduler may operate at a fraction of a hertz; the receiver's channel revisit may repeat every few seconds; the timestamp processor may empty buffers at a different rate; and the investigator may finally bin events at a chosen sampling frequency. These scales interact. The visible periodicity of accepted event counts may arise from a scheduler, but it may also arise from a beating or alias between the physical and observation operations. The word harmonic should therefore be used with precision. A series of equally spaced lines at multiples of a rate is a feature of a periodic sequence, yet the existence of such lines in a measured count spectrum does not identify which physical or procedural element supplied that periodicity. The experiment must include independent timing references and deliberate changes to acquisition conditions.

A quantitative example illustrates the care required. Suppose a benign training source produces an accepted event intensity that fluctuates sinusoidally, $\lambda(t)=\lambda_0[1+a\cos(2\pi f_0 t)]$, with $\lambda_0=0.4$ events per second, modulation depth $a=0.5$ and $f_0=0.025$ hertz. This gives a 40-second intensity cycle, with minimum intensity 0.2 and maximum 0.6 events per second; the expected number of physical events in a full 40-second period is $0.4*40=16$. But the actual event intervals are random even when the rate changes periodically. The observed gaps need not cluster neatly at forty seconds; a periodogram of sufficiently long, correctly observed event counts may instead reveal the modulation. If a scanner visits the frequency for only two seconds every forty seconds, the instrument's exposure also has a forty-second cycle. The observed modulation may then be dominated by the scanner, and the model will not be identifiable from a single schedule.

Copyright 2026, James M. Atkinson

We should test whether the schedule survives an alteration of the observation operation. Keep the calibrated source unchanged in a controlled experiment, then repeat acquisition with an incommensurate revisit period while logging the actual, rather than commanded, tuning epochs. For example, change a 40-second receiver revisit to 37 seconds while preserving total live exposure as closely as feasible. A feature caused by the exposure mask should change its phase relationship or spectral position in a way predicted by that mask. A genuine source modulation can persist at 0.025 hertz, though its observed amplitude and precision may change because the new sampling window weights events differently. The two schedules must be compared using a common clock calibration, prespecified frequency region and uncertainty model. In a live field environment the source may not remain stationary between these tests; the report must therefore treat the result as conditional and, where possible, use simultaneous independent channels.

The choice of spectral method should match the stochastic process. A conventional Fourier transform of a uniformly sampled count sequence implicitly assigns zero count to each bin, but a bin in which the receiver was off-channel is missing exposure, not a genuinely observed zero. Replacing missing bins with zeros can manufacture apparent duty cycles and low-frequency modulation. One may instead analyse event likelihood conditioned on exposure, use a point-process spectral method that accounts for censoring, or restrict comparison to suitably matched live intervals. Each method has assumptions to test. The response of a spectral estimator to gaps should be characterised with simulated ground-truth data passed

Copyright 2026, James M. Atkinson

through the recorded observation mask. That process exposes whether an attractive feature is robust or an algebraic echo of the sampling schedule.

Our statistical decision should be hierarchical. First establish that accepted events are real RF-related detections rather than false triggers, buffer duplicates or calibration pulses. Next establish that their temporal structure is inconsistent with selected benign baselines under the correctly modelled receiver observation process. Next determine whether a candidate family of known lawful devices predicts the observed combinations of timing, waveform shape, spectral occupancy and controlled response better than a sufficiently broad set of alternatives. Only then may one describe a limited class-level resemblance, with quantified uncertainty and a stated domain of validation. At no point does statistical resemblance alone identify a particular concealed device, an operator, an intended recipient or a malicious purpose. Those are different propositions requiring independent evidence.

A negative search should be formulated in the same disciplined way. A receiver that observes a frequency for only ten percent of a survey does not provide evidence equivalent to a continuously monitored receiver with the same elapsed time. Consider a physical process with independent events at rate lambda=0.02 per second and an ideal live fraction d=0.10, with live intervals sufficiently dispersed and event detection perfect when live. Over T=1,000 seconds, the expected accepted count under the simplified independent-thinning approximation is lambda*d*T=0.02*0.10*1000=2.0, and the probability of zero detections is exp(-2)=0.1353. A null result thus remains quite plausible despite twenty expected physical events over elapsed time. If the duty windows happen systematically to miss scheduled

Copyright 2026, James M. Atkinson

physical events, the zero-detection probability could be higher still. One must report the temporal alignment assumption and the observed live-time mask, not merely the nominal exposure fraction.

I should expect the final evidence package to include the raw or least-processed lawfully retained observations, a timestamp ledger in a documented time scale, receiver live-time and retune logs, detection and merger thresholds, calibration evidence, a frozen analysis script, representative negative controls, independent validation results, and a concise statement of the hypotheses that remain indistinguishable. An appendix might include the normalised interval histogram, burst-cycle summaries, selected conditional-intensity diagnostics, and a periodogram calculated on an exposure-corrected basis. These objects serve different questions and should not be collapsed into one number. A line on a screen may catch the eye; only a documented sequence of measurements can support a conclusion about the process which produced it. I return the token with the observation that sober uncertainty is itself a valuable technical result when the alternative is a confident misclassification.

Peter Elias, Peer Question: Professor Whittle, your proposal treats the event catalogue as one of several lossy representations of a radio waveform, but a sophisticated classifier might take advantage of the dependence between pulse timing and the actual encoded payload. Where encryption or unfamiliar modulation prevents decoding, engineers may be tempted to use timing alone as a proxy for the function of the communication. Suppose a lawful training series establishes that one type of automation controller emits short bursts at irregular intervals after a sensor threshold is crossed, while another periodically announces status without requiring a command.

Copyright 2026, James M. Atkinson

In an unknown observation both may show clustered bursts and similar latency distributions, especially when the receiver misses portions of the spectrum. Would you allow the words 'control link' on a report in those circumstances? Can the technical conclusion be phrased in terms of observable input-output behaviour without implying that the analyst decoded a command? Finally, what independent intervention or measurement would most efficiently reduce the ambiguity while remaining wholly within authorised defensive inspection?

Peter Whittle, Response: Dr. Elias, the phrase should be constrained by the actual evidence. If the analyst has only timing and no independent observation of message content or controlled input-output behaviour, the strongest safe statement may be 'intermittent RF burst process with timing features similar to selected reference automation devices'. The term control link implies an exchange in which information is used to influence the state of a recipient. It is not established by a waiting-time distribution alone. An encrypted payload may prevent decoding, but inability to decode should neither be treated as evidence of innocence nor as evidence of a concealed command. The unobserved semantics remain unobserved.

The most useful lawful intervention depends upon what part of the mechanism can safely be controlled. In an authorised laboratory exemplar, deliberately vary a known physical stimulus and record whether a specified response follows within a predeclared latency window. Repeat with sham stimuli, independent clocks and a reference receiver capable of retaining the burst waveform. Such a design supports statements about the exemplar's stimulus-response behaviour. At an unknown site one should not manipulate an unidentified apparatus without authorisation; instead, one

Copyright 2026, James M. Atkinson

can characterise the receiving instrument through known reference injections, observe changes across receiver configurations, or compare signatures with independently validated exemplars. A controlled change in the receiver's observation schedule, by itself, can eliminate a scan artefact without interacting with the source at all.

It is helpful to divide the conclusions into successive levels. At the measurement level, the report can say that N accepted bursts occurred within a particular live-time mask and can give their timestamp uncertainty. At the statistical level, it can compare predicted interval distributions or holdout log scores under named models. At the engineering level, it can state which waveform, timing and environmental features resemble those of a calibrated reference class. At the functional level, it can claim actual control behaviour only if a linked response or independently verified protocol function has been established. Confidence at one level does not automatically transfer upward to the next. The mathematical description of intervals cannot convert an unknown payload into a decoded command.

For a practical example, suppose an authorised training device is stimulated in 40 randomised trials and a prespecified corresponding burst appears within 0.5 second in 34 cases, while 2 of 40 sham trials produce an apparently similar burst. The observed triggered proportion is 34/40=0.85 and the sham proportion 2/40=0.05. This difference may support a controlled association in that specific training apparatus, but confidence intervals, selection of latency window, independence of trials and possible environmental cues require assessment. It says nothing by itself about an unknown emitter that merely resembles the reference waveform. A genuine identification would need evidence connecting the unknown source to an

Copyright 2026, James M. Atkinson

equivalent controlled behaviour. A rigorous report gains authority by marking precisely where a measured fact ends and a provisional explanatory hypothesis begins.

Dr. James M. Atkinson, Moderator: I thank Professors Feller, Cox, Box, Smith and Whittle, and their questioning colleagues, for the disciplined distinction between event timing, observation artefacts, statistical classification and physical source attribution. The conclusions are confined to lawful defensive measurements and are presented as a fictional scholarly reconstruction. Question 077 remains an exercise in inferential method, not a historical transcript or an allegation about a particular radio system. We pass the token to the next question only after the independent structural and editorial controls have been satisfied.

QUESTION 078

Copyright 2026, James M. Atkinson

When do adaptive detection thresholds conceal a rising RF noise floor?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

SCHOLARLY RECONSTRUCTION. This hypothetical academic roundtable brings deceased scientists and engineers into a contemporary discussion of radio-frequency monitoring. Their contributions are newly written pedagogical interpretations, not authentic spoken testimony, verified quotations, or claims that these historical specialists personally worked with modern SDR consoles. All numerical case studies are stipulated illustrations requiring validation against the actual deployed equipment.

Dr. James M. Atkinson, Moderator: Professor Neyman, our monitoring system appears disciplined. Its alarm-rate graph stays nearly level, the operators hear the same modest sequence of alert tones from one watch to the next, and the event counter suggests nothing material has changed. Yet an independent calibrated probe reveals that broadband noise at the receiving input has gradually increased, while a lawful reference emitter of constant received power is disappearing from the detection log. What distinction must be made between regulating false alarms and preserving sensitivity? Please examine the decision hypothesis, the observable RF reference plane, the statistical assumptions, and the engineering evidence required before the operator may assert that a negative surveillance finding remains meaningful.

Copyright 2026, James M. Atkinson

Jerzy Neyman, Principal Contributor: Dr. Atkinson, an alarm is a decision conditioned upon a statistical model; a quiet alarm register is not a measurement of sensitivity. It is tempting to regard an almost constant count of reported excursions as evidence that the receiving installation remains unchanged. That inference confuses the distribution of the decision variable under the no-signal hypothesis with the distribution under the signal-present hypothesis. I would insist upon two separate measured properties. Let P_{FA} be the probability of deciding that a signal is present when it is absent, evaluated under a stated noise and interference condition. Let P_D be the probability of correctly deciding that a specified signal is present, evaluated for its strength, waveform, duration, arrival geometry, and the same receiving chain. A detector can regulate the first while the second deteriorates. Neither probability is a universal property of the instrument independent of its operating state.

Consider the deliberately simplified scalar experiment in which an observable X, measured in calibrated linear power units after a declared bandlimiting operation, is exponentially distributed with mean noise power μ under the null hypothesis H0. A threshold γ yields $P_{FA}=\Pr(X>\gamma|H0)=\exp(-\gamma/\mu)$, provided the exponential model and sample conditions apply. To obtain the illustrative target $P_{FA}=0.01$, choose $\gamma=-\mu \ln(0.01)$, approximately 4.605μ. If the actual mean noise power doubles from one to two arbitrary units, an adaptive algorithm preserving that target raises the threshold from approximately 4.605 to 9.210 power units. A steady false-alarm fraction is then perfectly compatible with a threshold that doubles. The model concerns one independent tested cell and does not directly

Copyright 2026, James M. Atkinson

describe threshold crossings clustered in time, millions of dependent FFT bins, or the event-level false-alarm count of a live console.

For an especially transparent illustration, suppose a narrow-band reference source contributes an additional fixed power $S=4$ units to the tested statistic and the decision statistic is approximated by $X=S+N$, where N is nonnegative exponentially distributed interference. This additive-power simplification is not the exact distribution of a complex voltage detector under a coherent signal, but it exposes the decision logic without pretending to a universal receiver law. At $\mu=1$ and $\gamma=4.605$, the illustrative detection probability is $\Pr(N>0.605)=\exp(-0.605)$, approximately 0.546. At $\mu=2$ and $\gamma=9.210$, the fixed signal falls farther below the threshold, and the probability is $\exp[-(9.210-4)/2]$, approximately 0.074. Thus the false-alarm probability is regulated at one per cent in both conditions, while detection of the fixed signal falls sharply. A proper laboratory test should replace this toy distribution with the actual waveform and processing statistics rather than publishing those numbers as equipment performance.

The inferential difficulty is not solved by replacing an adaptive threshold with a fixed one. Under rising noise, a fixed power threshold calibrated to the quieter environment generates more false alarms and can overwhelm the decision system. A sensible instrument may legitimately maintain a chosen false-alarm level as the noise varies. The forensic failure occurs when the instrument presents that design achievement as evidence of unchanged coverage. I require the report to retain the estimated noise in linear units, the threshold in the same calibrated units, the gain and attenuation state, a reference-signal detection curve, and the time series of changes. A graph of

Copyright 2026, James M. Atkinson

alarm counts alone omits the changing denominator against which signals are being judged.

The reference plane is equally important. An apparent noise rise at the digitiser output might be generated by a preamplifier, reference oscillator, switching converter or automatic-gain-control state rather than arriving through the antenna. The observed signal power can fall even while environmental noise stays fixed, for example when a connector changes loss or an attenuator enters the path. Consequently define the tested quantity at the antenna terminal, receiver input, or digital detector input, state every transformation and calibrate them. A second receiver sharing the same cable or amplifier does not automatically provide independence. Challenge the system using an input termination, calibrated noise source and injected weak reference waveform, observing the detection threshold and measured input-referred noise under each state.

A detection claim must also specify duration. A fixed test tone injected for ten seconds may survive an adaptive threshold that rejects a twenty-millisecond pulse, because integration time, dwell, triggering and the effective degrees of freedom differ. For each signal class, measure P_D as a function of calibrated input power, and retain the full curve or its appropriately bounded confidence interval rather than merely quoting one sensitivity figure. Include known negative controls and non-detections. If the detector's threshold follows its own test signal into the estimated background, the experiment must reveal that contamination. Guard windows, holdout frequencies and a separate reference input can help, but only when their independence and band responses are established.

Copyright 2026, James M. Atkinson

The decisive legal and scientific conclusion must be conditional. An unchanged reported false-alarm rate proves neither that the same weak emissions would be detected nor that the RF environment was unchanged. A defensible statement would say that the alarm controller met its nominal false-alarm criterion within the tested statistical assumptions, while the instrument's measured detection probability for specified reference signals changed in the documented way. An adverse conclusion based on absence of alarms must identify intervals when absolute noise or threshold changes made the survey materially less capable of seeing the relevant emissions. Exact confidence requires calibration data, not an elegant but untested formula.

Sir Ronald A. Fisher, Peer Question: Professor Neyman, your illustrative exponential statistic is attractive because the resulting threshold can be written in one line, yet the real receiver rarely supplies independent identically distributed power samples. It may average overlapping transforms, report maxima across correlated cells, and select a detection window only after the operator has noticed something suspicious. How should the calibration distinguish the false-alarm probability of one preselected cell from the probability of at least one alarm over an entire search, and what information must be retained if the analyst chooses a detection threshold after examining the same data? I am especially concerned that an estimated one-per-cent false alarm probability might become an unsupported statement about a night's monitoring, during which millions of opportunities existed and the opportunities were neither statistically independent nor uniformly observed. Could you specify a

Copyright 2026, James M. Atkinson

replication scheme in which the calibration and the evaluation of the decision rule remain genuinely separate?

Jerzy Neyman, Response: Sir Ronald, the unit of inference must be named before the probability is computed. A single-bin false-alarm probability concerns one predeclared tested statistic under H0. The probability of at least one false alarm across m independent tests would be 1−(1−p)^m, where p is the per-test probability, but that formula ceases to be exact when the tests are dependent or the number of tests was itself selected after inspection. At p=0.01 and m=100 independent tests, the probability is 1−0.99^100, approximately 0.634, not 0.01. A monitoring console that groups neighbouring exceedances into events may report an entirely different event-level count. One must therefore calibrate the actual pipeline, including its window overlap, clustering, detection masks and operator selection protocol.

I would partition the experimental record into at least a development set and an untouched validation set, with partitions chosen by independent acquisition runs where possible rather than by adjacent, strongly correlated samples from one capture. The development set defines the threshold rule and its parameters; the validation set estimates its performance without readjustment. A designed noise-only exposure measures false detections, and an independently generated sequence containing known weak signals measures missed detections. For periodic or slowly varying environmental noise, an additional held-out day or temperature condition tests generalisation beyond the development regime. When the analyst changes thresholds after seeing the validation results, that set has become part of development and cannot support the same untouched claim.

Copyright 2026, James M. Atkinson

A useful reporting table contains the number of independent trials as defensibly defined, the number of false alarms and misses, confidence intervals that acknowledge clustering, and the operating state. Do not manufacture independence by taking every FFT line as a separate replicate. Resampling can preserve blocks or entire acquisition sessions to retain dependence, but it cannot correct a fundamental absence of relevant operating conditions. For every claim, distinguish the per-cell nominal criterion, observed event-level rate, and achieved detection probability. The mathematical model should be audited against deliberately injected weak signals and against alternate noise-only configurations. If one detector version was selected because it looked best among many investigated versions, document that selection and avoid attributing the winning estimate to a model that was fixed in advance.

David R. Cox, Peer Question: Professor Neyman, the measurement equation still seems incomplete to me. An adaptive threshold is not updated by a disembodied noise law; it is updated by a sequence of observations, some delayed and some missing. The algorithm may use a moving median, a trimmed mean, or exponentially weighted measurements, while the receiver can change gain and preselector settings. Could two records with the same present noise power yield different thresholds because their histories differ? If so, the state of the estimator becomes an unobserved confounder in a naive comparison between two survey locations. Please describe the minimum history and intervention needed to demonstrate a deterioration in sensitivity without confusing it with delayed adaptation, and say how one should handle a constant weak reference signal that is sometimes included in the estimator's training windows. Would the

Copyright 2026, James M. Atkinson

comparison also report the number of qualified receiver dwell visits, the duration of each unobserved interval, and the order in which injected references are encountered? Without those covariates, an apparent time trend might simply be a different sampling frame rather than a genuine change in signal visibility.

Jerzy Neyman, Response: Dr. Cox, a threshold generated by a recursive estimator is a state variable as well as a function of current RF observations. Two systems with equal current input noise may produce different thresholds if one has just left a high-noise interval and the other has been quiet for an hour. The history can be scientifically relevant even when the adaptive algorithm is operating exactly as its designer intended. A record limited to a current noise estimate and threshold cannot always reconstruct how the decision was formed. Retain the update equation, estimator initial state, effective time constant, reference-cell selection, exclusions, gain state, lost-sample indicators and every manual or automatic reset. These controls make it possible to replay the decision from contemporaneous information rather than from a retrospective reconstruction that silently assumes steady conditions.

For example, an exponential estimate might obey $\mu\text{hat}_k=(1-\alpha)\mu\text{hat}_{(k-1)}+\alpha X_k$, where α lies between zero and one, X_k is a measured reference-cell power and k indexes qualified updates. If α=0.1, an abrupt noise increase is reflected slowly; if α=0.8, the threshold follows quickly but is also more sensitive to transient contamination. The count k should represent actual admitted updates, not merely wall-clock seconds. A receiver visiting one frequency infrequently does not acquire the same history as a continuously observing instrument. A missing update must not

Copyright 2026, James M. Atkinson

be silently replaced by a zero-power observation, since that would introduce its own bias. In a nonstationary environment the threshold is a filtered history, and any claim about preserved sensitivity must be tested over the time path, not just at its final equilibrium.

I would expose the receiver to a controlled sequence: quiet baseline, gradual broadband-noise ramp, stable elevated noise, then recovery, with a constant independently verified weak signal present throughout. Repeat the sequence after changing update rate, gain and signal placement; use a third condition in which the reference signal is absent from the estimator's reference windows. Compare observed threshold history and miss rate to an instrumented fixed-threshold observer, making clear that each serves a different inferential purpose. The fixed observer helps reveal absolute noise movement, while the adaptive observer may better regulate nuisance alarms. If the reference signal contaminates the training cells, its own power can elevate the threshold and cause self-masking, a separate hypothesis from broadband noise alone. Only an experiment that distinguishes those mechanisms should support the final technical explanation.

Jerzy Neyman, Cross-Peer Question to Walter A. Shewhart: Dr. Shewhart, I have insisted on separating false alarms from detection probability, but your control-chart tradition confronts a question my simplified test leaves unsettled. When may the analyst call a rising baseline a genuine process change, rather than a transient fluctuation or a reference disturbance caused by the instrument? If an adaptive detector regards the new baseline as normal within a few updates, does that amount to a loss of evidence about the change point? Please identify which streams should be treated as measurements to preserve and which may legitimately be treated as control

Copyright 2026, James M. Atkinson

variables. I would also welcome a worked example contrasting a display that normalises each period to its contemporary noise with a fixed metrological monitor whose calibration does not itself drift. How should a survey report communicate these two viewpoints without suggesting that either one is the whole truth? Please name a control rule that responds to an absolute calibrated-power trend independently of the self-adjusting alarm rule, including the conditions under which the two instruments must be judged to disagree.

Walter A. Shewhart, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, the principal correction is to distinguish a measured process from the control rule designed to respond to it. An adaptive detector may maintain approximately stable alarm frequency by redefining its baseline whenever the observations change. That is a useful operating strategy for certain purposes, but it is a poor sole witness to whether the receiving environment has changed. I would maintain an immutable reference stream in a fixed, calibrated measurement system. From that record one can evaluate the absolute input-referred noise, its time sequence and possible shifts. The operational detector's normalised statistic is a different derived record, governed by its own update law. Neither ought to overwrite the other.

Suppose a monitoring channel reports 10 arbitrary calibrated linear-noise units during a reference period and 16 units after a change in the environment, whereas an adaptive processor divides every observation by its current estimate of baseline. A stable normalised quotient near one can coexist with a 60 per cent increase in measured power. In decibels, the ratio is 10 log10(16/10), approximately 2.04 dB. The normalised graph and the

Copyright 2026, James M. Atkinson

calibrated graph are not contradictory, but they answer different questions. A control chart computed over the unaltered absolute record can identify a sustained rise that the decision controller was deliberately designed to follow. Whether the rise warrants an alarm depends on the documented control limits, the uncertainty of the reference, the serial dependence and the operational consequences.

The control limits must not be selected solely from the affected interval. Establish a stable reference period with verified instrument configuration, identify known maintenance and calibration actions, and record the sensitivity of the conclusions to window length. In practical monitoring, the environment may possess predictable daily variation; comparing a day to a night without modelling this pattern can manufacture a change. Likewise a broadband surge in a neighbouring transmitter can temporarily alter the apparent baseline without establishing a permanent defect. For change-point inference, examine persistence, repetition and physically discriminating tests. Switch to a terminated input to challenge antenna-origin noise; use a calibrated noise source and independent receiver to test whether the apparent increase follows the front end or the environment.

A complete report would present two parallel timelines: one of absolute input-referred noise and one of operational decision threshold and alarm rate. The historical baseline, reference plane and update policy must be recoverable. It is legitimate that an adaptive detector chooses a different threshold to limit false alarms, but that action must not erase the evidence that the threshold rose. Where negative detection findings are important, augment both streams with scheduled weak-signal challenges and measure their probability of detection. The operator should hear the distinction

Copyright 2026, James M. Atkinson

between a quiet alarm bell and a healthy receiver; one is a property of the configured decision, the other requires an independent performance test.

Dr. James M. Atkinson, Moderator: Dr. Shewhart, Professor Neyman has distinguished the statistical target from the ability to detect a real signal. I now ask you to examine the physical record as a process whose operating point changes. What can a properly preserved control history reveal when the receiver's own adaptive baseline makes the outward alarm record appear stationary?

Walter A. Shewhart, Principal Contributor: Dr. Atkinson, the sound of an unchanged alarm cadence can conceal a most important shift in the underlying measured process. I would begin with the instrument's traceable engineering measurements, rather than with the detector's designation of normality. A control rule is developed for a purpose: it may maintain the workload of an operator, prevent excessive nuisance reports, or keep an event rate approximately steady across changing environments. Such regulation need not protect the forensic meaning of a negative search. When the regulator succeeds, the observer may see fewer signs of change in the derived outputs precisely because a new threshold has absorbed it. That is not a contradiction. The instrument can be statistically in control in the limited sense of its decision policy while the environmental noise experienced by the antenna has materially increased.

I distinguish three timescales in this problem. There is the physical timescale of the broadband interference: it may rise in seconds as a machine is activated, drift over hours with temperature, or vary periodically with the site schedule. There is the estimator timescale, determined by averaging

Copyright 2026, James M. Atkinson

windows and the selection of observations used to update the baseline. Finally there is the reporting timescale: an operator may receive only five-minute summaries, hourly alarm counts, or selected event screenshots. A fast physical change can be diluted by a slow report; a slow physical change can be followed continuously by a fast estimator and thereby disappear from a normalised trace. To interpret the result, one must retain enough temporal resolution to reconstruct all three histories and state exactly which trace is a raw measurement and which has been transformed.

Suppose a receiver stores a power estimate P_k every qualified second and uses a moving average of the previous 60 admitted values to generate an adaptive threshold. A gradual noise increase over 30 minutes will cause the baseline to climb while the ratio of current power to baseline remains close to its historically expected value. The nominal alarm rate may therefore remain stable. A separate, frozen reference chart of input-referred power, measured in a fixed bandwidth and referenced to the same connector plane, could demonstrate that the absolute noise is rising. The analyst must not reconstruct that reference chart by taking the adaptive output and multiplying it by an unavailable estimated baseline. Preserve the actual values, estimator state and configuration changes at acquisition time, because the inversion may be impossible once observations have been discarded or censored.

It is also essential to separate common-cause variation from assignable causes. An ambient RF environment is naturally variable, particularly around electrically noisy equipment and changing antenna geometry. A single upward sample does not establish deterioration. Yet a sustained run of increasing noise, synchronised with an identifiable change in supply,

Copyright 2026, James M. Atkinson

antenna location or receiver configuration, warrants a controlled challenge. The objective is not to pronounce a cause from the chart but to design experiments that would make competing explanations behave differently. A terminated-input measurement may challenge whether the excess noise enters through the antenna, but it changes the physical configuration and must be interpreted cautiously. A safe calibrated noise injection downstream of the antenna can measure the receiving chain, while a separately positioned sensor can test whether the environment changed. No one test establishes the whole case.

A control chart's nominal false-alarm probability depends on its assumptions. If the measured power sequence is serially correlated because overlapping FFT windows or estimator smoothing are used, three successive excursions are not three independent warnings. If the baseline distribution is heavy-tailed, a control limit computed under a Gaussian idealisation can trigger too often or too rarely. The act of choosing a threshold after seeing the largest excursion also changes the inferential question. I would therefore divide the work into reference qualification, ongoing monitoring and challenge-testing. The reference period is chosen and documented in advance. Its uncertainty and likely environmental variability are evaluated before the operator interprets any excursion as anomalous. A sustained absolute noise rise should then be evaluated against those limits, independently of the adaptive detector's internal decision rule.

One can construct a useful experiment using two otherwise equivalent software channels fed from the same digitised samples. The first channel operates at a fixed, calibrated input-referred threshold; the second uses the adaptive estimator under study. In addition, a known weak reference

Copyright 2026, James M. Atkinson

waveform of fixed power is inserted intermittently under a schedule withheld from the detector's threshold calculation. Record the true injection schedule, both alarm outputs, the adaptive threshold, the absolute power baseline and all automatic-gain-control changes. During a controlled broadband noise ramp, the fixed channel may show a rising false-alarm fraction; the adaptive channel may maintain stable false alarms while increasingly missing the reference waveform. That experiment demonstrates the trade-off directly and allows the operator to explain it without calling either architecture universally superior.

Measurement discipline requires one further precaution. Apparent gain changes and log-power shifts may arise from arithmetic or representation errors. A mean of decibel values is not generally the logarithm of the mean linear power, and a detector that updates its baseline in dB may behave differently from one whose threshold is estimated in linear units. If the physical power increases by a factor of four, the change is 10 log10(4), approximately 6.02 dB. A displayed rise of six decibels is meaningful only when the measurement bandwidth, detector, gain state and calibration plane remained comparable. Operators should be shown both the physical transformation and the uncertainty in its calibration, not a numeric display with unexplained decimal places.

In the final report, I would require an explicit change log, an immutable absolute-noise series, the adaptive-baseline history, and the results of both positive and negative controls. The absence of detections can support only a bounded assurance statement for the signals, powers and intervals over which the instrument remained demonstrably capable. A stable alarm cadence should be treated as evidence about the behaviour of the algorithm

Copyright 2026, James M. Atkinson

under its specified operating conditions. It is not independent evidence that the environment was quiet or that the instrument remained equally sensitive. The most useful control design preserves the measured disturbance even when the decision system successfully adapts to it.

George E. P. Box, Peer Question: Dr. Shewhart, your distinction between the physical process and the adaptive display is persuasive, but I worry about the phrase 'fixed reference' becoming another hidden model. A reference chart based on an unusually quiet morning, or on an antenna whose gain changed when someone moved a cabinet, can give a dramatic indication of change without demonstrating deterioration of the receiver. How would you decide which environmental covariates belong in the baseline and which ought to remain as separately reported disturbances? Could a model that adjusts for temperature, time of day and known transmissions inadvertently remove the very broadband increase we wish to discover? Please explain how the engineer should test model adequacy using data beyond the calibration interval, and how to resist the temptation to redesign the control limits until the preferred diagnosis appears. Where would a separate calibrated tone or noise witness fit into that decision? Would you randomise the test-order of the injected weak references, and would you state the temporal sampling plan before inspecting the adaptive alarm trace, so that the independently observed change is not retrospectively selected to fit the apparent result?

Walter A. Shewhart, Response: Professor Box, a fixed reference is a defined experimental condition, not a declaration that one morning represents the whole world. I would require the survey plan to distinguish the operating envelope from the specific hypothesis. If temperature is a

Copyright 2026, James M. Atkinson

recognised source of receiver noise-figure variation, the qualified model may include its independently measured effect. If broadband electromagnetic interference is the phenomenon of interest, it would be improper to subtract it away merely by adding a flexible environmental trend that learns every excursion as normal. The model must represent a causal measurement system and not a curve fitted to the desired conclusion. Pre-registering the relevant covariates and their expected directions provides some protection against retrospective explanation.

Use separate calibration experiments to determine the receiver's gain and noise response as a function of temperature and configuration. Then monitor the live environment with those corrections and with uncertainty bands that retain the calibration error. A model that predicts an exact power change because of a temperature sensor should be challenged at more than one temperature and on another day; the observation being corrected must not itself be the sole evidence for the correction coefficient. For a survey location, preserve the antenna position, cable state and nearby equipment operations as explicit covariates. If the target hypothesis is that external noise increased, report the raw observation and the corrected estimate side by side rather than hiding the raw series.

I would also reserve independent days or controlled trials that were not used to select limits or covariate terms. A quiet reference emitter, injected at a known level after a declared RF reference plane, helps test gain stability. A calibrated broadband noise witness helps distinguish an environmental rise from an instrument change. Neither should be embedded thoughtlessly in the baseline estimator's reference cells; contamination can alter the very threshold under investigation. Where removal of an expected

Copyright 2026, James M. Atkinson

environmental effect reduces an observed rise, the report should document both results and the justification. If the conclusion changes materially under plausible models, the uncertainty is epistemic and must not be replaced with a narrow ordinary error bar.

Control limits remain conditional on the chosen process. I would not accept a revised limit merely because the first one generated too many uncomfortable warnings. An authorised improvement can be introduced with a versioned date and a fresh prospective qualification run, while retaining the earlier classification and the reasons for changing it. The analyst should state the coverage for which the limits were validated, the extent to which data were serially correlated, and whether the change tested was sustained. A model is a tool for organising evidence, never a device for making the history look cleaner than it was. That is especially important when a negative surveillance report may later be read as a claim that no relevant emission existed.

Walter A. Shewhart, Cross-Peer Question to Norbert Wiener: Professor Wiener, I can preserve the absolute power series and a parallel adaptive-threshold history, but the receiver's estimator is a dynamical system. Its smoothing creates memory, and its response to a rising background may be delayed in ways my simple static control limits do not explain. Would you formulate the relationship among the physical input, estimator state, gain-control feedback and detection output without pretending all errors are stationary? How should one measure the effective time constant when updates occur only during intermittent frequency visits, and what would distinguish a benign transient from an estimator that has incorporated the constant weak reference signal into its own noise model? I would also ask

Copyright 2026, James M. Atkinson

whether seemingly smooth transitions can conceal genuine step changes through interpolation or data loss, especially when the hardware clock and software reporting clock disagree. Can one derive a practical step-response acceptance test from the estimator equation, then specify what independent instrument measurement is required to detect an estimator that follows the changing environment correctly but thereby conceals a physical sensitivity loss?

Norbert Wiener, Cross-Peer Answer to Walter A. Shewhart: Dr. Shewhart, an adaptive detector is properly considered a causal dynamical system whose output depends upon its input history and internal state. Let x_k be the calibrated observation admitted at update k, let m_k be the estimated background, and let α be a weighting factor between zero and one. An elementary estimator has $m_k=(1-\alpha)m_{(k-1)}+\alpha x_k$. For a step from baseline m0 to constant x1, after n valid updates its estimate is $m_n=x1+(m0-x1)(1-\alpha)^n$. The effect of the initial baseline decays geometrically, but the number of qualified updates matters. A receiver that revisits the tested band once per minute will adapt far more slowly in wall time than one that continuously receives a new observation each second, even when both use the same α. A report must identify this difference, not quietly replace sample count with elapsed time.

For α=0.1, the weight of the initial state after ten updates is 0.9^{10}, approximately 0.349. After twenty updates it is approximately 0.122. Those are not necessarily ten or twenty seconds; they could represent minutes or an irregular sequence of visits. An increasing background may therefore be followed with a lag determined jointly by the algorithm, the observation schedule and the loss of qualified samples. During the lag, a fixed-level

Copyright 2026, James M. Atkinson

signal may briefly pass the threshold and subsequently disappear, giving the impression of a transmission that stopped. The relevant evidence includes the estimator state at each decision, whether an update was admitted, the temporal sampling map and independent measurements of actual input noise.

Automatic gain control adds another feedback path. If analogue gain g_k changes, the digital statistic might decrease while input-referred noise increases, depending on how the calibration and detector normalisation are applied. A well-designed system records g_k, attenuation, ADC full-scale reference and gain uncertainty, then transforms observations to a stable input plane where physically defensible. A displayed baseline can remain visually flat while the receiver's absolute detection capability falls because of overload, compression or altered preselection. Conversely, a gain-control transient can create a digital-noise rise without a corresponding external field change. The controller state must therefore be challenged separately from the environmental hypothesis.

Self-masking is established by selective experiments. Inject the same weak signal into a known cell, first with that cell excluded from training and then with its spectral skirts allowed into the reference window. Observe whether the estimator rises and whether the decision threshold follows it. Vary the guard interval and test under a broadband ramp with a second independently monitored signal. If the feature is lost only when its own power contaminates the estimator, the cause differs from ordinary noise-induced loss of SNR. Repeat with controlled phase, amplitude and duty-cycle changes, because leakage can vary with windowing. One must not infer a unique mechanism merely from the correlation of two curves.

Copyright 2026, James M. Atkinson

Finally, interpolation of a missing background estimate is a processing assumption, not a measurement. It can make the threshold trace smooth while hiding a sudden equipment-state transition or an unobserved RF event. Preserve the original sequence, missing-data markers, state resets and separate monotonic hardware chronology. The model is valuable precisely when its limitations are visible. A smooth red line on a control display should not persuade a forensic reviewer that the underlying physical path was continuous, just as a stable false-alarm counter should not persuade them that sensitivity remained fixed.

Dr. James M. Atkinson, Moderator: Professor Wiener, Dr. Shewhart has placed the historical process and the modern control law on separate records. Please examine the filtering, feedback and sampling mathematics in greater depth, especially the circumstances under which the threshold's own adaptation will make a gradual loss of sensitivity appear as an orderly, quiet monitoring operation.

Norbert Wiener, Principal Contributor: Dr. Atkinson, the essential point is that a receiver is not a passive window through which a fixed background is viewed. It is a chain of transformations, and some of those transformations depend upon previous observations. An adaptive threshold is a filter driven by a statistic of the measured signal, a choice of reference cells and a model of nuisance variation. The output is a controlled decision. If the filter tracks the physical disturbance, the disturbance can disappear from the normalised display without disappearing from the antenna. Conversely a transient introduced by the filter or a changing gain state can create a displayed anomaly even while the incident electromagnetic field is unchanged. The engineering task is to identify these pathways by

Copyright 2026, James M. Atkinson

perturbation and measurement, not by assigning intention to a characteristic-looking trace.

For a simple linearisation, let $n(t)$ represent the input-referred background power over a declared bandwidth and $m(t)$ an adaptive estimate. An ideal first-order continuous-time approximation is $\tau\, dm/dt + m = n(t)$, with τ positive and measured in seconds. The approximation is useful only when observations are effectively continuous and the algorithm behaves approximately linearly. For an abrupt step of size Δn at time zero, the model gives $m(t)=n0+\Delta n[1-\exp(-t/\tau)]$ for $t\geq 0$, assuming the system was initially at $n0$. The physical input jumps immediately while the estimated threshold approaches its new value gradually. When an operator inspects only the ratio of observed power to $m(t)$, the apparent disturbance depends upon the time constant and may fade even when the input remains permanently elevated.

A realistic frequency-agile receiver complicates the model. It can tune the channel for a short dwell, skip intervals while other bands are visited, and retain the last threshold across those gaps. The effective filter is updated on a sequence of sample admissions, not on an idealised continuous clock. Define t_k as the actual physical time of qualified update k, and $\Delta t_k=t_k-t_{(k-1)}$. A time-constant-consistent exponential smoother can use $\alpha_k=1-\exp(-\Delta t_k/\tau)$, whereas a fixed α applied once per received block weights each block equally regardless of elapsed wall time. Neither approach is universally correct, but they imply different threshold histories. Missing data, stopped counters and variable revisit schedules therefore matter directly to the conditions under which one can rely upon a negative finding.

Copyright 2026, James M. Atkinson

The receiver may also include feedback in automatic gain control. Let g(t) denote analogue gain, and suppose the output statistic is approximately g(t) times the sum of external signal and noise, subject to the device's nonlinearities and calibration. A controller reducing g(t) to prevent overload can make the digital power look stable. Yet the signal-to-noise relationship at the input has changed, and a small input tone may no longer cross the post-detection threshold in the same way. A fixed noise figure is not sufficient to characterise gain and compression under a powerful blocker. The analyst must record attenuator settings, gain-control command, compression indicators and the calibration that converts digitised observations to an input-referred quantity. When the conversion is invalid during overload, mark the observation rather than force a tidy calibrated number.

The RF scene can change slowly while a filter is designed to remove slow changes. A high-pass operation on estimated residuals makes sudden excursions conspicuous and drift inconspicuous. A median reference window resists isolated bright cells but can absorb broad interference covering much of the reference region. An order-statistic detector may behave differently when the distribution of reference-cell powers changes shape, even though their mean stays constant. In each case the difficulty is not merely an estimated noise level; it is the mismatch between the assumed nuisance model and the physical mixture of thermal noise, interference, true weak emissions and internal artefacts. The statistics should be challenged with known input conditions representing each mixture.

Copyright 2026, James M. Atkinson

There is a useful distinction between regulating P_FA and preserving P_D that must be read aloud in the laboratory. An adaptive detector may set a threshold proportional to a local noise estimate. Under ideal homogeneous assumptions the probability of false alarm can remain approximately constant as that estimate rises. But the signal-to-noise ratio of a fixed input waveform declines. If its calibrated signal power S remains at −110 dBm while input noise in the relevant bandwidth rises from −120 dBm to −114 dBm, the nominal signal-to-noise ratio falls from 10 dB to 4 dB. Those are illustrative input powers; a logarithmic subtraction is valid for the power ratio when the same bandwidth and reference plane are used. Maintaining the same nuisance alarm rate does not restore the six decibels of lost SNR. Detection probability can deteriorate even though the control chart looks quiet.

How does one expose the loss? Use an independently generated weak signal injected before the elements whose performance is being evaluated, and schedule it blindly to the detector where possible. Measure its detection probability at several calibrated input powers under each noise condition. Place a second wideband witness channel alongside the adaptive detector and do not allow both to share all calibration errors. Introduce a controlled broadband ramp and separate controlled gain changes. A constant false-alarm criterion is valuable operationally, but should be accompanied by a minimum detectable signal or receiver operating characteristic measured under conditions comparable to the actual survey. The word 'sensitivity' must be attached to a specified waveform, dwell duration and probability of detection; otherwise the operator has only a catalogue slogan.

Copyright 2026, James M. Atkinson

The final complication is that feedback can make an instrument appear stable even when its underlying assumptions have become invalid. A strongly nonstationary disturbance may alter the distribution of the statistic within each smoothing window, and a moving estimate can fail to track abrupt transitions while responding to persistent noise in a misleading way. A noise floor measured in a logarithmic display can be numerically averaged in ways that do not reproduce mean physical power. An estimator can be trained on its own intermittent signal of interest and inadvertently suppress it. For these reasons, preserve raw digitised evidence, the filter state and every derived decision so that an independent reviewer can replay alternatives. Without this provenance, one cannot establish whether the quiet console reflects an unchanged environment, successful nuisance regulation or degradation of the measurement chain.

Claude Shannon, Peer Question: Professor Wiener, your treatment of threshold adaptation as filtering is persuasive, but I would like to press the informational consequence. A monitoring computer may store only alarms and their timestamps, discarding raw samples and the threshold state because it judges the other observations uninteresting. If a weak signal falls below a rising adaptive threshold, is its loss merely a reduction of sensitivity, or has the compression of the original record also destroyed evidence that could have been recovered by a different detector? In evaluating a negative finding, how should one distinguish an inaccessible waveform whose samples were retained from one whose samples were never recorded? Please also explain why applying a more elaborate retrospective classifier cannot recreate information destroyed by clipping, saturation, non-observation or deliberate event-only logging, even if the classifier's

Copyright 2026, James M. Atkinson

estimated confidence appears mathematically precise. Please distinguish a display that retains the full power spectrum from one that archives only Boolean alarms, and specify which claims can be reconstructed from each representation after the monitoring period has ended. The distinction determines which hypotheses can ever be tested.

Norbert Wiener, Response: Dr. Shannon, the distinction is between a lost decision opportunity and a lost physical observation. If the receiver retained the original complex samples, a later analyst may apply a different detector, calibrate a changed noise floor, vary integration time and test a more suitable waveform model. Its eventual conclusion remains conditional on the data's actual bandwidth, noise, time continuity and instrument state. If the computer saved only threshold-crossing events, it has reduced an analogue or complex-valued observation to a sparse decision record. The absence of an event then does not disclose the statistic's distance below threshold or even whether a valid measurement was available for the interval. One cannot generally reverse that transformation, because many distinct physical histories produce the same event log.

A second type of loss occurs before the detector. If the ADC saturated during a strong broadband disturbance, the clipped waveform may suppress or distort a weak component. A more elaborate algorithm cannot uniquely reconstruct information about the unclipped waveform from the saturating samples without additional assumptions. If the receiver was tuned elsewhere or the hardware dropped samples, no observation of that portion of the spectrum exists in the affected interval. Mathematical interpolation can produce a smooth substitute but not an independent measurement of the omitted emission. These limitations are distinct from a

Copyright 2026, James M. Atkinson

case in which a good waveform record was retained but an unsatisfactory threshold suppressed its online alert.

Consequently I would keep an acquisition ledger recording tuning state, sample counters, clock reference, gain, overload flags and the exact interval of actual coverage. A rolling retention scheme may be necessary for storage efficiency, but it should retain enough pre-event and background data to evaluate whether the threshold was functioning and what the RF environment looked like. If only events are preserved, the report should not assert that the receiver proved an absence of transmissions; it should state that its configured decision system produced no qualifying alerts under the limitations of its retained record. The wording may appear conservative, but it preserves the distinction between inference and observation.

For testing a proposed retrospective classifier, keep a separately recorded known-signal challenge set with ground truth and full raw samples. Compare what the algorithm could detect when full data are available with what a replay limited to event-only logs can establish. No amount of classifier complexity changes the information content of the shorter record. A machine learning system may assign an impressive probability to its own features, but the probability pertains to a model conditional on the observations supplied. If the relevant signal's evidence was physically clipped or never stored, a probability cannot make it reappear. The crucial forensic question remains what was actually acquired, what was preserved, and what was inferred afterwards.

Richard W. Hamming, Peer Question: Professor Wiener, the receiver's software may implement the correct mathematical filter on paper yet give a

Copyright 2026, James M. Atkinson

misleading field result through numerical representation and state handling. One implementation updates a power estimate in linear units, another averages decibels, and a third resets its running state whenever a USB stream times out. A detector may also process repeated blocks after a transport retry while treating them as independent fresh evidence. Which software assurance tests would reveal these failures, and how would you distinguish them from genuine adaptive control behaviour? Please outline a replay-based test that a second laboratory could perform with the same recorded I/Q data and configuration, while taking care that the replay's wall clock, buffer order and floating-point arithmetic do not introduce a different threshold history from the deployed hardware. Would a test using irregular dwell times, numerical overflow guards and a reboot between two noise states demonstrate the same decision rule as a continuous ideal simulation? Explain what belongs in the reproducibility record when thresholds are computed in fixed-point arithmetic.

Norbert Wiener, Response: Dr. Hamming, the software must be tested as an implementation of a state machine, not merely as a function mapping one instantaneous number to another. Define the exact units of the estimator and threshold, input transformation, initial state, update trigger, sample count, handling of missing blocks, numerical precision and event-clustering rule. A running estimate of linear power followed by a logarithm is not generally equal to the average of logarithmic power samples. For example, two equally weighted linear observations of 1 and 9 units have mean 5, whose decibel value relative to one unit is approximately 6.99 dB. Averaging their individual decibel values gives (0+9.54)/2, approximately

Copyright 2026, James M. Atkinson

4.77 dB. This is an illustrative difference of about 2.22 dB caused solely by the order of operations, not an RF field change.

A reproducible replay begins with immutable raw I/Q blocks and a complete acquisition ledger, including sample order, actual hardware timestamps, selected channel, gain and dropped-block markers. Fix the algorithm version and test vectors, then execute the same sequence without using the replay machine's current wall clock as a substitute for original acquisition time. Where state updates are triggered by each qualified block, reproduce exactly those triggers. Where elapsed time is a model input, use the saved monotonic device chronology and record how gaps are handled. The reference implementation and field implementation should agree within specified numerical tolerances; exact bitwise agreement may be impossible across some hardware floating-point implementations, but any difference affecting an alarm outcome must be explained.

Test state reset, stream interruption, packet duplication and out-of-order delivery deliberately. If the driver repeats a block after a retry, the threshold should not silently count it as a new independent observation. If a gap occurs, the algorithm must apply its declared missing-data policy rather than treating absent samples as zero-power measurements. If a threshold-history file is overwritten by later calibration, reconstructability is destroyed. Preserve both the original output and any subsequent corrected replay with versioned transformations. Software alarms should include the contemporaneous threshold, background estimate, gain state, and update count to permit a reviewer to reproduce the decision.

Copyright 2026, James M. Atkinson

The replay should include controlled waveforms and an independently verified reference noise ramp, so that detection probability can be compared against actual ground truth rather than against the field program's own classifications. Run a quiet reference condition, a gradual noise increase, a sudden noise step and a recovery sequence; include constant weak signals at several levels. A software pass means that the implementation behaves as specified over these tests. It does not independently prove that the specification is the correct model for every RF environment. That further scientific claim requires external calibration and tests of model adequacy. This distinction prevents a perfectly reproducible algorithm from being presented as a perfectly reliable survey instrument.

Norbert Wiener, Cross-Peer Question to John W. Tukey: Professor Tukey, your methods of exploratory analysis may reveal distributional changes that a fixed parametric noise model overlooks. Yet a monitoring programme can become a statistical fishing expedition if an analyst chooses whichever threshold or reference-cell method gives the most reassuring event count. How should one compare a moving mean, a percentile, a trimmed estimate and an ordered-statistic rule when the RF background contains clustered interference and a constant weak reference emission? What diagnostic displays would expose contamination of reference cells, and how would you protect an independent evaluation set from choices made during exploration? In particular, I ask whether a stable median noise estimate could coexist with a rising tail of rare interference and therefore support a misleading conclusion about effective detectability even when the absolute mean is not obviously changing. In particular, will a robust location statistic still expose rare intervals when a short authorised test pulse is

Copyright 2026, James M. Atkinson

systematically suppressed? I ask for a prospective failure criterion defined before the analyst looks at which estimator performs most attractively.

John W. Tukey, Cross-Peer Answer to Norbert Wiener: Professor Wiener, exploratory methods are valuable precisely because a single summary does not characterise every relevant property of the distribution. A stable median can coexist with a growing upper tail, increased clustering or more frequent short broadband disturbances. Conversely, an increasing mean may be caused by a handful of interfering cells rather than a uniform rise in the thermal background. A detector whose threshold uses an order statistic may be relatively insensitive to sparse outliers but can still become compromised when contamination occupies enough of its reference window to change the chosen percentile. No one number describes the whole environment. I would display quantiles, the proportion of saturated or excluded cells, time-frequency occupancy, and the distribution of reference-cell values together with the final adaptive threshold.

For a simple illustrative distribution, suppose ninety of one hundred equal-duration background observations have linear power 1 and ten have power 11. The median is 1, while the arithmetic mean is (90×1+10×11)/100=2. A median-based estimator might report stability if the ten high-power observations became progressively larger without crossing half the sample. Yet an intermittent weak emission that coincides with those ten intervals can be masked more severely even when the typical observation remains quiet. This is a constructed example, not a claim that the median estimator is defective. It shows why a performance statement must specify whether it addresses typical noise, tail risk, or the probability of missing a specified signal during actual monitored intervals.

Copyright 2026, James M. Atkinson

I would organise the experimental record into labelled physical configurations, not simply a long undifferentiated sequence. In the first condition generate homogeneous stationary noise; in the second add rare high-power bursts; in the third impose a smooth broadband increase; in the fourth introduce a constant weak signal whose timing is blinded to algorithm selection. Evaluate the moving mean, median, trimmed mean and ordered statistic under all four conditions, with guard cells and reference bandwidth specified. Record performance at a common event definition and a common duty cycle. The method that best regulates nuisance alarms may differ from the method that best protects a low-power signal, and neither should be called optimal without a declared objective and tested distribution.

Exploratory analysis may select plausible models, useful plots and hypotheses, but once those choices are made they should be frozen before evaluation on an untouched set of recordings. If the analyst repeatedly inspects the held-out set and modifies the threshold until the desired performance appears, the holdout is no longer independent. A new prospective sample or separate laboratory trial is required for an unbiased check of the final procedure. The report should retain failed variants as part of the design history, especially when the chosen variant substantially changes a negative survey conclusion. Robustness is not established by the neatness of a single final trace; it is demonstrated by performance across controlled departures from the assumptions that made the original model convenient.

Dr. James M. Atkinson, Moderator: Professor Tukey, the panel has identified estimator memory and loss of raw information. Please test

Copyright 2026, James M. Atkinson

whether the distributional assumptions underlying the threshold have remained adequate. In particular, what can the operator learn from the tails and spatial structure of the observed spectrum that a well-behaved median or average might conceal?

John W. Tukey, Principal Contributor: Dr. Atkinson, it is a dangerous habit to replace the RF environment with a single reassuring summary and then mistake the summary for the environment. A broadband power record may have a median, a mean, a high percentile, a maximum and a duration distribution, each revealing something different. If an adaptive detector adjusts its threshold from a median or a selected order statistic, that choice determines which changes are made conspicuous and which changes are accepted into the background. The choice may be sound for the operating objective, yet it cannot by itself support a claim about the probability of detecting every emission of interest. We should inspect the distribution and its temporal ordering before assuming that a stationary estimate is evidence of stable conditions.

Begin with the practical contrast between a quiet majority of observations and a growing minority of severe disturbances. A median can remain almost unchanged as the upper tail grows dramatically. A conventional mean can rise because a small number of strong events contaminate the reference region, while a lower percentile remains stable. An adaptive detector using the median might maintain a moderate threshold but miss weak signals in the disturbed intervals. Another using the mean might raise its threshold across the whole survey and thereby miss weak signals even during quieter intervals. Neither outcome is proved merely by looking at a threshold graph. The performance of interest is the conditional detection probability for

Copyright 2026, James M. Atkinson

specified signals under specified interference states, integrated over the actual time coverage of the survey.

One may use a conditional mixture model to explain the problem without pretending the true distribution is known. Suppose a monitored interval is quiet with probability $1-q$ and disturbed with probability q. Let $P_{D,q}$ be the probability of detecting a fixed reference signal under the quiet condition and $P_{D,d}$ the probability under the disturbed condition. Then the overall detection probability under the stipulated mixture is $(1-q)P_{D,q}+q\,P_{D,d}$, provided the condition is classified correctly and the probabilities refer to the same signal definition. For example, let $q=0.2$, $P_{D,q}=0.95$ and $P_{D,d}=0.20$. The mixture gives $0.8\times0.95+0.2\times0.20=0.80$. If the disturbed fraction rises to $q=0.5$ while conditional probabilities remain unchanged, the overall probability falls to $0.5\times0.95+0.5\times0.20=0.575$. A detector might maintain a stable false-alarm rate in both mixtures, yet its actual survey coverage for the reference signal is substantially different.

The analyst must not treat the examples' q values as probabilities derived automatically from a spectrogram. The disturbed state must be defined and measured, perhaps using a calibrated input-referred power threshold, an independent broad-band witness or known equipment-operation records. Its temporal duration is important. Twenty per cent of isolated samples does not have the same practical meaning as twenty per cent of an evening concentrated in one continuous outage. A brief burst of interest may be much more likely to occur during certain equipment cycles than under an independent random-time assumption. If the signal and disturbance processes are correlated, the simple mixture with fixed conditional

Copyright 2026, James M. Atkinson

probabilities may require a conditional-intensity model or a scenario-bound analysis instead of a single aggregate percentage.

I favour displays that expose how the estimator was trained. For each decision, preserve the distribution of powers in the reference cells, their frequency positions, guard windows, exclusion rules, and the number actually used. A bright emission leaking into neighbouring bins can contaminate a cell-averaging threshold. A percentile threshold might resist several contaminated cells but fail once contamination becomes widespread. A sudden change in frequency occupancy can affect the reference set without affecting a distant clean test channel. A claim of stable sensitivity therefore needs a frequency-specific performance map, or at least a carefully justified set of representative bands and signal types. No one global baseline can be assumed representative of every preselector state and antenna direction.

The exploratory process must be honest about selection. An operator may compare several thresholds on the same file and choose the one that yields the fewest nuisance reports. That is a legitimate part of engineering development, but it is not independent validation of the chosen detector. The evidence for an eventual field conclusion should come from a separate test set or prospective measurement under known physical conditions. If the detector was repeatedly tuned after the practitioner examined the weak reference detections, it may have overfitted that particular waveform and environment. Record all candidate configurations, their training data, their objective function and the final frozen choice, then assess the selected rule against different days, temperatures, bandwidths and interference mixtures.

Copyright 2026, James M. Atkinson

A further distinction concerns amplitude distributions and event processes. The background-power values may have a stable histogram while their order in time changes: several isolated high-power cells become clustered into one long interference episode. The fraction of elevated samples may be constant, yet the probability that a short target burst coincides with a blind interval can rise or fall, depending on temporal dependence. One must inspect run lengths, conditional detection probabilities, dwell schedules and time-frequency clusters rather than relying solely on a power quantile. This connects the present discussion to the preceding roundtables on blind time and event grouping, but its particular contribution is to show that baseline estimation itself can conceal changes in the distribution of nuisance power.

The recommended report would contain, for each qualified operating state, the input-referred power distribution, robust and ordinary summaries, adaptive threshold history, false-alarm counts and measured detection probability for known reference signals. It would explicitly show whether conclusions change under reasonable reference-cell methods, window lengths and assumed dependence models. A quiet median or a quiet alarm counter is useful information, but neither is a complete performance certificate. The investigator should prefer a transparent account of the conditions in which the detector remains capable to a universal assurance statement derived from a carefully selected and ultimately fragile statistic.

George E. P. Box, Peer Question: Professor Tukey, I agree that a mixture of quiet and disturbed conditions should be considered, but your formula assumes the analyst can assign each interval to the correct condition. In a real monitoring system the condition label may itself be determined by the same adaptive detector under examination. Would that not lead to circular

Copyright 2026, James M. Atkinson

reasoning, particularly where weak signals contribute to the reference-cell power or a receiver's gain change shifts the observed distribution? How should the practitioner distinguish a genuine rise in environmental noise from a changed front-end transfer function without declaring the detector's own estimate to be independent ground truth? Please describe a prospective study that uses external reference measurements, varies source level and bandwidth, and permits the resulting probability-of-detection estimate to be reported with uncertainty rather than as an exact number from a convenient toy model. How would you prevent a weather condition, preselector state or receiver-temperature shift from becoming a convenient retrospective label that explains away every miss? The design requires a prospective cross-condition challenge rather than a perfect fit to old data.

John W. Tukey, Response: Professor Box, the condition label should not be defined solely by the algorithm whose sensitivity one seeks to evaluate. That would permit the tested detector to decide both which examples count as difficult and how well it performed. A separate calibrated witness can provide a reference classification of environmental noise, with its own limitations recorded. One might use a broadband power receiver operating at a fixed reference plane and independently logged gain state, supported by a known injected waveform and terminated-input tests. The witness should record its physical bandwidth and calibration uncertainty. An independent channel sharing a common oscillator, preamplifier or cable may still have correlated errors, so independence must be specified rather than assumed from separate software windows.

I would define the weak test signals by their known source generation and measured received power, not by whether the candidate detector happened

Copyright 2026, James M. Atkinson

to alarm. Randomise or otherwise conceal the injection schedule from the classifier wherever practical. Use several fixed input levels near the anticipated decision boundary and multiple durations and waveforms, retaining non-detections and recordings of failed trials. Independently vary environmental background through lawful laboratory noise injection, while also repeating receiver-only controls with a terminated input. A change that follows the antenna environment but not an injected receiver-only condition has a different causal interpretation from one that follows the amplifier or gain controller. Each inference should be supported by a stated comparison, not by an appealing spectral colour map.

The final statistical estimate should acknowledge the number and dependence of valid trials. If eighty independent scheduled reference bursts are injected at a specified power and sixty-four are detected, the observed fraction is 0.80. That empirical proportion is not an exact probability of detection; it has sampling uncertainty and may be condition-specific. If those eighty bursts are grouped into four long episodes with shared noise and hardware state, the effective information is less than eighty fully independent trials would suggest. Use a confidence interval or a cluster-aware method matched to the design, and present results across the different noise states rather than a single aggregate. The reporting unit is the physical injection opportunity, with valid capture status recorded, not merely the detector's successfully reported events.

I would pre-register the classification rules used for quiet and disturbed conditions and then assess how results change under a defensible range of alternate rules. The uncertainty due to classifying the noise state is distinct from the sampling uncertainty of observed detections. If the result changes

Copyright 2026, James M. Atkinson

materially when the threshold separating states moves by one calibration uncertainty, report that sensitivity. A claim about the installed receiver should also identify the preamplifier, antenna, cables, reference source and gain configuration, since they determine whether the laboratory result can transfer to field operation. A cleanly estimated probability for the wrong configuration is not useful assurance. It may nonetheless be a valuable diagnostic when the limits are clearly identified.

John W. Tukey, Cross-Peer Question to Harold S. Black: Mr. Black, the statistical analysis has depended upon the hypothesis that the receiver's measured noise rise is a change in the input environment. But the electrical chain itself can adjust, compress, introduce correlated spurs or alter its equivalent input noise while making the digitised noise appear deceptively stationary. Would you challenge the physics underlying that interpretation? I ask particularly how automatic gain control, front-end overload, cascaded noise figure and reference coupling can create situations in which the adaptive threshold remains steady but the minimum detectable input signal worsens. Please formulate an instrument-challenge sequence which would distinguish a rise in incident broadband power from an internal noise or gain defect. And can a simultaneous increase in external noise and gain compression render a simple fixed-threshold comparison especially misleading? Could an input-referred absolute-power witness and a separate gain-state record discriminate those causes when the console presents the same flat alarm history? Please state the physical calibration boundary and explain how an uncertain connector loss enters the result.

Harold S. Black, Cross-Peer Answer to John W. Tukey: Professor Tukey, your question restores the physical receiving chain to a statistical argument

Copyright 2026, James M. Atkinson

that could otherwise lose sight of it. A receiver's digital output power is not identical to the input-referred noise at the antenna terminal. Its filters, cable losses, preamplifier gain, mixer conversion loss, analogue-to-digital reference and automatic-gain-control policy all contribute. A strong blocker may compress a preamplifier or mixer, reducing the gain available to a weak signal while altering the output-noise distribution. An attenuator inserted automatically to protect the front end can reduce both the wanted signal and some noise components, but the resulting input-referred noise figure may worsen. If a detector renormalises the digital baseline after that change, its alarm count can remain outwardly well regulated even though the weak input signal is no longer observable.

One must test the chain from a declared reference plane. Measure calibrated input power through an authorised reference tone and broadband noise source, while logging amplifier gain, attenuation, preselector state, ADC headroom and any compression indicator. Begin with the antenna replaced by a suitable termination to determine internal contributions under safe controlled conditions. Then use a characterised input stimulus whose power is stepped through the weak-signal region, with and without an independently controlled out-of-band blocker. A blocker-induced decrease in observed weak-signal gain under constant injected input is evidence of desensitisation; a rising calibrated environmental witness without comparable receiver-state change supports a different component. The comparison should preserve the physical settings and a repeatable source path, rather than relying on a screenshot made after automatic corrections.

Copyright 2026, James M. Atkinson

For a cascade of stages, one may use the linear Friis noise-factor relation $F_{total}=F1+(F2-1)/G1+(F3-1)/(G1G2)+\ldots$, where F1, F2 and F3 are stage noise factors and G1, G2 are preceding available power gains, under matched, linear, small-signal conditions. If first-stage gain falls because an attenuator enters before the low-noise amplifier, later noise contributions become more important when referred to the input. The effective input sensitivity may therefore worsen even while the detector's software estimate adjusts to preserve a nominal false-alarm rate. The relation should not be forced onto a compressed, time-varying or mismatched chain without stating that its assumptions fail. In overload one must make an empirical measurement of gain and unwanted-product generation, not merely cite the small-signal cascade calculation.

External noise and overload can coexist. A stronger environment may trigger gain-control action that further reduces the weak-signal margin; the two effects should not be counted as statistically independent sources of loss without measuring their interaction. Run the calibrated weak signal across noise and blocker levels, retain the absolute threshold and achieved detection probability, and record every gain transition. Use a second receiver or reference configuration to challenge common-mode errors while being candid about shared paths. A stable alarm count then becomes one useful operational indicator among several, rather than the deciding evidence of receiver health. The practitioner should record the physical mechanisms and the uncertainty in each transition before concluding that no relevant emission occurred in the monitored space.

Dr. James M. Atkinson, Moderator: Mr. Black, Professor Tukey has challenged the integrity of the physical input measurements, and your

Copyright 2026, James M. Atkinson

answer has shown why an algorithmically stable output can conceal a deteriorating receiver. Please complete the roundtable by examining gain, noise factor, overload and testability as a coherent engineering problem, and by specifying how those measurements should qualify a negative RF search.

Harold S. Black, Principal Contributor: Dr. Atkinson, a detection threshold has no physical significance until the entire receiving chain has been described. The signal entering an antenna terminal may traverse a cable with frequency-dependent loss, a preselector, a low-noise stage, an automatic attenuator, a mixer, analogue filters and a digitiser. A decision algorithm sees the final transformed samples. Its claimed sensitivity depends upon what those samples represent and upon the state of the analogue chain that produced them. A fixed alarm rate at the digital output can coexist with substantial loss of input sensitivity. An ordinary engineering audit must therefore trace each measurement to the input reference plane and distinguish changes in the RF environment from changes introduced after the wave reaches the instrument.

Noise figure is an informative quantity when used correctly. In a linear, matched, small-signal receiver, the noise factor F is the ratio of input signal-to-noise ratio to output signal-to-noise ratio, both expressed in linear units. The noise figure is NF=10 log10 F decibels. If an initial stage has noise factor F1 and available gain G1, its gain suppresses the input-referred effect of later stage noise as shown in the cascaded noise-factor relation, within that relation's assumptions. But a lossy cable before the first amplifier raises system noise figure, and automatic attenuation inserted ahead of a sensitive stage can reduce the weak-signal margin. A gain-control setting may

Copyright 2026, James M. Atkinson

compensate for a powerful signal at the cost of small-signal detectability. Therefore a manufacturer's best-case noise-figure number does not certify the effective sensitivity of a deployed installation with changing attenuation and uncertain cable loss.

Consider two hypothetical operating states. In the first, a receiver has a calibrated input-referred noise power of −120 dBm over the measurement bandwidth, and a weak reference emission of −110 dBm therefore has nominal SNR 10 dB before any algorithmic processing. In the second, external background rises to −116 dBm and an automatic input attenuator or a changed front-end state adds an effective two-decibel sensitivity penalty for the same test waveform. The total degradation of the weak-signal margin cannot be inferred by simply adding two alarm-screen readings. It requires a calibrated test that characterises the noise contribution and the gain change in their actual physical order. In a simplified budget one might expect approximately six decibels less usable margin, but the final detection probability depends upon the waveform, detector, bandwidth, integration and interference distribution. The correct result should be measured, not assumed from an attractive round figure.

A receiver can be 'quiet' because it has become less sensitive. Under overload, mixer products and gain compression may suppress a weaker emission while producing apparent noise or a forest of spectral lines. If the detector tracks the increased measured background and raises its threshold, nuisance alarms may fall or remain constant even while the receiver cannot see its intended targets. Conversely an internally generated noise increase can cause the adaptive threshold to rise although incident RF energy is unchanged. The source of the change matters operationally:

Copyright 2026, James M. Atkinson

moving an antenna, repairing a cable, adjusting a preselector, changing gain or reducing blocker exposure addresses different causal mechanisms. It is irresponsible to advise such intervention without identifying the mechanism and preserving the unmodified evidence.

The first diagnostic should define a reference plane. At the input of the receiving instrument, use a correctly terminated and calibrated test connection to measure its noise and response with safe laboratory equipment. Repeat after inserting the deployed cable and preamplifier to locate the additional loss or noise contribution. Next introduce the expected antenna environment and compare independent input-referred observations, noting that the change in termination, coupling and impedance itself affects some noise measurements. When the test source is injected before a preamplifier, its power must be measured at the declared plane. A signal generator setting on its front panel is not automatically the level delivered to the device under test. Include mismatch, splitter and connector loss where material.

A positive-control signal is particularly important during unattended monitoring. Choose several safe power levels near the expected sensitivity boundary, vary duration and frequency, and schedule the test so that the operating detector cannot simply memorise its pattern. Retain the actual injection state, raw samples where available, estimated noise, adaptive threshold, gain configuration, preselector state and final alarm decision. From these records compute or bound the detection probability for the tested signal class at each RF state. A control signal that is always comfortably strong does little to demonstrate weak-signal sensitivity. A proper challenge must include levels at which the receiver sometimes

Copyright 2026, James M. Atkinson

succeeds and sometimes fails, because the shape and displacement of that detection curve are the object of the experiment.

Frequency agility makes the duty cycle a further limitation. A reference tone may be on the channel at precisely the times the receiver is tuned elsewhere. One cannot call that a threshold failure without first establishing that the signal was actually presented to the receiver's decision chain. Record channel dwell, revisit, preselector settling and sample continuity. Repeat the test with the waveform injected at known times both inside and outside qualified observation windows. This separates blind-time losses from threshold-induced missed detections. A stable false-alarm rate averaged over an hour may conceal both effects. The percentage of time under observation and the probability of detection conditional on observation belong in different columns of the report.

The essential assurance framework contains three independent lines of evidence. First, a traceable physical measurement establishes the absolute input-referred noise and gain state over time. Secondly, the decision algorithm's threshold, learning state and measured false-alarm properties are preserved as derived quantities. Thirdly, controlled weak-signal challenges establish actual probability of detection under a declared range of environmental and instrument conditions. Agreement among these lines justifies a bounded claim that an instrument would probably have detected a specified signal during the covered intervals. Disagreement is a diagnosis requiring further tests, not an invitation to select whichever chart looks most reassuring. Without all three, 'no alarms' remains a statement about software output, not evidence that the RF scene was empty.

Copyright 2026, James M. Atkinson

I would finally insist that uncertainty be honest about shared influences. Several receivers using one antenna distribution and clock can share the same sensitivity impairment. Three simultaneous quiet displays are then not three independent demonstrations of absence. A second input path and an independently calibrated receiver can challenge this dependence, but only if their actual shared components and signal conditions are disclosed. Where power uncertainty, gain transitions or overload defeat a defensible probability estimate, the negative finding must be qualified. The aim of engineering is to create a measurement chain that admits correction and challenge; the aim of the report is to preserve the truth of what was measured. A quiet, adaptive dashboard can be useful, but it cannot replace measured sensitivity.

Charles Proteus Steinmetz, Peer Question: Mr. Black, your laboratory sequence separates cable loss, preamplifier behaviour and receiver gain in a manner I appreciate, but I am concerned that a simple injected test tone can itself be a poor representative of the emissions for which the surveillance system was designed. An impulsive, phase-modulated or frequency-agile waveform interacts differently with filters, detectors, switching transients and clipping. How would you qualify a family of test signals without turning the acceptance programme into an endless list of arbitrary waveforms? Please also distinguish the case of external broadband electrical noise arriving through an antenna from conducted noise travelling along common-mode cable paths or the instrument supply. Both may raise a displayed spectrum while requiring different corrective action, and both can be correlated across several receivers. What minimum practical controls would establish which impairment has damaged the weak-signal sensitivity

Copyright 2026, James M. Atkinson

that the operator claims to maintain? For the blocking-signal condition, please also specify how a strong adjacent emission could change the receiver operating point while leaving the weak reference at exactly the same antenna-terminal power. The repeatability requirement must include frequency placement and instrument settling time.

Harold S. Black, Response: Mr. Steinmetz, the calibration signals should be selected from a declared class of relevant threats or measurements, not from a desire to demonstrate the highest possible detection score. Describe the class using physical properties: occupied bandwidth, duration, duty cycle, modulation, polarisation, input amplitude and known uncertainty. Choose representative signals covering the expected extremes of detector response, including a narrow carrier, a brief burst, and an appropriately bandlimited modulated waveform where those are relevant. The aim is a defensible coverage envelope rather than a universal promise. A single unmodulated tone is useful for measuring gain and frequency response, but it cannot by itself demonstrate correct detection of a short or frequency-agile signal after a preselector switch.

The reference path must be challenged. To test conducted coupling, compare measurements with an appropriately terminated antenna port and then with the deployed antenna and cable, maintaining equipment safety and a known reference plane. A conducted noise current on a coaxial screen may couple into the receiver in ways not eliminated by terminating the central conductor alone. Use an appropriate common-mode current probe or controlled isolation arrangement, with calibration and safety qualifications, to investigate that hypothesis. Separately record supply ripple and instrument state; do not automatically classify a spectral line at a

Copyright 2026, James M. Atkinson

convenient mains-related offset as evidence that the supply is its cause. A different antenna position or cable route that changes the indication supplies useful evidence but can also alter the legitimate incoming field, so the experiment requires controls and repeated conditions.

For an actual sensitivity test, inject a known weak waveform at a documented point after any component deliberately excluded from the test, then repeat upstream to include the additional cable, filter and preamplifier. If detection is good downstream and poor upstream, the differential result directs attention toward components in between; if both degrade under a blocker, the receiver or its current configuration may be responsible. Challenge the automatic-gain-control state by recording its commands and measuring the incremental response to the weak signal at each state. Where the frontend is nonlinear, the small-signal relation must be verified rather than assumed. An isolated quiet-noise plot cannot reveal desensitisation that occurs only when the environment is strong.

The validation matrix should cross signal type with noise state, gain setting and observation interval, but avoid treating highly correlated trials as independent evidence. Document each physical injection opportunity and separately record whether the instrument was tuned, whether it acquired valid samples, whether the detector saw the signal, and whether it reported an alarm. A weak signal missed during genuine blind time is not identical to one rejected by an adaptive threshold, and a clipped waveform is not equivalent to a clean low-SNR waveform. This classification makes the testing finite and informative rather than an uncontrolled catalogue. It also permits a later investigator to express a carefully bounded assurance statement for the specific combinations actually tested.

Copyright 2026, James M. Atkinson

Ultimately the repair decision follows the causal evidence. A rising environmental noise witness may justify changes to antenna placement, shielding or operating conditions; a measured gain defect may require recalibration or service; a contaminated reference window may justify detector redesign. Every intervention should be followed by a fresh prospective challenge rather than a retrospective improvement to the appearance of old traces. The original samples and decision history should remain intact. That preservation makes it possible to distinguish a real improvement in detection probability from a mere reduction in audible alarms, the central distinction of this discussion.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has established that a constant false-alarm rate and constant receiver sensitivity are not equivalent requirements. Professor Neyman separated error under the null hypothesis from detection of a specified signal; Dr. Shewhart preserved an absolute control history; Professor Wiener showed how estimator memory and gain feedback can obscure change; Professor Tukey demonstrated the importance of distribution tails and contaminated reference windows; and Mr. Black restored the physical measurement chain, including noise factor, overload and input-referred calibration. The proper evidential record contains raw observations or their defined retention limits, the absolute noise and threshold histories, receiver state, timed coverage and independently scheduled weak-signal challenges. A negative survey conclusion must be bounded by the measured detection probability under the relevant conditions. No constructed historical dialogue here should be mistaken for testimony by its named participants.

QUESTION 079

Copyright 2026, James M. Atkinson

How should false-alarm probability be controlled across millions of spectral comparisons?

Dr. James M. Atkinson, Moderator: Professor Neyman, a defensive technical-surveillance team may examine millions of frequency-time-receiver cells while searching for rare, weak emissions. A test threshold described as having one false alarm in a million trials sounds stringent, yet a search with many opportunities may produce numerous apparent discoveries even under noise alone. Would you define the appropriate unit of inference and describe how an examiner should allocate error probability across the entire monitoring protocol rather than merely print a persuasive per-cell figure? I ask our colleagues to challenge both the independence assumption and the tendency to confuse a statistical discovery with attribution of an emitter.

Jerzy Neyman, Principal Contributor: Dr. Atkinson, statistical error must be associated with a decision rule, a specified population of possible observations, and a declared repeatable procedure. Calling a spectral cell unusual is not the same decision as alleging that a coherent transmitting system exists. Nor is either equivalent to identifying an individual device or purpose. A defensible protocol should articulate separate hypotheses: background compatible with the calibrated receiver-noise model, energy inconsistent with that model, a structured emitter, and finally an attribution hypothesis requiring evidence beyond spectral significance. A false alarm means rejecting a specific null hypothesis when it is true. The term has no stable numerical meaning if the hypothesis or decision rule changes after the data are inspected.

Copyright 2026, James M. Atkinson

Suppose there are M tests, each with a nominal null false-rejection probability p. Under independence and a common p, the probability of no false rejections is (1-p)^M, so the family-wise probability of at least one is 1-(1-p)^M. For M equal to one million and p equal to one in a million, the limiting Poisson approximation gives 1-exp(-1), approximately 0.6321. Thus a threshold that sounds extraordinary for a single test would yield at least one nominal false discovery in about sixty-three percent of such complete null searches. This is a calculation under an explicit model, not a measured rate for any particular receiver. If p is reduced to 0.05/M, the union bound guarantees that the chance of at least one false rejection cannot exceed 0.05, provided the individual marginal error bounds are valid. The union bound itself does not require independence.

The family must be defined before the inspection begins. Is it one receiver for one hour, the complete survey across sixteen antennas, all retries after operator intervention, or the combined survey repeated each morning? If analysts quietly choose the most impressive display among twenty configurations, the number of effective selection opportunities extends beyond the cells initially advertised. A threshold calibrated for one window or antenna cannot be used without adjustment when multiple alternative windows, FFT sizes, preselectors, and detection algorithms are also searched. The family can be structured hierarchically, with a global test for evidence of any anomaly followed by narrower location or frequency questions under controlled procedures. That structure is preferable to pretending that every pixel is a free-standing scientific experiment.

The relevant null is seldom ideal white Gaussian noise. Real instruments exhibit correlated spectral estimators, window-overlap dependence, local

Copyright 2026, James M. Atkinson

oscillator phase noise, interference and drift. One may begin with a tractable mathematical model but must test it using receiver data under states known to be free of the target signal. Calibrated noise-only captures should be processed through precisely the same bandpass filters, FFT windows, threshold adaptation, event clustering and reporting pipeline as operational captures. This produces an empirical distribution of the maximum statistic across the family, rather than merely a histogram of marginal cell values. If the intended family-wise probability is five percent, the threshold is the ninety-fifth percentile of that maximum distribution, with appropriate sampling uncertainty and out-of-sample validation.

The experiment must preserve genuine dependencies rather than erase them by randomising individual cells independently. For example, resampling entire nonoverlapping background records preserves within-record correlations and synchronised receiver artefacts; resampling each FFT bin independently destroys precisely the dependence whose consequences must be assessed. Conversely, if records share a clock or power supply, treating entire receivers as independent bootstrap units is also suspect. The sampling unit ought to coincide with the physical independence unit, perhaps a day, installation, clock state or environmental episode, depending on what can be justified. Uncertainty from the limited number of calibration records must accompany the advertised false-alarm level.

Power matters alongside error control. A threshold stringent enough to make the family-wise probability tiny may miss a low-power signal of interest. Let Pd denote detection probability under a defined signal model, and let Pfa denote probability of a false detection under a defined null. The

Copyright 2026, James M. Atkinson

entire Pd-versus-Pfa curve should be evaluated across signal power, occupancy, bandwidth and receiver states. No investigator should hide a loss of power by displaying only the attractive false-alarm rate. The finding should say, for example, that under stipulated calibrated states the complete search procedure met an empirical global alarm criterion, while detection probability for a weak burst of specified duration was separately measured. That is more informative than announcing an unexplained significance threshold.

Finally, statistical significance is not a licence to infer malicious intent. A rejected noise-only null may arise from ordinary communication, an instrument defect, a laboratory stimulus or unanticipated environmental coupling. The correct sequence is detection, challenge, classification and evidential interpretation, each with its own uncertainties. Under formal inquiry the raw acquisition, calibrated null records, threshold policy, software versions and all rejected candidates must survive, not merely the most alarming waterfall frame. I pass the question to the other panel members with the warning that a numerical guarantee applies only to the procedure and hypotheses for which it was established.

Peter Elias, Peer Question: Professor Neyman, your proposed calibration uses the maximum statistic of a whole search, but the word 'whole' becomes slippery when an operator can change the observation interval, receiver bandwidth and analysis window after seeing a suspicious feature. Suppose a short pulse is discovered with one spectrogram window and appears less impressive with two others. If the investigator reports only the most favourable result, does the original family-wise calibration retain its interpretation? I would also question the data reduction chain. Spectral

Copyright 2026, James M. Atkinson

estimates may overlap in time and frequency, and interpolation may create many displayed pixels from a much smaller number of independent measurements. How should a team register exploratory choices, handle reruns on the same captured data, and distinguish the number of rendered pixels from the number of distinct statistical selection opportunities? Can the answer be more practical than simply forbidding post-event analysis, which is often necessary for forensic interpretation?

Please distinguish the initial exploratory selection from the later physical challenge, since otherwise the same waveform can be used twice to support a claim of independent confirmation.

Jerzy Neyman, Response: Mr. Elias, exploratory analysis need not be prohibited, but the status of its claims must be made explicit. An exploration can reveal a useful feature, a plausible bandwidth or a new instrument fault. It cannot then turn around and treat the same selection as a fresh prespecified test with its old nominal p-value. The investigator may separate discovery and confirmation records, use a reserved independent acquisition, or calibrate the entire adaptive procedure against background records in which the same sequence of algorithm choices is repeated. If the latter is automated, one can record the maximum detection score across every permitted window, overlap and parameter setting and derive its empirical null distribution. That calibrates the search protocol, not just an arbitrary pixel.

A practical register should include the fixed menu of candidate bandwidths, FFT lengths, thresholds, antennas and revisit policies; the order in which human or automated decisions may change them; a permanent log of all candidates, not just selected detections; and the versioned code

Copyright 2026, James M. Atkinson

implementing the final statistic. Reprocessing one stored data set ten times does not create ten independent corroborations. It creates one set of observations with ten correlated analyses. Independence must be established by physical or statistical argument and cannot be obtained from file names or screen captures. Where human judgement cannot be reproduced, describe the result as exploratory and require a separate blinded challenge before claiming a calibrated alarm probability.

The number of display pixels is likewise not automatically M. Window overlap and interpolation make neighbouring pixels dependent, but choosing an 'effective number' by eye is unsafe because the dependence can be strong, nonstationary and non-Gaussian. A rigorous family-wise upper bound can still use the full count with valid marginal bounds, though often conservatively. Better power may be obtained by empirical maxima of the exact decision pipeline. If the independent noise-only calibration record is scarce, disclose uncertainty in the estimated tail rather than report six significant decimal places. The proper contrast is not between forensic flexibility and statistical discipline; it is between an auditable procedure whose adaptations are included in calibration and an undocumented search through alternatives whose reported significance cannot be reconstructed.

David Slepian, Peer Question: Professor Neyman, in communications theory the exact geometry of signals and noise in a finite observation interval matters, and a receiver's filtering can create correlations between nominally separate spectral cells. A procedure that counts one million cells may represent fewer independent degrees of freedom, but a correlated field can also generate extended excursions that persist across many cells. If the detection unit is changed from a cell to an event cluster, will the nominal

Copyright 2026, James M. Atkinson

false-alarm guarantee remain valid? I am concerned about whether a cluster is identified after the threshold is applied and whether threshold selection, clustering radius and event merging are all calibrated together. What would you require before treating a hundred adjacent above-threshold pixels as one false alarm, and could the opposite mistake occur when a single receiver transient is broken into several supposedly independent events?

I would welcome an explicit distinction between counting spatially contiguous bins and detecting a physically coherent temporal event, because each definition has different reproducibility requirements.

Jerzy Neyman, Response: Dr. Slepian, the choice of decision unit changes the statistical proposition. A cluster-count alarm means that a prescribed rule maps a spectral field to connected components or other events. The null distribution of that output cannot be inferred merely from the marginal p-value of each pixel. Define the connectivity in time, frequency and receiver space, the threshold, minimum duration or area, exclusions around known receiver artefacts, and merge conditions before evaluating error rate. The full procedure then maps a known noise-only record to a number of candidate events, a maximum cluster score or another clearly defined statistic. Its distribution is what must be calibrated.

Suppose a receiver's phase-noise transient produces thirty adjacent bright bins during a reference switch. Calling them thirty independent 'signals' overstates the event evidence; merging them into one labelled reference-associated cluster may be justified if the same logic is applied in background and operational analysis. But merging cannot be an ad hoc response to an embarrassing false-alarm count. Likewise one external burst could excite several separated filter outputs or create multiple detections during

Copyright 2026, James M. Atkinson

scanning. A documented, validated merging rule can prevent counting that burst repeatedly. The rule must be challenged with injected single bursts and deliberately separated pairs to measure false splitting and false merging. No universal cluster radius suits all instrument configurations.

If the question is simply whether any suspicious event occurred within the complete survey, a maximum cluster score can provide a family-wise decision after empirical calibration. If the question concerns the expected fraction of false reported event clusters among all reported clusters, a different multiplicity concept is required. These definitions do not become interchangeable because both are printed as percentages. Finally, records must retain the raw pixels, the list of cluster memberships and the software transformations, allowing a subsequent examiner to challenge whether a rejected or combined event concealed independent evidence. It is the operational reproducibility of the family definition, not the convenience of the event count, that preserves the meaning of the error guarantee.

For an operational decision, the number of identified clusters is itself a random variable, and its uncertainty should be reported across multiple controlled background runs. An investigator must not infer cluster independence from visual separation alone; one power-supply transient can generate several separated spectral products. Keep the event ledger and all associated instrument-state records for that reason.

Jerzy Neyman, Cross-Peer Question to Ronald Aylmer Fisher: Professor Fisher, I invite a challenge to the relation between individual evidential strength and a long search. You have historically emphasised the interpretation of experimental evidence rather than a purely mechanical accept-or-reject ritual. Suppose a receiver yields one narrow line with a local

Copyright 2026, James M. Atkinson

tail probability of 10^-8 after two million spectral comparisons, and an analyst has also tried several alternative filters that were not recorded. How would you express the weight of the observation without pretending that a local p-value establishes an external emitter? Could the likelihood of a persistent narrowband component, evaluated on a fresh observation, be separated from the process that originally selected the frequency? Please identify where an apparently spectacular result can be an artefact of selecting the greatest departure among many opportunities.

Would you also separate the magnitude of the selected spectral feature from the reliability of its physical origin, particularly when a receiver-side spur can remain stable through many repetitions? A numerical result may be strong evidence against simple thermal noise and yet weak evidence for the specific emitter alleged by a report.

Ronald Aylmer Fisher, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, I would first describe the reported number as conditional on a precisely specified test statistic and null distribution. Selecting the most extreme component from a large field changes the reference distribution for that selected component. The probability that a single prespecified cell is as extreme as observed is not the probability that at least one of a million cells is equally extreme. If the analyst inspected unspecified alternative filters, the actual selection history is part of the evidence and cannot be tidily dismissed. One might calculate a corrected global tail probability with a known, predetermined family, but an unrecorded search makes a confident correction implausible.

Evidence is strengthened by a new experiment whose purpose and analysis are registered beforehand. Prespecify the observed candidate frequency,

Copyright 2026, James M. Atkinson

reasonable tolerance for drift, antenna and preselection conditions, reference-source checks and a statistic chosen to distinguish an incoming signal from receiver-generated products. Then collect a genuinely new receiver record with a different temporal opportunity, or where practicable a different measurement chain. Under the new test the candidate is no longer chosen as the maximum among the original millions of cells. Its local behaviour has a new evidential meaning, provided the follow-up protocol does not itself expand into an uncontrolled hunt.

The alternative must also be physically meaningful. A stable carrier can persist because a local oscillator spur persists; repeated detection in the same instrument does not establish external origin. A calibrated termination, antenna substitution, controlled attenuation, independent clock or different frequency-conversion plan can supply the needed physical discrimination. A well-defined null should include ordinary interference and instrument responses where those mechanisms are relevant. Significance against an oversimplified white-noise null merely tells us that reality differs from that null, not which explanation is true. A disciplined report could say that an exploratory wideband search selected a candidate, and that a prespecified second-stage measurement found an external-input-dependent feature within specified uncertainty. That is persuasive without claiming certainty or inventing a tail probability for the total human search.

The examiner should retain the complete set of alternative receiver configurations attempted in the follow-up, including those in which the feature disappears. Disappearance is not automatically proof of an artefact, because changing a preselector can reduce sensitivity, but the predicted

Copyright 2026, James M. Atkinson

pattern of change should be specified before interpreting it. This controls both statistical selection bias and physical misattribution.

Dr. James M. Atkinson, Moderator: Professor Fisher, please now examine what a strikingly small local significance level contributes to a scientific inference, whilst acknowledging the large number of opportunities offered by a modern RF waterfall.

Ronald Aylmer Fisher, Second Principal Contributor: Dr. Atkinson, the instrumental display tempts an observer to treat every bright point as an isolated experiment, but the origin of a discovery matters. A cell chosen in advance and a cell chosen because it is the most extreme among many cells have different statistical distributions. I begin with the distinction between a tail-area calculation and a physical hypothesis. A p-value is a probability, under an assumed null and test rule, of a statistic at least as extreme as the observed value. It is not a posterior probability that the null is true, nor the probability that a displayed feature is a real transmitter. The analyst should state the null, the score, the selection process and the conditions under which the mathematical probability was calibrated. These declarations are part of the substantive scientific claim.

A useful example is a detector with a nonnegative, exponentially distributed noise-power statistic X, normalised to mean one. Under a valid noise-only null, P(X greater than x)=exp(-x) for x at least zero. For a single prespecified cell a threshold x=ln(10^6), approximately 13.8155, gives nominal p=10^-6. Across one million independent cells, however, the probability that the maximum exceeds that threshold is 1-(1-10^-6)^1000000, approximately 0.6321. If the entire search is to have a five-percent probability of any false alarm, the threshold must be raised to the solution of 1-(1-exp(-

Copyright 2026, James M. Atkinson

x))^1000000=0.05, which is approximately x=ln(1000000/[-ln(0.95)]) or 16.7856 using the rare-tail approximation. These numbers describe an idealised model, not a measurement of a deployed receiver. Correlated cells require re-evaluation.

A single extreme finding invites an over-optimistic estimate of effect size. The selected maximum has been selected partly for favourable random fluctuation, so its displayed power is subject to selection bias. An independent second measurement can correct the evidential impression, even when it shows a weaker but repeatable component. If an investigator averages many new samples only at the previously selected frequency, that follow-up addresses a different question from the original search. The follow-up should preserve its own prespecified frequency tolerance, analysis window and signal classification criteria, rather than adapting them until a desired confirmation appears. The difference between discovery and confirmation is essential in the presence of high-dimensional opportunity.

I would also distinguish the physical units of the scan. A frequency-time tile from an FFT has noise power dependent upon window normalisation, equivalent noise bandwidth, detector and gain setting. The null distribution for one tile is not transferable to another simply because both tiles are coloured green. If the receiver changes its preselector, reference clock, FFT size or gain, standardisation is necessary before pooling tail probabilities. The mere presence of a value called 'p' in a software record does not ensure comparable calibration. Some estimators are based on adjacent bins presumed to contain noise; those reference cells can be contaminated by a broad signal or by leakage from a powerful adjacent transmission, turning the derived significance into an instrument-dependent quantity.

Copyright 2026, James M. Atkinson

We must be equally cautious with repeated visual scrutiny. A human may notice a pattern, enlarge the plot, adjust gain and decide the feature is extraordinary; these choices produce valuable hypotheses but not an automatic independent test. In a defensible scientific report label the first result exploratory, record the search provenance, then test the finding in a blinded or reserved record. Calibration may include an automated search policy if it is sufficiently reproducible. Where judgement dominates, the evidence should be narrative and physically corroborated rather than dressed as a probability from a nonexistent selection model. A good descriptive figure is not automatically a calibrated significance test.

The analyst should consider alternatives to the noise-only model: a common power-supply spur, a receiver intermodulation product, an antenna resonance, a false clock lock and electromagnetic leakage from nearby equipment. An extremely small noise-only tail probability may be correct while the source attribution remains incorrect because the null omitted these mechanisms. Comparing hypotheses requires experiment. For instance, if an apparent carrier remains under a properly terminated input, grows with front-end gain in an unexpected manner and changes with local oscillator retuning, the instrument-artifact explanation deserves attention. If it tracks antenna geometry and survives independent receiver changes, an external signal explanation strengthens. Neither observation alone identifies intent.

A final distinction concerns scientific importance. A tiny p-value can accompany a minuscule spectral difference of no operational concern when enormous data volumes confer detection power. Conversely, a weak, short signal of high defensive interest may fail a harsh family-wise threshold. The

Copyright 2026, James M. Atkinson

report ought to state effect size in physical units, uncertainty, probability of detection over a defined signal class and the false-alarm criterion, not one impressive p-value. The value of a measurement lies in its reproducible bearing on a properly stated question. When the receiver has inspected millions of alternatives, the question must include that fact before any conclusion is pronounced.

I therefore pass the token to colleagues who will ask whether a family of thousands of correlated tests ought to be evaluated through false-discovery proportions, global maxima or some other criterion. The answer depends on the decision's consequences. One false attribution in a high-stakes forensic finding is not equivalent to a handful of false exploratory candidates sent for inexpensive technical challenge. Different loss functions justify different error budgets, and the words 'statistically significant' should never conceal the policy choice.

David G. Kendall, Peer Question: Professor Fisher, I should like you to consider the tendency to treat an event count as if it were a sequence of independent trials. Suppose the same intermittent external transmission appears in seven adjacent FFT bins, across ten overlapping time windows, and on two simultaneously clocked receivers. A software dashboard may report a hundred and forty significant cells, but the physical evidence may comprise one emission. Conversely a local oscillator perturbation can produce the same multiplicity without any external transmission. If the operator first selects the maximum cell, then forms clusters, and finally chooses one striking cluster for verification, how should the degrees of selection be represented? Must we calculate a fresh multiplicity correction for every stage, or can a single, prespecified global statistic represent the

Copyright 2026, James M. Atkinson

entire detection chain? Please explain how the answer changes when clustering was chosen only after inspecting the event.

I would also wish to know whether the cluster definition remains identical for the null calibration and actual survey, including any operator-controlled review or manual merge decisions.

Ronald Aylmer Fisher, Response: Dr. Kendall, the physical event and the statistical selection unit should be distinguished at the outset. A hundred and forty displayed cells may derive from one waveform, but the investigator has still encountered a collection of opportunities for a high score. A prespecified processing chain can use a global statistic such as the highest cluster-integrated energy, maximum likelihood-ratio estimate, or number of qualified events. The null distribution of that statistic should be calibrated by running the complete chain on representative background acquisitions. Then there is one global decision rule, and the internal clusters are intermediate computations rather than unaccounted second-stage experiments. This avoids the false necessity of multiplying separately calculated corrections when a joint calibration is feasible.

If clustering was chosen after the striking observation, however, one may not treat the choice as if it had been independent of the data. The correct path is either to reconstruct and calibrate the broader search over plausible clustering rules, or to regard the selected rule as exploratory and confirm its predictions on reserved observations. The latter may be more realistic for a forensic investigator who must understand unexpected receiver behaviour. A history of candidate merge gaps, frequency tolerances and chosen filters reveals how much discretion shaped the reported event. The acquisition

Copyright 2026, James M. Atkinson

data should remain intact so that a reviewer can test whether a different documented clustering policy would reverse the inference.

The number of correlated cells should not be replaced by an intuitive effective-trial count without validation. A simulation that preserves window overlap, frequency leakage, common clock disturbances, noise adaptation and actual event clustering offers a more direct check. Ideally the simulation's generating assumptions should themselves be challenged by recorded noise-only surveys from differing installation states. Any failure to reproduce the extreme tails should be stated as a model limitation. If clustering algorithms include nonstationary thresholds or learned classifiers, their training and tuning records must be excluded from the held-out calibration set or accounted for explicitly.

Your example also shows why one must keep separate layers of the scientific claim. The dashboard may present one cluster, and the formal global test may detect an anomaly. To say that this anomaly arose at the antenna requires challenge tests against receiver-generated products. To say that it belongs to a particular transmitter requires further waveform, temporal, spatial and lawful contextual evidence. Statistical multiplicity correction addresses the calibrated detection question; it does not eliminate the need for physical attribution tests. This separation preserves the usefulness of numerical statistics without allowing them to overwhelm the engineering interpretation.

Ronald Aylmer Fisher, Cross-Peer Question to Solomon Kullback: Dr. Kullback, may I ask you to distinguish information in a waveform from the multiplicity of tests applied to it? A very large number of frequency-time cells may each offer a small increment of evidence, and the investigator may

Copyright 2026, James M. Atkinson

maximise a likelihood-ratio statistic over unknown bandwidth, onset time and modulation. How should a practitioner interpret the resulting score when the parameters were selected from the same data? Would it be reasonable to treat the maximum as if the best-fitting alternative had been specified in advance? I also invite you to examine the distinction between a likelihood ratio comparing two explicit generative models and a posterior statement about an identified device, which would require additional assumptions not contained in the spectral measurement. Please include the possibility that a technically attractive signal model is misspecified because it omits correlated receiver artefacts.

If the alternative has been optimised against a finite catalogue of templates, should an apparently precise estimated source strength be interpreted with a selection correction as well as a detection correction?

Solomon Kullback, Cross-Peer Answer to Ronald Aylmer Fisher: Professor Fisher, a likelihood ratio measures relative support for specified probability models at the observed data; it does not free the investigator from declaring how those models were chosen. If bandwidth, onset, carrier offset and modulation are fitted by maximising over a large parameter family, the maximum likelihood ratio has a null distribution different from the ratio for a fixed, prespecified template. A threshold derived from the latter can be badly anti-conservative when applied to the former. The appropriate calibration must reproduce the maximisation itself, including the parameter grid, estimator constraints and stopping rules. If the statistic is adjusted after looking at the detected line, that adaptation must be represented or the result must be treated as exploratory.

Copyright 2026, James M. Atkinson

Information-theoretic quantities may help describe how distinguishable the signal and noise models are, but they do not replace an error criterion. A divergence between two stipulated distributions can be large even when neither distribution realistically describes a receiver affected by gain changes, oscillator phase noise or intermittent interference. A physical challenge should therefore compare predicted changes under attenuation, reference substitution, preselector state and noise-floor variation, not merely search for the model with the most favourable numerical score. The trained and tested parameter spaces must be separated so that model complexity does not masquerade as external evidence.

For a mathematical example, let X be a vector of complex spectral observations, with null covariance matrix $\Sigma 0$ and alternative mean vector μ. Under a complex Gaussian approximation the quadratic evidence for μ depends upon $\mu^* \Sigma 0^{-1} X$ and $\mu^* \Sigma 0^{-1} \mu$, where * denotes conjugate transpose. If $\Sigma 0$ contains nonzero off-diagonal terms from window overlap and common receiver states, replacing it with a diagonal matrix changes both the score and its calibration. If μ is estimated by trying thousands of templates, the distribution of their maximum is the relevant null. A small score from a marginal cell cannot simply be promoted to the value of a jointly optimised detector.

Finally, likelihood evidence alone does not assert that a particular physical device is present. The alternative model may describe an internally generated spur just as well as an external emitter if both produce the assumed spectral shape. To claim a device identity, one must connect model parameters to independently observed properties and challenge competing explanations. A posterior probability also requires prior model weights and

Copyright 2026, James M. Atkinson

properly specified alternatives; a p-value or likelihood ratio does not silently provide those priors. The engineer's duty is to preserve the calibrated inference and the bounds of the physical model as separate statements.

Dr. James M. Atkinson, Moderator: Dr. Kullback, would you now examine the decision to report many candidate signals, some of which are expected to be false, rather than impose a requirement that the entire survey almost never produces a single false indication?

Solomon Kullback, Third Principal Contributor: Dr. Atkinson, an instrument that produces an extensive candidate catalogue may serve an operational function different from one that issues a formal evidential accusation. The first stage may legitimately tolerate some false leads if each candidate is inexpensive to challenge. The second stage, particularly where reputation, privacy or legal consequence is involved, requires much stronger evidence. The statistical question should therefore be framed by a decision loss, not by an arbitrary fashion for a particular percentage. Family-wise error rate concerns the probability of making at least one false rejection in a family. False discovery rate concerns the expected proportion of false rejections among all rejections, ordinarily defined with that proportion set to zero when nothing is rejected. These are not interchangeable guarantees.

Let V be the number of false discoveries and R the number of all reported discoveries in a defined family. The false discovery proportion is V/max(R,1), and false discovery rate, FDR, is its expectation. A method controlling FDR at level q=.05 does not guarantee that each reported individual signal has a five-percent chance of being false, nor that no more than five percent of the reports in every particular survey will be wrong. It is an expectation over repetitions under the stated model. If the result set is later filtered by an

Copyright 2026, James M. Atkinson

undocumented human selection, the achieved false discovery proportion in the selected subset need not retain the same formal guarantee. The meaning of the chosen family and the downstream reporting rule must be preserved in the record.

The modern Benjamini–Hochberg step-up procedure, an editorial development subsequent to the lives of some historical panel members, illustrates this distinction. Given m valid p-values $p_{(1)} <= \ldots <= p_{(m)}$ and a target q, find the largest index k for which $p_{(k)} <= k\, q/m$ and reject the hypotheses corresponding to the first k sorted p-values. Under independence of true-null p-values, the original proof controls FDR, with suitable extensions under specified positive dependency. The procedure is not justified by merely sorting arbitrary detector scores labelled p. Each p-value must be calibrated under its null, and the full dependencies and reporting process must satisfy the procedure's conditions. For arbitrary dependence, the Benjamini–Yekutieli correction uses the harmonic factor $H_m=\sum_{j=1}^{m} 1/j$ in a conservative threshold; the price can be substantial lost power.

Consider a hypothetical calibrated catalogue with m=100,000 candidate cells, q=.05 and a sixth-smallest valid p-value of 2×10^{-6}. The sixth Benjamini–Hochberg boundary is (6x.05)/100000, or 3×10^{-6}, so that p-value passes the rank-six inequality. But the algorithm must identify the largest qualifying k over all ranks, not simply stop on one favourable comparison. Other p-values may or may not pass, and dependence assumptions matter. These numbers are teaching values. They should not be converted into a statement that any selected candidate has a posterior error probability exactly equal to q.

Copyright 2026, James M. Atkinson

A major difficulty in RF surveys is that the nulls can be composite and spatially heterogeneous. One frequency region may contain quiet receiver noise, another licensed ambient traffic, another a strong carrier whose spectral leakage contaminates neighbouring bins. If 'no signal of interest' is the null, the distribution of a test statistic depends upon which ordinary emissions and receiver states are deemed allowable under that null. Miscalibrated p-values can overwhelm the multiple-testing correction. If a receiver estimates the null from the same candidate-contaminated region, its threshold may respond to signal density and invert what was intended as evidence. Null calibration must therefore be tied to known input conditions, realistic occupancy and the actual front-end measurement chain.

Filtering hypotheses before testing is legitimate only under appropriate conditions. A prefilter based on independent technical information, such as an authorised frequency allocation or a known receiver mask, can reduce unnecessary tests. A filter chosen because a candidate looks impressive is another selection step and must be included in calibration. Likewise a hierarchical scheme might first test broad bands globally, then analyse narrow subbands whose parent test passes. The error accounting depends on the hierarchy and testing policy. An investigator should log this structure before the survey, maintain a separate record of exploratory branches and avoid treating omitted tests as if they had never occurred.

Dependence may help or harm. Many spectral cells are correlated because they share an analogue filter, FFT overlap, a digitiser or common noise modulation. Some positive dependence structures permit certain FDR procedures; arbitrary dependence does not. It is not sound to claim that fewer effective independent bins automatically permits the ordinary

Copyright 2026, James M. Atkinson

Benjamini–Hochberg result. A practical approach is to calibrate event-level p-values against complete noise-only traces and then test dependence assumptions or use conservative procedures. Where the number of hypotheses is enormous and valid null simulations are limited, report the uncertainty of the tail calibration and treat estimated false-discovery rates as conditional on the model.

A further issue is the relation between discovery and identification. FDR control may be useful for deciding which candidate events receive additional lawful investigation. A candidate is not a device, and an event cluster is not an emitter identity. Several reported candidates may originate from one instrument failure or one transmitter, so a list of 100 rejections may not be a list of 100 distinct physical objects. A responsible report states its unit: spectral tests, event clusters or putative source classes. The testing procedure should be challenged against independent signals and receiver artefacts, so that the meaning of 'false discovery' is stable and understandable to another examiner.

In conclusion, choose the error criterion based on the decision. A broad, reversible screening list may use a calibrated expected-false-proportion rule, accompanied by individual physical challenge tests. A high-stakes attribution claim should not rely solely on the catalogue's FDR. It should demand independent corroboration, explicit uncertainty and careful legal interpretation. Control of error is an instrument of honest inquiry, not a substitute for professional judgement about the measured world.

Sir Harold Jeffreys, Peer Question: Dr. Kullback, you have distinguished family-wise error and false-discovery-rate control, yet I remain concerned about what either quantity tells us about a named candidate. The

Copyright 2026, James M. Atkinson

investigator may tell a tribunal that the survey's false discovery rate was five percent and infer that there is a ninety-five-percent probability that this particular suspicious carrier is real. Such a statement resembles a posterior probability but seems to arise from an expectation over many possible repetitions, not from a probability model for the specific signal. What evidential expression would avoid this confusion? How should we deal with a candidate detected during highly unusual receiver conditions that were rarely represented in calibration data? I should also like you to distinguish a result that merely rejects a noise model from one that discriminates an external signal against internally generated radio-frequency products, especially when those competing physical explanations are not exhaustively modelled.

Please address how the burden of demonstrating an external physical origin differs from the mathematical burden of rejecting one narrow null hypothesis.

Solomon Kullback, Response: Sir Harold, your objection is decisive. A five-percent FDR refers to the expected proportion of false rejected hypotheses under a specified repeated-testing model and selection policy. It is not a direct posterior probability for the particular carrier under consideration. Individual posterior beliefs would require a model for the relative prevalence of genuine and spurious candidates and the likelihood of the actual observed evidence under the relevant alternative explanations. Neither the FDR calculation nor a small p-value supplies those priors or an exhaustive list of causes. To convert the result into an individual probability by verbal sleight of hand would be a serious misrepresentation.

Copyright 2026, James M. Atkinson

The correct statement is bounded. The survey applied an algorithm calibrated to control an expected catalogue-level false-rejection proportion under its reference background population. The particular candidate crossed the stated threshold. Its amplitude, duration, frequency stability and response to controlled input changes are measured separately. The examiner should disclose the calibrated family, model limitations and candidate-specific evidence. An unusual operating state that scarcely appears in the calibration records weakens the applicability of the nominal error guarantee; such an event may deserve targeted challenge, but its formal score should be labelled out-of-distribution or otherwise qualified.

A useful practical test is to subject the candidate to source-path interventions designed to distinguish an external signal from an internal product. Retain the raw samples, then change the antenna or terminate the receiver input under proper conditions, substitute an independently calibrated receiver, vary attenuation and check whether the feature responds as the proposed physical model predicts. None of these interventions should be treated as a magic test in isolation, because changing the circuit can alter gain, intermodulation and sensitivity. The strength arises from coherent predictions across several interventions with separate failure modes. A source that changes with an antenna does not automatically belong to an intrusive device; ordinary lawful emissions remain possible.

If the survey used several receivers sharing the same clock or computer, coincidence among their alarms may reflect a common error source. A conditional posterior model or likelihood calculation must include that dependence. If the relevant physical alternative is absent from the model,

Copyright 2026, James M. Atkinson

apparent numerical confidence can be greatly overstated. A forensic report should therefore provide clear findings at different levels: a calibrated anomaly detection, a receiver-chain-origin challenge, a signal classification if supported, and an attribution conclusion only if independently justified. The numerical FDR is relevant to the first level, not a universal substitute for the rest.

David H. Blackwell, Peer Question: Dr. Kullback, I would press the decision-theoretic consequences. Suppose the operator can afford to inspect one hundred candidate bursts a day, but the instrument can produce many more low-significance indications. A strict family-wise threshold might generate too few leads and miss rare signals, whereas a liberal false-discovery criterion might overload the investigators and create unnecessary privacy intrusions. How should a team choose its loss function and allocate review resources without pretending that cost ratios or event prevalences are known precisely? I am also concerned that a rule tuned to the first week's environment may be used for months, even though the background occupancy and instrument noise state drift substantially. Can one preserve a formal error guarantee under such adaptation, or must the investigator characterise every operating epoch separately?

If the decision rule is altered after a series of false leads, must subsequent measurements be regarded as a separate calibration epoch rather than pooled under the originally advertised error guarantee? I ask especially about the treatment of candidate queues with fixed maximum capacity, since truncation changes which false leads reach an examiner and can make an apparently improved false-discovery rate merely the result of selective retention.

Copyright 2026, James M. Atkinson

Solomon Kullback, Response: Dr. Blackwell, a decision rule is an agreement about consequences under uncertainty. Start by distinguishing reversible internal triage from intrusive or consequential external action. A false lead retained in a private engineering queue may cost only analysis time; an unjustified allegation or interception can have substantial legal and ethical cost. It follows that the same numerical threshold need not govern every stage. A high-recall screening detector may feed a slower, independent verification stage, while final attribution requires much stronger physical evidence. The performance metrics should be stated separately, and the operator should not publish a screening hit as though it were a final finding.

Resource limits can be represented through a prioritisation function involving estimated detection value, expected inspection cost and an uncertainty penalty, but the quantities must not be invented to create spurious optimisation precision. Sensitivity analysis over plausible cost and prevalence ranges is more defensible than one unexplained utility number. A capacity-limited catalogue can also introduce selection bias: if only the hundred highest-scoring candidates are stored, the saved record has been truncated. Retain at least aggregate counts and calibrated score distributions for rejected events, together with the selection algorithm, so that reviewers can understand how opportunities were discarded.

Background drift requires explicit monitoring. Establish operating epochs tied to instrument gain, antenna configuration, preselector state, calibration, environmental occupancy and reference-clock status. Evaluate whether held-out noise-only controls and known test signals remain compatible with the original null calibration. If not, suspend the old formal error statement and recalibrate. An adaptive procedure can retain

Copyright 2026, James M. Atkinson

guarantees under specialised sequential testing frameworks, but one cannot simply apply a fixed-sample theorem to an evolving, retrospectively tuned threshold. When conditions change without an independent calibration record, label the significance as conditional and uncertain.

A robust two-stage protocol would periodically introduce an authorised synthetic weak reference signal to measure detection power while separately recording background maxima to assess false alarms. It would also challenge high-ranking candidates with different receiving apparatus. The operator can then report how many candidates were triaged, how many passed physical challenge, and how often controls revealed degradation. In that structure resource allocation is transparent without smuggling an unverified posterior probability into the software display. The true objective is to make better, lawful decisions with calibrated limitations, not to force every uncertainty into a single attractive percentage.

Solomon Kullback, Cross-Peer Question to David R. Cox: Sir David, the reference tests are not isolated observations. Neighbouring FFT windows overlap, frequency bins leak into one another, and multiple receivers may share clocks or environmental interference. The original independent-test false-discovery-rate result does not automatically extend to every such dependence structure. How would you design a statistically honest calibration when we know correlations exist but do not possess a complete joint distribution? In particular, should the operator estimate an 'effective number of independent trials', use blockwise null records, or evaluate the maximum and the complete reporting procedure empirically? I invite you to distinguish the difficult finite-sample tails, where very small probabilities are demanded, from the central part of the noise distribution that is easy to

Copyright 2026, James M. Atkinson

measure. What consequence follows if the null model is wrong only during rare high-power blocker events?

Could a configuration-specific maximum statistic be preferable even when it is conservative, because the assumptions are observable and the consequences of a false external-emitter allegation outweigh the loss of a few weak exploratory candidates?

David R. Cox, Cross-Peer Answer to Solomon Kullback: Dr. Kullback, the dependence must be treated as a property of the measurement process, not an inconvenience that can be removed with a convenient scalar correction. An effective number of trials may be a useful descriptive approximation for a restricted stationary model, but it is not a universal multiplier valid across thresholds or operating states. Extreme-value behaviour depends upon clustering, tail dependence and the statistic being maximised. If the purpose is to calibrate the complete monitoring system, I would prefer to obtain representative noise-only records containing the true window overlap, receiver configuration, common-clock effects and intermittent interference, then process those records through the exact operational pipeline. The resulting empirical distribution of a whole-search maximum is a direct observable, though still subject to sampling uncertainty and representativeness.

One should not pretend that a thousand calibration records can directly establish a one-in-a-million tail with exquisite precision. Without an extrapolation model, zero exceedances merely bounds the probability rather than proving it zero. For an independent Bernoulli event observed zero times in n trials, a rough one-sided ninety-five-percent upper bound is about 3/n, with an exact binomial expression available. If complete searches

Copyright 2026, James M. Atkinson

are dependent across calibration days, even that approximation requires reconsideration. Tail modelling may improve efficiency but demands diagnostics and sensitivity analysis. The claim must disclose its extrapolative character.

A second problem is the changing null. A clean receiver under quiet conditions may produce an orderly correlation structure; a high-power adjacent blocker can create nonlinear mixing and nonstationary threshold behaviour. It is unsafe to pool these states and assume the resulting marginal p-values are uniform under each one. Stratify calibration by relevant operating state, or define a conservative null encompassing all supported conditions. When a rare blocker produces an unmodelled burst, the guarantee for the normal state does not extend to that episode. Store the blocker level, gain and filter states and treat the observation as potentially outside the calibration domain.

For false-discovery-rate methods the dependence theorem and selection policy must be checked, not asserted. A procedure proven under particular positive-dependence conditions cannot be justified for arbitrary shared receiver interference merely because the correlations seem positive on one histogram. An explicitly conservative method may be necessary for publication claims. Alternatively, the team might retain a less formal exploratory catalogue and use an independently calibrated second-stage hypothesis test for each consequential finding. That arrangement often aligns better with forensic practice than insisting that an enormous adaptive discovery pipeline deserves one precise tail probability. The measurement record should allow another analyst to repeat the calibration and identify

Copyright 2026, James M. Atkinson

where the evidence ceased to be supported by the assumed stochastic model.

Dr. James M. Atkinson, Moderator: Sir David Cox, please extend the inquiry to experimental design, dependence and post-selection inference, particularly where the receiver changes its own detection rule as the electromagnetic environment evolves.

David R. Cox, Fourth Principal Contributor: Dr. Atkinson, practical inference from a large RF monitoring system requires the statistical procedure to be described as an experiment, not merely as a calculation applied to a final spreadsheet. We must know when frequencies were observed, how candidate scores were formed, which measurements share components, and whether the selection rule evolved during the search. Millions of tests do not constitute millions of independent experiments; they may represent repeated views of a small number of physical noise states. The selection mechanism, observation geometry and nuisance variables should therefore be components of the model. A report that starts with the final p-values while omitting these foundations may be numerically elaborate and scientifically underdefined.

The most direct way to address dependence is to define a global statistic at the level of the operational decision. If one alarm anywhere in the surveillance interval would trigger a consequential action, calibrate the maximum alarm score over the full frequency-time-receiver field. If the decision instead concerns the number of candidate event clusters sent for verification, calibrate the event-generation process, including cluster formation and thresholding. If individual device attribution is intended, spectral tests alone are insufficient; the physical challenge stage must be

Copyright 2026, James M. Atkinson

part of the evidential model. This separation prevents a correct calculation at the pixel level from being used to justify a different decision at the device level.

An idealised example begins with m independent null p-values uniformly distributed on [0,1]. Then $P(\min p_i <= t)=1-(1-t)^m$. But real spectral p-values often share correlation through filtering, overlap and receiver state, and their marginal distributions may depend upon gain or local interference. A simple estimate of m_{eff} obtained from covariance eigenvalues might give a rough impression of effective dimensionality, but it generally does not guarantee the far-tail distribution of the minimum or maximum. Two fields can have similar covariance and dissimilar extreme clustering. The engineer should compare candidate approximations against full-chain background records and avoid representing a guessed m_{eff} as a verified correction factor.

Sampling the null is an experimental undertaking. Reserve contiguous intervals known to lack the target signal, but do not assume that an interval is representative merely because the investigator did not hear a transmission. Include multiple antenna orientations, temperature regimes, interference levels, clock states and preselection conditions. Preserve entire multichannel time blocks when resampling so that cross-channel dependence remains. Exclude records used for detector training from final performance evaluation. If null calibration was chosen or revised in light of an observed suspicious feature, the same evidence cannot also be used as an untouched validation set. Partitioning by calendar day or physical test campaign may be more robust than randomly splitting neighbouring FFT windows, which are strongly dependent.

Copyright 2026, James M. Atkinson

Extreme tails present their own measurement problem. A survey advertised as having global false-alarm probability 10^-4 should not be calibrated solely from two hundred simulated backgrounds; the estimated tail would be dominated by extrapolation. One may use a justified parametric model, importance sampling or conservative statistical bounds, but each introduces assumptions and needs diagnostics. An exact zero false-alarm count in a limited validation does not establish an absolute zero risk. In a publication report show the number of independent validation units, their provenance, the observed exceedance count, the uncertainty interval and any model-based extrapolation. This prevents an alluring threshold figure from concealing a weak evidence base.

Post-selection inference must also be recognised. A detector may scan several threshold policies, choose the one with the lowest observed false-alarm count on a particular calibration data set, and then report that count as if it were independent confirmation. The optimisation has fitted noise fluctuations in the calibration set. A reserved holdout or nested validation experiment is needed to estimate performance after tuning. Similarly, choosing the most prominent carrier from a live scan and reporting its local significance as if the carrier had been specified beforehand is a form of selection. The remedy is not to ban exploration, but to distinguish exploratory formation of a hypothesis from prospective evaluation of its predictions.

Operating states can drift. A quiet installation on Monday may differ from a crowded radio environment on Friday; a receiver may silently switch attenuation, reference lock or FFT policy. The null distribution should be monitored using known test inputs and background statistics, with clear

Copyright 2026, James M. Atkinson

criteria for when an established calibration ceases to apply. Adaptive control has virtues, but retrospective use of fixed-sample p-values after an indefinite sequence of threshold adjustments is not automatically valid. Sequential testing requires its own error accounting, including stopping times and repeated looks. The software should retain the adjustment ledger so a later reviewer knows which policy produced each signal claim.

No statistical procedure identifies a hostile emitter from a spectral fluctuation alone. A rejected noise-only null is only the beginning of physical investigation. The team should attempt antenna and termination challenges, change receiver architecture where feasible, inspect common oscillator and power paths, and seek reproducible signal properties in a fresh acquisition. It should also report negative control results and failures of the detector during injected-signal validation. A statistical guarantee is then accompanied by a measured account of engineering sensitivity and alternative explanations, which is necessary for defensible forensic interpretation.

Finally, the analyst should consider the cost of errors explicitly. A broad search that generates a queue for technical inspection can tolerate a higher candidate false-discovery proportion than a report making a consequential claim about a particular person or place. The error budget and confirmation policy should be agreed before data collection rather than improvised once a dramatic feature appears. A responsible conclusion states the family and target risk, how they were calibrated, how many opportunities and alternatives were actually considered, and where the interpretation extends beyond statistical detection into physical inference. That is a scientifically auditable architecture for a very large spectral search.

Copyright 2026, James M. Atkinson

George E. P. Box, Peer Question: Sir David, your discussion assumes we can represent the background of the receiver with a reasonable family of statistical models. But spectrum occupancy, instrument gain and interference all change over time, and the same input conditions may recur in predictable operational cycles. If an engineer selects a Gaussian null because it is mathematically convenient, should the anomaly alarm be judged against its estimated tail even after the residuals reveal heteroscedasticity and outliers? How ought model criticism be built into the formal acceptance test, rather than performed only after an attractive result has been announced? I am also interested in the distinction between robustness to a small number of outlying calibration records and a model that wrongly treats an entire physical regime, such as strong adjacent-channel interference, as merely rare random noise. What diagnostic failures should cause the instrument to suspend its numerical false-alarm guarantee?

Would you specify whether a failed null-model diagnostic should block the detector from generating an attributed finding while still permitting raw acquisition to continue?

David R. Cox, Response: Professor Box, a probability model is an instrument of inquiry and ought to be assessed by its observable predictions. If the null assumes stationary exponential or Gaussian statistics, verify the residual distribution after conditioning on gain, frequency, bandwidth and instrument state. Examine tail quantiles, spatial correlation, time clustering and the frequency of events during known reference-clock transitions. An impressive fit in the middle of the distribution is inadequate when the operational threshold resides far in the tail. The validity of a nominal false-

Copyright 2026, James M. Atkinson

alarm rate at that threshold depends especially upon the model's behaviour in the rarely observed region. One cannot rescue a poor model by calling every disagreement a nuisance outlier.

A practical diagnostic programme should include withheld background records from multiple installations or dates, controlled changes of preselector and attenuator state, and known benign test sources that stress nonlinear response. Compare observed maximum statistics with their predicted quantiles and test whether the frequency of false alerts exceeds predefined acceptance bounds. A distribution that repeatedly underpredicts large scores during a strong blocker indicates that the null is missing a physically distinct regime. It may be appropriate to stratify, enlarge the null to include the blocker, or mark such conditions as outside calibrated operation. Merely increasing a scalar variance estimate cannot necessarily represent new spectral lines caused by intermodulation.

Robust methods are useful when a few contaminated records would distort parameter estimation, but robustness does not relieve the team from investigating why those observations occurred. A trim-and-average policy can hide systematic faults if it discards all the very episodes relevant to forensic risk. Preserve excluded observations, document exclusion criteria, and check performance both with and without them. The correct question is whether the intended decision rule still meets its declared error control under every state in which it will be used. If not, it should fail closed: continue capturing raw data if safe and authorised, but suppress numerical confidence claims until the state has been diagnosed and recalibrated.

The consequences are especially important when a candidate is selected on the basis of the model's failure. If the unexpected line appears only in a

Copyright 2026, James M. Atkinson

regime absent from training, its extremeness under the training model is not meaningful as a calibrated p-value. It remains an interesting technical observation, properly labelled as such. A separate physical challenge may reveal an instrument spur, a new environmental signal or an unmodelled disturbance. The evidential record should contain the failed diagnostics and the engineer's reasoning, not only the later corrected curve. In this way model criticism becomes a safeguard against false certainty rather than a decorative paragraph at the end of a report.

David R. Cox, Cross-Peer Question to Abraham Wald: Dr. Wald, I should like you to examine a monitoring system that never has a predetermined stopping time. It scans continually and reports when any statistic exceeds a threshold. The operator may celebrate a nominal five-percent significance threshold calculated for one hour, but the same test is repeated during thousands of hours, under shifting nuisance conditions, and the survey may stop precisely when an alarming candidate appears. How ought repeated looks and optional stopping be incorporated into the error statement? Could a sequential design express a valid risk of a false alarm over the monitored horizon without simply applying a one-hour p-value afresh at every update? Please distinguish a finite planned monitoring campaign from indefinite surveillance and explain what must be recorded when instrument configuration changes during the decision process.

I would welcome a distinction between a scheduled test that consumes a preassigned risk allowance and an opportunistic extra look prompted by a borderline feature, because those opportunities must not be silently omitted from the accounting.

Copyright 2026, James M. Atkinson

Abraham Wald, Cross-Peer Answer to David R. Cox: Sir David, the stopping rule is part of the experiment. A fixed-sample tail probability calculated for one predetermined analysis is not automatically a guarantee after repeatedly inspecting the accumulating data and stopping on a favourable fluctuation. A sequential probability ratio test, for example, compares the evolving likelihood ratio of observations under two fully specified hypotheses against boundaries chosen to control error probabilities under a valid observation model. The relevant statistic and boundaries depend on the joint distribution of the increments; independence or other model assumptions may be essential. The method does not confer a universal guarantee when the receiver silently changes filters, null calibration or the hypotheses under consideration.

For a finite campaign one may allocate a total false-alarm budget across scheduled looks using a prespecified plan. A simple conservative method assigns marginal budgets α_t whose sum does not exceed α_{total}, so the union bound ensures that the probability of any false alarm does not exceed α_{total} if each constituent test has a valid bound. This may lose power, but it makes the risk accounting transparent even without independence. More efficient sequential methods are possible when the mathematical conditions can be defended. For indefinite monitoring, a fixed positive per-look false-alarm probability applied forever will eventually make a false alert exceedingly likely in many ordinary models; indefinite operation requires a specified long-run rate, time-varying risk allocation, or an always-valid sequential construction.

The instrument's operational policy should therefore record each eligible look, its threshold, its test statistic and calibration regime, the accumulated

Copyright 2026, James M. Atkinson

error budget, and the decision whether to continue or declare an event. Changing an FFT window or reference-clock source may change the distribution of subsequent evidence; the procedure must either update its model in a planned way or mark the old guarantee as inapplicable. It is not legitimate to erase the previous tests from the ledger when a filter change makes the current result more attractive. A reviewer needs the complete path by which the decision was reached.

Sequential error control also cannot turn poor physical discrimination into good evidence. Repeated observations of one internal oscillator spur may generate a very large likelihood ratio against a white-noise null, yet the external-transmitter hypothesis would remain unsupported if the alternative model ignored internal artefacts. The sequential design must be coupled to instrument challenge tests and responsible source attribution. A formal bound on a specified false rejection does not identify why the null was false, and every consequential conclusion should make that distinction audible in its language and visible in its raw evidence.

Dr. James M. Atkinson, Moderator: Dr. Wald, may we now consider how an uninterrupted monitoring programme can retain an intelligible error budget when no particular burst time, frequency or final observation count is known in advance?

Abraham Wald, Fifth Principal Contributor: Dr. Atkinson, long-duration surveillance differs from a finite experiment because its termination and opportunities for finding a surprising feature depend upon the data itself. A survey that claims 'one false alarm in a million' must state whether that probability applies to one sample, one FFT cell, one hourly scan or the entire operational period. Without a defined family or temporal horizon, the

Copyright 2026, James M. Atkinson

number conveys little about the chance that an operator will eventually encounter an ordinary noise excursion. I would begin with a design that treats time as an essential part of the decision policy, rather than an afterthought added when the first intriguing waterfall line appears.

Let E_t denote an alarm event at scheduled look t, with valid marginal probability no greater than α_t under the stated global null. The union bound gives $P(\text{at least one } E_t \text{ over all scheduled looks}) <= \Sigma_t \alpha_t$, regardless of dependence between looks, provided the per-look bounds genuinely hold for the operational procedure. A predetermined summable allocation such as $\alpha_t=\alpha_{total}/[t(t+1)]$ for t=1,2,… has $\Sigma_t \alpha_t=\alpha_{total}$. This is deliberately conservative and can give extremely small thresholds at late times, but it makes an indefinite horizon mathematically meaningful. In real RF monitoring the unit of a look must be defined, and adaptive choices require their own calibration; the formula is not a free pass for uncontrolled changes in how tests are generated.

Sequential likelihood methods offer another route when models are specified. Let L_t be a likelihood ratio of accumulated observations under an alternative H1 against a null H0. In an idealised independent-increment setting, log L_t is a sum of log likelihood ratios. One may stop when L_t reaches a specified upper boundary, continue between boundaries, or accept a different decision at a lower boundary. Error guarantees arise from the actual likelihood model and boundary choice; arbitrary products of detector scores do not have the required interpretation. A receiver affected by correlated time windows, repeated observations of one transmitter or an unknown oscillating interference source may violate the increment assumptions if they are simply ignored.

Copyright 2026, James M. Atkinson

Consider the distinction between running a fresh test on an hour of data and accumulating evidence about a persistent narrowband source. The first approach creates many opportunities for at least one extreme noise value. The second must address whether the source model predicts continuity, how retuning or missing data alters the evidence, and whether the observations are independent conditional on the physical source. A stable internal spur can persist just as a genuine transmitter can. The sequential likelihood should therefore include relevant instrument-state alternatives or require a separate challenge before identification. A high likelihood ratio against a simplified stationary-noise model does not prove that the observed energy came from the antenna.

A practical budget can be divided between exploration, candidate verification and formal reporting. Exploratory alarms may trigger nonintrusive checks, with their counts and thresholds retained but without claims of final attribution. Confirmatory tests use prespecified features of a candidate in newly collected data, ideally through a different clock or receiver path. A final evidential declaration invokes validated physical controls. The stages need not share one undifferentiated p-value, but the transition between them must be documented so that repeated exploratory looks are not quietly relabelled as confirmatory replications. The burden of proof and the cost of a false assertion should influence the stage at which a strong guarantee is required.

An important alternative is to monitor the rate of false alarms rather than the probability of any false alarm over an indefinite horizon. Suppose the validated system reports an average of λ false candidate clusters per hour under a clearly defined stable null. For a hypothetical Poisson model, the

Copyright 2026, James M. Atkinson

count over T hours has expected value λT and P(at least one)=1-exp(-λT). If λ equals 0.01 per hour, a hundred-hour record has expected count one and probability about 0.632 of one or more; the figures are modelling illustrations. A false-alarm rate can be a sensible operational measure for a continuously monitored installation, but it is not the same as family-wise error probability and must not be reported under that name. If alerts cluster strongly, the Poisson assumption should be challenged experimentally.

Nuisance states demand attention because long-run operation will expose rare conditions absent from short laboratory tests. Oscillator reacquisition, power-line disturbances, temperature excursions, antenna movement and high-power nearby transmitters can create temporally correlated false events. The validation set must include such conditions or the report should restrict the formal guarantee to operating states that were actually supported. A system can fail gracefully by recording an 'uncalibrated state' rather than producing a numerical false-alarm probability drawn from the wrong regime. This is a scientific improvement, even if a dashboard designer regards an explicit uncertainty warning as unattractive.

The monitoring record should retain timestamps for each eligible testing opportunity, not merely for successes. Store the null-calibration version, reference input, gain and filter state, the number of frequency cells considered, all adaptive threshold changes and the reason for any stop or reset. Without that ledger, a later investigator cannot reconstruct the number of opportunities for random fluctuation or test whether a false alarm was a predictable consequence of prolonged searching. This matters particularly for legal disclosure, where a selected event cannot be evaluated

Copyright 2026, James M. Atkinson

properly if the surrounding failed searches have disappeared from the electronic record.

The sequential framework should be challenged on known noise-only records with an appropriately long duration and on controlled injected signals whose power, timing and bandwidth are specified. Evaluate both when the system alarms falsely and when it fails to alarm on a known weak source. The difference between control of false alerts and power to detect rare relevant emissions must not be hidden behind one impressive operating characteristic. If increasing thresholds protect an indefinite false-alarm budget but destroy sensitivity after months of operation, the engineering system requires redesign or a different, explicitly declared risk metric. This is the measurable tradeoff a sound survey should disclose.

My final answer is that one must budget error over the actual opportunities and stopping policy of the monitoring system, not simply over the number of cells displayed at one convenient instant. A persistent surveillance console is a repeated statistical experiment with physical dependencies and changing calibration. The proper conclusion is conditional upon those features, and the final forensic finding must still be supported by external-input tests, independent equipment and an exact chain of custody. A mathematical boundary controls a specified decision error; it cannot alone decide whether an electromagnetic feature is intentional, intrusive or attributable to a person.

Walter A. Shewhart, Peer Question: Dr. Wald, a receiver can retain a constant numerical alert threshold while its background noise, amplifier gain and operating temperature drift throughout the week. An analyst may then treat each hour as another identically distributed trial, although the assumptions

Copyright 2026, James M. Atkinson

behind the advertised per-look probability are no longer met. How would you combine sequential error control with a separate process-state check that detects when the instrument has ceased to resemble its calibration population? I am particularly concerned that a control chart could itself generate repeated alerts during ordinary warm-up and that the operator might either ignore those warnings or incorporate them into the substantive emission catalogue. Could you distinguish an alarm about measurement-process instability from an alarm about external RF energy, and specify what should be preserved for subsequent review?

The challenge is particularly acute when nominally independent receivers inherit the same drifting reference; their concordant alarms might then reflect a measurement-process fault rather than several corroborating observations of external activity.

Abraham Wald, Response: Mr. Shewhart, I would make measurement-process health a separate state variable with separate decisions. The system should monitor known references, injected benign signals, internal gain estimates, noise-floor measurements and clock-lock transitions in parallel with its external-signal detector. A control chart can help identify departure from the validated calibration regime, but its own threshold and repeated-look behaviour require characterisation. It is not logically sound to treat a health-warning event as a new external transmission, nor to suppress it merely because it is frequent during warm-up. The proper response may be to mark the affected observation period as uncalibrated and continue retaining raw samples if authorised and safe.

If a reference signal shows a gain change, the detector's null and alternative score distributions may both shift. Under those conditions the old false-

Copyright 2026, James M. Atkinson

alarm threshold could become either too liberal or too conservative. An adaptive threshold that keeps the observed false-alarm count constant is not enough to establish that detection sensitivity has remained intact. The procedure should periodically measure detection probability with a controlled weak test signal and compare it with the declared operating characteristic. When performance fails predefined acceptance limits, invalidate the corresponding calibrated inference until the cause is diagnosed and corrected.

Warm-up can be treated as a distinct operating epoch if the hardware behaviour is reproducible and the calibration documents that epoch. A process chart with predictable start-up transients might have state-specific limits, but the transition times and control actions should be retained. The risk budget for substantive detections should apply only to data satisfying the corresponding measurement-state conditions; an out-of-state record is neither positive nor negative evidence at the old sensitivity. Such separation protects the investigator from drawing conclusions about absence of emissions during intervals in which the apparatus could not reliably measure them.

For audit, preserve each health statistic, its source, calibration reference, timestamp, detector settings and the decision that changed the operating state. Do not delete suspect periods or silently change their labels. If observations from those periods are later reanalysed, the new result should be linked to the original file and accompanied by the revised model and uncertainty. A monitor that admits when it is not calibrated produces a stronger evidential record than one that never displays an error but quietly

Copyright 2026, James M. Atkinson

changes its statistical meaning. This is the essential cooperation between sequential decision theory and engineering process control.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has identified distinct quantities that are too often confused: the probability of a false rejection in one calibrated spectral cell; the probability of at least one false rejection across a prespecified family; the expected false proportion among reported discoveries; and the long-run rate of false candidate events during indefinite monitoring. These quantities require different assumptions and report different risks. Correlation, window overlap, common oscillator artefacts, threshold adaptation, post-selection tuning and repeated stopping opportunities can defeat apparently impressive per-cell figures. The proposed acceptance protocol therefore defines the family and decision unit in advance, preserves complete noise-only calibration blocks, uses independent prospective confirmation, records all detector alternatives and settings, challenges candidates with physical receiver controls, and makes the uncalibrated operating state explicit. The participants' dialogue is a fictional modern reconstruction of statistical and engineering principles, not authentic historical speech. A statistically significant RF feature is not by itself evidence of an unlawful transmitter or its origin.

QUESTION 079. TECHNICAL SOURCES AND EDITORIAL QUALIFICATIONS.

1. Y. Benjamini and Y. Hochberg, 'Controlling the False Discovery Rate: A Practical and Powerful Approach to Multiple Testing', Journal of the Royal Statistical Society, Series B 57 (1995), pp. 289–300, DOI 10.1111/j.2517-6161.1995.tb02031.x. Publisher record: https://academic.oup.com/jrsssb/article/57/1/289/7035855. Establishes the

Copyright 2026, James M. Atkinson

independent-test step-up FDR procedure and distinction from family-wise error; historical dialogue discussing its modern use is explicitly hypothetical.

2. Y. Benjamini and D. Yekutieli, 'The Control of the False Discovery Rate in Multiple Testing under Dependency', Annals of Statistics 29 (2001), pp. 1165–1188. Author copy: https://www.math.tau.ac.il/~ybenja/depApr27.pdf. Describes positive-dependence conditions and a conservative modification for arbitrary dependence.

3. S. Holm, 'A Simple Sequentially Rejective Multiple Test Procedure', Scandinavian Journal of Statistics 6 (1979), pp. 65–70. This is background to family-wise step-down control; any claim applying it to a specified RF procedure requires additional calibration of valid constituent p-values.

4. A. Wald, Sequential Analysis (John Wiley & Sons, 1947). Historical foundation for sequential hypothesis testing; modern indefinite RF monitoring and specific spending examples are editorial mathematical illustrations rather than claims that the historical author analysed SDR systems.

5. Technical and legal qualification: All RF scenarios, times, sample counts, noise powers, and numerical values are hypothetical. No field receiver, emitter identity or empirical false-alarm rate has been independently established in this manuscript.

QUESTION 080

Copyright 2026, James M. Atkinson

What experiment distinguishes stimulus-responsive RF activity from accidental coincidence?

SCHOLARLY RECONSTRUCTION. This moderated exchange is fictional educational dialogue among deceased historical specialists. No statement is an authentic quotation, and no participant is represented as personally having operated contemporary software-defined radios. The experimental settings, numerical examples and potential RF responses described here are hypothetical. They concern authorised defensive testing on controlled premises and devices, not unauthorised communications interception or intrusive stimulation.

Dr. James M. Atkinson, Moderator: Professor Wald, the appearance of an intermittent RF emission shortly after an operator changes a room condition may seem persuasive, particularly when the temporal sequence repeats. Yet a receiver may revisit its band periodically, a noise-floor fluctuation may cross a threshold without any external transmitter, and the operator may unconsciously select only the interventions that are followed by an interesting trace. What intervention design would distinguish a reproducible stimulus-dependent emission from ordinary temporal coincidence? Please address sham trials, concealed random allocation, outcome definitions, uncertainty in event timing, and the evidential distance separating a statistical response from attribution of the source.

Abraham Wald, Principal Contributor: Dr. Atkinson, the strongest initial correction is to replace a memorable sequence of occurrences with a fully enumerated experiment. One must decide, before seeing the next observations, precisely what constitutes a trial, which circumstances make a

Copyright 2026, James M. Atkinson

trial eligible, what observation window is assigned to it, and which RF outcome is to be counted. Without those decisions a remarkable-looking event can be chosen after its timing becomes known. That is a form of selection, not independent proof of a controlling stimulus. The first estimate should be of a treatment contrast within a deliberately constructed population of trials, not of a story built from one striking temporal arrangement.

Let Z_i equal one when eligible trial i receives the predesignated real stimulus and zero when it receives the sham procedure. Let Y_i equal one if a prespecified and instrument-qualified RF event is observed within the defined post-trial window, and zero otherwise. The simplest risk difference is $D = \text{mean}(Y_i \text{ given } Z_i=1) \text{ minus } \text{mean}(Y_i \text{ given } Z_i=0)$. Its value measures the difference in observed event fractions under those two conditions. It does not by itself measure the likelihood that any particular transmitter is present, nor identify how the physical stimulus could produce an emission. Such interpretation would demand further experimental discrimination and a documented observation chain.

Random allocation should be concealed from the person classifying the RF record, wherever operationally feasible. A laboratory controller can select true and sham trials according to a precomputed sequence and disclose that sequence after the analytic code and outcome ledger have been sealed. The sham should reproduce the mechanical movement, operator presence and audible indications of the real procedure while withholding the particular causal element being tested. A sham that differs in obvious sound, power consumption or observer behaviour will not isolate the intended mechanism. Nor should the randomising device itself radiate a

Copyright 2026, James M. Atkinson

distinctive cue that the receiver might detect. The allocation implementation must be tested with an independent spectrum witness before the formal trial.

Consider a hypothetical first series comprising forty true and forty sham trials. Suppose thirteen true trials and five sham trials contain a qualifying event. The descriptive proportions are 13/40 = 0.325 and 5/40 = 0.125, producing D = 0.20, or twenty percentage points. Those figures may motivate an inference, but neither the observed difference nor a calculated significance value automatically supports the mechanism claimed. Trial-to-trial dependence can arise because the detector's threshold adapts slowly, because an emitter remains active across several trials, or because a reference oscillator experiences a shared state transition. A model assuming eighty independent Bernoulli outcomes may be unsuitable if the apparatus changes state after every stimulus. The complete time-ordered outcomes are needed to diagnose the dependence.

The experiment should include washout periods selected by engineering rather than convenience. A receiver's automatic gain control, resonant filter, data queue or digital threshold estimate may retain memory from the preceding trial. A device under test may also have a true physical state with persistence. If another stimulus arrives before that state has returned to baseline, an emission in the next trial cannot unambiguously be attributed to the later intervention. The data ledger should therefore record eligibility exclusions, antecedent condition, time since last actuation, instrument-state transitions, source-reference health, and the laboratory's measured detection coverage. I would prefer explicit exclusion rules established

Copyright 2026, James M. Atkinson

before opening the outcome file to informal post hoc labels of contamination.

The trial schedule must be planned against the receiver's scan cycle. An instrument that samples a frequency for only one tenth of each minute can make an effect appear to depend on stimulus timing merely because the observer tends to act when the waterfall is visible. Randomising the actuation sequence without randomising or documenting the receiver observation state does not solve that problem. A continuous independently clocked witness channel, if available, is preferable. Otherwise estimate a separate exposure variable C_i describing the measurable fraction of the post-trial window and incorporate it into the analysis. A trial with an unobserved window should not silently become a negative result; neither should a trial be dropped because its missingness looks inconvenient.

I would also require a negative-control outcome, such as activity in a spectral region where the proposed mechanism predicts no change but where common receiver artefacts might appear. That outcome helps reveal broad receiver response to the action. A known injected calibration signal supplies a positive control for detectability and timing, though its injection must be physically separated from the contested environment. One ought to test whether a threshold excursion remains when the antenna input is properly terminated or replaced with a documented laboratory source. An RF peak that responds to the sham as strongly as to the true stimulus may indicate human activity, mains disturbance or instrumentation rather than a targeted device response.

A sequential continuation is permissible only with a stopping policy. If a technician inspects the results every ten trials and stops precisely when a

Copyright 2026, James M. Atkinson

favourable difference appears, an ordinary fixed-sample significance test no longer has its advertised error properties. A sequential likelihood-ratio procedure, a prespecified maximum sample size with adjusted boundaries, or a held-out confirmation phase can address this. The rule must include every look that affected the decision, even if the investigator did not produce a formal written statistical test at that moment. Repeatability in a new concealed allocation schedule should be treated as new evidence rather than as an opportunity to reselect whichever earlier parameters appeared best.

Finally, the claimed causal chain should be tested at successive reference planes. At the weakest level, one may establish that the detector's output became more likely during true trials. A stronger finding requires that raw RF energy, not merely detector state, changed after a calibrated stimulus. A still stronger finding may show the change persists across different receivers and antenna arrangements, with identifiable spatial behaviour and a plausible physical coupling pathway. None of these stages alone proves the purpose, owner or lawful character of an emitter. My recommendation is to preserve and report the ladder of claims separately. Only then does a controlled experiment improve the evidence rather than lend a mathematical seal to an attractive coincidence.

Jerzy Neyman, Peer Question: Professor Wald, the design seems admirable in outline, but what exactly should be fixed before the first formal trial? In a complex receiver system the observer might define a successful event by amplitude, a frequency band, a decoded label, a time separation, or a visual classification, and those choices do not have equal false-positive behaviour. Would you specify an operational acceptance rule that can be implemented

Copyright 2026, James M. Atkinson

without discretionary operator judgement, together with a rule for pulses straddling the response window and a treatment for trials in which the receiver temporarily loses acquisition? Please also distinguish the statistical target of an association between trial assignment and observable RF response from the much stronger hypothesis that a particular hidden mechanism is responsible. Finally, can the calibration observations used to choose an event definition later be recycled as if they were independent confirmation of that definition? I am concerned that a well-concealed allocation is insufficient if the result itself is still chosen after inspecting the data.

Abraham Wald, Response: Professor Neyman, the acceptance rule should be committed to a dated protocol and, preferably, executable code before outcomes are available to the analyst. It should include the receiver's centre frequency or defined band, the detection statistic and its units, threshold and duration conditions, the maximum allowed overlap between clustered triggers, the post-stimulus window and its latency allowance, as well as rules for censoring intervals when acquisition integrity fails. If a pulse begins before the trial's response window but continues into it, the protocol must decide in advance whether onset time or any overlapping energy qualifies. Those definitions answer different questions and must not be exchanged after the fact. A sample-counter gap invalidating a large part of a trial should be marked missing or censored, not assigned zero.

A useful eligibility criterion requires the hardware counter to have continuity evidence over the entire scoring interval and the timing offset to remain within a specified bound. If the record contains an acknowledged gap, a sensitivity analysis can treat the missing observation as either possible

Copyright 2026, James M. Atkinson

success or failure to bound the result; one cannot claim the true outcome was observed. The primary estimate concerns an instrument-qualified event under the assigned condition, and its uncertainty must reflect the randomisation and relevant dependence. Attribution to a transmitter requires separate physical tests, including changes to antenna path, independent clocks and local injected controls.

The calibration record used to choose the threshold is training evidence. It is not simultaneously an untouched confirmation set. The investigator may employ a pilot series, openly labelled exploratory, to choose the detection rule, then freeze it and apply it to a new randomised series. If the method must be modified because a fault is found, the record should show a new protocol version and a new confirmation epoch. One may report both series with their different purposes, but they should not be collapsed into one claim that the rule was prospectively specified throughout. This distinction preserves the meaning of the nominal error rate and allows a later examiner to reconstruct why a particular event was admitted.

This procedure also requires preserving the exact observation opportunity: a device whose clock has reset during the scoring interval may have an unknown latency mapping even if its data file is readable. The uncertainty of that mapping should be recorded as a measurement qualification, not absorbed into a favourable probability estimate. A blind analyst should see the same qualification rules for true and sham trials.

Abraham Wald, Cross-Peer Question to David R. Cox: Dr. Cox, I accept that random assignment protects the treatment contrast against some sources of bias, but I question whether it adequately protects the measurement chain itself. Suppose the act of operating the laboratory controller drives a

Copyright 2026, James M. Atkinson

transient through the mains or RF reference network, while the purported environmental stimulus is only one of several coupled disturbances. A sham that imitates operator motion but not electrical switching would produce a difference even if no subject device responded. How would you build the causal model so that the intervention assigned at random can be separated from the practical procedure used to deliver it? What observations would make the distinction identifiable without introducing so many auxiliary measurements that the team subsequently selects whichever one agrees with its desired account?

Please include the possibility that an electronic actuator produces both a legitimate field change and an internal receiver disturbance simultaneously. In that case a simple binary association can remain strong even though the contested emission is not uniquely identified; the experiment must distinguish mixtures rather than merely alternatives.

David R. Cox, Cross-Peer Answer to Abraham Wald: Professor Wald, the randomised contrast identifies the effect of the procedure as implemented, not automatically the effect of an imagined isolated component. If the true operation switches a relay, supplies power to a motor and alters the condition of interest while the sham merely has an observer press an inert button, the experiment identifies a bundled intervention. I would begin by drawing a causal diagram whose nodes include the random assignment, operator movement, controller switching, mains conditions, antenna-cable coupling, receiver state, actual RF field and final threshold indication. The graph is not proof of those pathways; it is a record of the alternatives that the experiment must distinguish.

Copyright 2026, James M. Atkinson

A better design uses a matched sham with controlled electrical load and a separately measured reference path. Under an authorised laboratory plan the actual environmental change can be enabled or disabled while a dummy load reproduces the relevant actuation current. The controller and receiver should have independent timing witnesses so an event in the spectrum analyser's internal clock is not confused with energy from the location under investigation. A crossover arrangement can exchange the true and sham loads across two physically equivalent paths, revealing whether the anomaly follows the supposed stimulus or the switching hardware. The experimenter should specify which contrasts matter before reviewing results.

Independent intermediate measurements are valuable only if their evidential purpose remains explicit. A supply-current probe tests conducted disturbance, a terminated antenna input tests receiver-side susceptibility, and a physically remote receiver challenges source attribution. None is a substitute for the primary outcome, and a favourable subsidiary trace should not replace an unfavourable primary result. If multiple exploratory measurements are reviewed, disclose them and reserve a subsequent confirmation series for the narrowed hypothesis. Thus causal design and randomisation reinforce one another, but neither can abolish confounding concealed by an unexamined instrument connection.

If both pathways operate, a factorial contrast may exhibit an interaction because the receiver becomes temporarily less sensitive while the external field actually grows. The investigator should therefore retain a calibrated test carrier through each stimulus and measure gain recovery directly. An apparently absent RF response during the interference interval could be a

Copyright 2026, James M. Atkinson

false negative, not evidence that the environmental device remained silent. Multiple outputs and a recorded causal graph guard against that ambiguity.

Dr. James M. Atkinson, Moderator: Dr. Cox, the preceding challenge reminds us that an operator's intervention is rarely a single physical act. Would you take the token and examine identifiability, controlled sham operations and observational confounding within a receiver laboratory?

David R. Cox, Second Principal Contributor: Dr. Atkinson, the central inferential error occurs when an experimentally observed association is given the name of a mechanism that has not actually been isolated. Randomisation is an exceptionally powerful design principle, but the causal object it identifies depends on the intervention implemented. Let Z denote random assignment and let T represent the complete realised procedure, which may contain movement, switching, acoustic disturbance, local electrical transients and a physical environmental change. Let E stand for actual external RF energy at a specified antenna reference plane and Y for the signal-processing decision. The chain Z to T to E to Y is only one possibility. There can also be a direct pathway T to Y through instrument coupling, and a confounder such as temperature or occupancy can influence both the environment and the ability to detect the event. A design that ignores these alternative arrows might discover a reproducible response of the test apparatus while mistakenly naming a remote emitter.

The first requirement is to articulate a counterfactual question. Under the same feasible laboratory conditions, would the probability of a qualifying RF observation differ had the true rather than sham procedure been performed? That is a legitimate experimental question. A more ambitious question asks whether the proposed environmental mechanism, separately

Copyright 2026, James M. Atkinson

from controller switching and observer movement, changed the incident electromagnetic field. This second question requires controls that disentangle the components. It cannot be settled solely by a difference in detected events, because the final detector has physical sensitivities of its own. The inquiry should be planned so that the decisive measurements distinguish competing causal models, not merely accumulate confirmations of one preferred description.

If a stimulus has two controllable components, A for the environmental change and B for controller activation, a small factorial study can test combinations (A=0,B=0), (A=1,B=0), (A=0,B=1), and (A=1,B=1), provided all combinations are physically safe and meaningful. For the outcome mean μ_{ab} under the indicated state, the contrast $\mu_{10}-\mu_{00}$ estimates the effect of A without B, while $\mu_{01}-\mu_{00}$ estimates B without A. An interaction may be assessed by $\mu_{11}-\mu_{10}-\mu_{01}+\mu_{00}$. These are descriptive causal contrasts under assignment compliance, comparable populations, and well-defined interventions. If A cannot be implemented without B, the independent effect of A is not identified by this design and must not be claimed. One might instead use a matched electrical sham or an alternative actuator technology to reduce the coupling.

The temporal aspect is as important as the treatment definition. A real RF response can be delayed, intermittent or conditioned on the device's prior state. If the expected response latency is uncertain, selecting the response window after the test will exaggerate evidence. I would require a primary window derived from a declared physical hypothesis or from a separate pilot study, together with secondary windows explicitly designated exploratory. The detector should preserve a raw time series so that later investigators

Copyright 2026, James M. Atkinson

can examine whether the observed pulse preceded the actuation rather than followed it. Trigger timestamps originating in a host computer should be mapped to receiver sample indices using measured latency and uncertainty. An apparent causal order is unpersuasive when the timing error is greater than the claimed delay.

Blind assignment can limit observer expectation, but concealment must be meaningful. If the operator feels a motor vibrating during true trials, the sham is not blind even though a computer conceals the allocation list. If true actuation produces a distinctive switching transient visible in the receiver's own spectrum, an analyst may infer assignment from the data without any actual target response. This is not necessarily a failure of detection. It is a failure to prevent the instrument from being an unacknowledged intermediary. Measure assignment cues in channels selected for that purpose, use balanced actuator noise where safe, and document residual differences rather than proclaim an impossible perfect sham.

Physical intervention controls should be ordered according to causal power. First replicate the observed effect with a benign calibration transmitter under controlled field strength and gain. Then substitute a properly terminated antenna input to see whether the recorded feature survives without the environmental field. Next change receiver architecture, reference source or antenna placement independently. If the feature follows the host power supply or controller lead rather than the antenna, the external-field account weakens. Conversely, if it follows geometric reception while disappearing under termination, the inference of external energy strengthens but still does not identify a particular device. The absence of a feature after switching receivers is not proof of its absence in the original

Copyright 2026, James M. Atkinson

configuration, because sensitivity and detection bandwidth may have changed.

The statistical analysis must account for unequal observation opportunities. Suppose the frequency-agile receiver visits the relevant band for a fraction c_i of the response window on trial i. A binary comparison treating every trial as fully observed will attenuate real effects and can produce spurious differences if the visit pattern aligns with assignment. One may block randomisation by scan phase, schedule actuation independently of the scan period, or maintain an independent continuous witness. A model for event counts may include an exposure offset $\log(c_i T_i)$, where T_i is the nominal window duration, but such an offset is justified only if event opportunity is proportional to observed time under the relevant process model. For a stimulus-locked brief burst the timing of the blind interval, not just its total duration, can dominate detectability.

Negative controls should be chosen for their causal interpretation, not numerical convenience. A sham trigger tests some procedure-linked effects. A remote shielded reference channel tests receiver and clock artefacts. A geographically separate receiving chain tests spatial localisation, but not necessarily common external interference. A control frequency expected to be free of the proposed response can reveal broadband transients, though a narrow-band impairment may evade it. Each control tests a different alternative explanation, and a satisfactory final report must state which alternatives were challenged, under what calibration, and which remain plausible. It would be methodologically unsound to count a control as independent merely because its display appears on a second screen connected to the same timing and power network.

Copyright 2026, James M. Atkinson

I would end with a layered causal conclusion. If true and sham conditions differ under random allocation, we may report an association between the specified implemented procedure and the qualified receiver observation. If that difference persists through antenna substitution and independent RF measurement, we may support a stronger claim that the incident electromagnetic field changed. If further controlled source-direction, frequency-plan and device-side testing links the change to one physical apparatus, a source-specific inference may be contemplated with its uncertainty disclosed. Intent, authorisation and purpose are distinct matters. The experiment should never be made to carry a conclusion it did not measure. In a mature forensic report the boundary between identified effect and untested mechanism is a mark of rigour, not a defect to conceal.

George E. P. Box, Peer Question: Dr. Cox, every experimental factor in your analysis is represented by a simplified variable, but real electronics seldom comply with the tidy divisions of a two-factor table. A switched supply can inject spectral components through its leads, the RF front end may undergo gain recovery, and the supposedly inert sham may change acoustic vibration or thermal load. How should the team test whether its factor model is an adequate approximation rather than merely an attractive set of symbols? I would particularly wish to know which residual patterns should trigger a model revision, and whether the investigator may revise the model after observing one unexpected strong candidate without destroying the interpretation of the preassigned confirmatory test. Finally, how should one state the limits of a factorial design when one factor combination is physically impossible or unsafe and thus lacks empirical support?

Copyright 2026, James M. Atkinson

I would also ask what a legitimate falsification of the original model looks like: not merely a poor fit statistic, but a physical control whose measured outcome lies outside the model predictions. A receiver artefact replicated under terminated input would be one especially useful counterexample.

David R. Cox, Response: Professor Box, the factorial contrast is meaningful only for configurations that can actually be implemented and measured. Its notation should not be mistaken for an assertion that every combination of A and B is accessible. Where one experimental cell is forbidden by safety or engineering, a main effect that requires that cell is not identifiable from the remaining observations without additional assumptions. The investigator should state the estimable contrasts rather than impute a fictional experiment. A suitable alternative may use two independently designed actuators, or a sham which reproduces the important electrical signature while withholding the alleged environmental change, then explicitly quantify the residual differences.

Model criticism belongs in the planned procedure. Inspect residuals by trial order, temperature, receiver state, scan phase, stimulus intensity and prior-trial condition. A time trend in the estimated treatment contrast, for example, can indicate a drifting noise floor or device memory rather than a constant effect. A sudden concentration of qualifying events at every reference-switch transition suggests an instrumental cause. A group of events occurring before rather than after the putative stimulus would directly challenge the causal chronology. Such diagnostics can be planned as model checks without assigning each one the status of a new primary hypothesis.

Copyright 2026, James M. Atkinson

If an unanticipated strong feature appears, preserve it and investigate; do not pretend the resulting revised model was specified before the observation. Write a versioned exploratory amendment recording what prompted it, including unsuccessful alternative configurations and changes to the event definition. Any subsequent confirmation should use newly allocated trials or a reserved dataset, with the revised protocol frozen before inspection. This allows model development and honest inference to coexist. The quality of the scientific account lies partly in whether another laboratory could repeat the distinguishing test from its description, including the cases in which the response should not occur.

For instance, an effect confined to one cable installation but absent after moving the receiver and retaining antenna geometry points towards an equipment path omitted from the original model. That observation should become a concrete design revision with recorded calibration, not an unexplained deletion from the analysis. The final report must retain the older model and show which result exposed its inadequacy, so a reviewer can separate discovery from a successful prospective test.

David R. Cox, Cross-Peer Question to Ronald Aylmer Fisher: Professor Fisher, suppose an investigator randomises the order of forty true and forty sham operations but then inspects the RF trace and discovers that the interesting line is present only after a long quiet interval. They consequently define a new class of 'eligible' trials based upon a retrospectively selected preceding gap. The original allocation was random, but the subset was chosen using an observed response. How does that change the status of an exact randomisation test? Would you insist on treating the condition as exploratory, or can one construct a valid conditional test from the original

Copyright 2026, James M. Atkinson

allocation without understating the choices made after seeing the data? I also ask how the proposed analysis would handle a receiver whose scan pattern was periodic and therefore made certain apparent response delays far more likely than others.

Please address whether a confirmatory test conditioned on an instrument state selected from pilot data is legitimate if that state is genuinely measured before each random assignment and the rule is frozen for a new series. The distinction seems important for experiments that cannot be performed safely in every operating mode.

Ronald Aylmer Fisher, Cross-Peer Answer to David R. Cox: Dr. Cox, randomisation does not grant retrospective freedom to choose whichever outcome or subgroup is most favourable. An exact randomisation test is exact for a specified statistic under its randomisation scheme and null assumptions. If the analyst searched many gap thresholds and reported the one with the largest contrast, the reference distribution for that selected maximum must account for the search; simply computing a permutation p-value for the chosen subset as though it had been specified prospectively will generally be anti-conservative. One may, in principle, repeat the entire selection algorithm within each permitted randomisation to calibrate a maximum statistic, provided the exchangeability and computational rules truly apply. That approach does not transform a selected subgroup into an independent replication.

For transparency I would report the original prespecified analysis on the entire eligible trial set, together with the exploratory gap-dependent observation and the number and nature of thresholds examined. Then I would conduct a fresh confirmatory series stratified or blocked on the

Copyright 2026, James M. Atkinson

preceding quiet interval, using a fixed threshold and concealed allocation. The periodic receiver requires its own design protection: assign trials within comparable scan-phase blocks or capture continuously with an independent witness. A permutation must respect the actual randomisation structure; freely permuting allocations across blocks when only within-block allocations were possible would invent an experiment that did not occur. Statistical legitimacy thus follows the physical execution as closely as it follows the algebra.

The distinctive virtue of randomisation is the ability to state what would have varied under a different permitted assignment. An instrument whose coverage depends on time is part of that assignment environment, not an irrelevant nuisance. Keep all scheduled stimulus times, all sham times, scan-state logs, rejected trials and raw detection statistics. A new subgroup finding can be scientifically valuable, but its evidential category remains discovery until tested against fresh observations under a prospectively determined rule. One should not conceal this distinction simply because a modern software package can issue a beautifully formatted significance table.

A state defined from pilot observations can be used as an eligibility or blocking criterion in a new randomisation without contaminating that new test, provided it is fixed in advance and does not depend on its hidden outcomes. The investigator must still report the narrower target population and any inability to generalise to other instrument states. This is a methodological restriction, not a source of additional evidence for the original exploratory result.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Fisher, the panel now turns to the logic of an experiment whose hypotheses and observation windows are settled before the decisive trials. Would you examine randomisation, blocked designs, chance association and the evidential limitations of a statistically significant response?

Ronald Aylmer Fisher, Third Principal Contributor: Dr. Atkinson, experiments deserve their reputation not because they banish chance, but because they create a controlled account of the role that chance may play. The central problem is to decide what would count as evidence against the hypothesis that the implemented true and sham operations have no differential effect on the chosen RF response. Once a statistic and permitted treatment assignments have been defined, randomisation allows the investigator to compare the observed result with the outcomes that could have arisen under other allowed assignments. This procedure is not a magical detector of intention or source identity. It is an inference conditional on the experimental arrangement, an event definition, and a sufficiently stable observation process.

A suitable primary statistic might be the difference between the fractions of qualifying trials in the two groups, with each trial scored by a predeclared detector and time window. In a balanced experiment with n true and n sham trials and a fixed number K of qualifying events under a sharp null of no treatment effect, the randomisation distribution of the true-group event count X can be hypergeometric when the treatment labels are assigned by complete randomisation and the relevant outcomes are fixed under the null. The probability mass is proportional to choosing x of the K event-bearing units and $n-x$ of the remaining units, divided by the number of ways to

Copyright 2026, James M. Atkinson

allocate n true labels among 2n trials. That distribution reflects the actual allocation design; an unrestricted permutation model is wrong if trials were paired or assignments were blocked.

This mathematics is not by itself a measurement of causation. Suppose the laboratory applies a true stimulus to twenty trials and sham conditions to twenty, with ten qualifying events following the true operation and four following sham. The observed event fractions are 0.50 and 0.20. If these were the only planned comparisons and the required assumptions held, a randomisation calculation could assess compatibility with a sharp no-effect hypothesis. But the difference may equally be due to the test controller's electrical signature if that signature differs between treatments. A perfectly small p-value can support the proposition that the instrument output changed with the procedure while offering little evidence that a concealed communications device responded. The causal interpretation must be earned at the physical reference plane.

Blocking can materially strengthen the experiment. A frequency-agile receiver may revisit the region at known phases, a building's electrical supply may have cyclical disturbances, and local temperature can alter receiver gain or oscillator drift. A blocked sequence assigns both true and sham within comparable short intervals or within receiver-state classes established in advance. This can improve precision by reducing irrelevant variation. It can also prevent the confounding of all true operations with one part of the day and all sham operations with another. Yet blocking requires care: if the proposed stimulus leaves persistent state, a true trial can contaminate the sham trial paired with it. The design should therefore

Copyright 2026, James M. Atkinson

include washout checks and document when a block cannot be completed as planned.

An especially deceptive circumstance is an experiment performed around a striking exploratory signal. An operator hears a familiar relay click, notices a narrow spectral peak some seconds later, repeats the procedure until a similar coincidence appears, and then proposes to score the next fifty trials. The original observation can rightly inspire a hypothesis. It cannot also be counted as a prespecified test of that hypothesis, because its timing, frequency and event classification were selected from the data. In subsequent analysis the pilot record may remain visible as background evidence, but the confirmation set should be genuinely new and the rule frozen. Disclosure of the exploratory search is necessary because many plausible hypotheses might have been generated from the same scene.

A second hazard is the use of many indicators without accounting for choice. If the investigator examines twenty bands, several lags, multiple amplitudes and different algorithms, then retains only the most striking correspondence, the probability of finding some apparent association under a broad null can far exceed the per-test probability. This is true even when indicators are correlated and cannot be treated as twenty independent trials. One remedy is to define a single primary physical outcome and a hierarchy of secondary outcomes. Another is to calibrate the maximum statistic under the actual selection algorithm using randomisation that preserves the physical trial and measurement structure. Such calibration must be performed on the same analysis procedure actually used, not on a simplified surrogate that ignores operator choices.

Copyright 2026, James M. Atkinson

The design should also include a challenge against the receiver's own transients. An injected reference tone, at a safely controlled level and outside the disputed source path, can establish that the receiver would have detected a true event in the selected window. Terminating the antenna port, where permitted, can test whether a purported RF response instead enters through power, cabling or internal mixing. An independent clock can test whether timing agreement arose from a shared oscillator transition. These controls need not all enter the primary test statistic. They define the physical interpretation of a detected statistical response. One must not confuse a statistical false alarm, an instrument artefact and an incorrectly attributed genuine RF signal, for they are different errors.

I would record trial labels under sealed allocation, raw data before filtering, the hardware sample-index clock, calibration state, all excluded intervals, the event-classification algorithm and its revision identifier. A suitable report includes the observed difference, its uncertainty or randomisation reference distribution, the range of possible effect sizes consistent with the data, and the experimental conditions under which the result applies. It should describe whether independent replication was conducted and whether it reproduced the predicted timing and spatial properties, not merely whether one new trace looked familiar. An experiment whose outcome is an alarm rate must not be converted into an allegation of intent without an additional chain of evidence.

Finally, no universal numerical threshold can substitute for scientific judgement about the consequences of the claim. A modest result may justify an inexpensive, harmless instrument challenge; a grave allegation that a person or organisation installed a covert transmitter would require

Copyright 2026, James M. Atkinson

independent, physically discriminating evidence of a much higher quality. Significance is not source attribution, and a result that is statistically incompatible with one narrow null may still be explained by another. The investigator must understand what has actually been excluded. A sound experimental design narrows possibilities while preserving the right to remain uncertain where the apparatus cannot distinguish them.

Sir Harold Jeffreys, Peer Question: Professor Fisher, your proposed randomisation distribution is useful if the treatment assignments are genuinely controlled, but may an examiner infer the probability of a particular mechanism merely from observing a small tail probability under the sharp no-effect hypothesis? I ask because field reports often use the phrase 'chance of coincidence' as though a significance calculation directly assigned a probability to random coincidence having occurred. Could you specify the relation between the tail probability, the observed risk difference and the likelihood of a physical hypothesis involving an external RF source? I would also like you to address what happens if the investigator chooses the expected latency after seeing the observed emission, then calls this chosen latency a natural consequence of the tested mechanism. Does repeating the same selected window on the same stored data produce genuinely new information, or only a more polished restatement of the initial selection?

An independent timing witness may itself suffer a shared clock or power-path disturbance. Would you include the requirement to document that witness's physical independence before promoting a temporal association to a source claim?

Ronald Aylmer Fisher, Response: Sir Harold, the tail probability answers a conditional question about the extremeness of an observation under an

Copyright 2026, James M. Atkinson

explicitly specified null model and test procedure. It does not measure the probability that the null hypothesis is true, nor the posterior probability that a suspected device exists. To infer a mechanism one would require evidence concerning alternative explanations, an identifiable causal pathway and the actual performance of the measuring instrument. A small p-value may show that a no-differential-procedure-effect model is uncomfortable given the data. It cannot tell whether the difference came from an external emitter, a relay spur, scan-phase bias or selective scoring unless the experiment has made those alternatives distinguishable.

The observed risk difference is a descriptive estimate on a specified population of eligible trials. Its interval uncertainty addresses effect magnitude under the selected statistical model. A source-specific claim involves a further inverse problem in which several different causes can lead to the same detector output. That inverse problem requires separate calibration and experiments. One cannot cross it by a change in vocabulary. The distinction holds even if the original result is highly reproducible, since an internal artefact can be faithfully reproducible whenever the test controller acts.

Choosing an expected latency after observing the emission is exploratory selection. The analyst can report the exploratory pattern and subsequently establish a prospective window in a new experiment, but applying that same rule repeatedly to the same observations produces no independent confirmation. If many latency windows were searched, one might construct a selection-aware reference distribution for the best window, provided all choices and their dependencies are correctly modelled. In most practical laboratories, a genuinely new randomised and concealed trial series is

Copyright 2026, James M. Atkinson

easier to interpret. Its strength lies in an exposure that had not already determined the detection rule.

I would record exactly when the hypothesis was proposed and when the primary window was frozen. Such chronological documentation matters as much as the eventual numerical result. The evidential sequence should move from an exploratory temporal pattern, to a controlled association, to an externally corroborated physical source change, and only then to a cautiously justified mechanism. Neither a p-value nor a visually striking waveform is a substitute for those successive steps.

David Harold Blackwell, Peer Question: Professor Fisher, suppose the receiver visits a narrow frequency every five seconds, while a true stimulus is delivered at varying times and the proposed external device, if present, responds for just forty milliseconds. A trial that includes no observation of the relevant band could be wrongly classified as a failure, and the chance of seeing a short response depends strongly on its phase relative to the visit schedule. How should the randomisation and response model account for these unequal opportunities without treating total elapsed monitoring time as though it were continuous coverage? Is it sufficient to divide observed event counts by the sum of receiver dwell times, or does the particular timing of a predicted stimulus-locked burst make that exposure correction misleading? Please explain what an independent continuous witness could actually establish and what it would still leave unresolved about attribution.

Please further distinguish a source that is silent from a receiver that temporarily cannot detect its pulses, since these states lead to different observation likelihoods even when both are recorded as zero.

Copyright 2026, James M. Atkinson

Ronald Aylmer Fisher, Response: Dr. Blackwell, total dwell time is not in general an adequate denominator when the putative response is sharply timed relative to an intervention. If an event is expected only in a narrow forty-millisecond interval and the receiver does not observe the band during that interval, a trial provides no relevant observation, however long the receiver monitored unrelated frequencies earlier in the same minute. A model based on a constant event rate per observed second could be suitable for a stationary background process, yet unsuitable for a stimulus-locked transient. The exposure correction must follow the scientific mechanism being tested and the exact observation schedule.

The cleanest arrangement is to monitor the designated response band continuously during the qualifying interval with an independently timestamped, appropriately calibrated channel. If that is unavailable, one may schedule trials only during predefined suitable receiver windows or randomise treatment within blocks with comparable scan coverage. The rules should be established before viewing the outcomes, and all ineligible or failed trials logged. A trial should not be called negative because it was blind. If partial observation is permitted, define and model the observable fraction of the primary latency window, taking account of its position, not merely its total duration.

A continuous witness can establish a substantially stronger record of whether a signal was present within the receiver's defined sensitivity during an assigned interval. It can also challenge gaps, host delays and scan artifacts in the primary receiver. Yet even this witness does not by itself prove that the field change arose from the proposed target; a supply-coupled switching transient might be recorded by both receivers.

Copyright 2026, James M. Atkinson

Independence requires examination of antenna pathways, reference clocks, grounding and physical separation. Its contribution is to reduce the set of plausible failures, not to eliminate every alternative.

I would therefore report separately the number of randomised assignments, the number of technically eligible observation intervals, the number of valid detected outcomes, the number censored for instrument reasons, and the estimated contrast among eligible trials. If eligibility itself differs by assignment, that is an additional warning: treatment could be affecting coverage rather than the proposed emission. Physical controls and a carefully stated estimand are necessary before a causal interpretation is warranted.

Ronald Aylmer Fisher, Cross-Peer Question to Karl Raimund Popper: Sir Karl, a statistical experiment is often criticised for permitting a favourable result to be described as verification without specifying which observations would contradict the proposed cause. Suppose a true stimulus produces an elevated event rate, but the same emission also occurs during sham trials and sometimes before the stimulus. What pattern of failures would make the proposed stimulus-dependent device hypothesis untenable, rather than merely less impressive? I ask also whether an experiment can honestly distinguish a narrow hypothesis of conditional RF response from the much broader claim that a device is intentionally controlled by the occupant's actions. What would you require the technical investigator to state in advance so that an unfavourable result is not repeatedly excused by adding an unmeasured hidden state or an arbitrary new response window?

A probabilistic response cannot be expected on every trial, but its permissible background and latency distributions should nevertheless be

Copyright 2026, James M. Atkinson

bounded before the confirmation. Please explain how failure probabilities and the smallest practically meaningful treatment effect can give a risky, testable prediction.

Karl Raimund Popper, Cross-Peer Answer to Ronald Aylmer Fisher: Professor Fisher, a useful hypothesis must incur the risk of being wrong. A claim that 'the signal sometimes appears when the operator acts, unless an unknown state prevents it, and may also appear without the operator's action' has almost no discriminating empirical content. I would demand explicit predicted conditions: the specified stimulus should raise the likelihood of a particular RF outcome in a defined latency window, and specified sham operations should not produce the same outcome under otherwise equivalent observation. The proposed mechanism should also predict a physical response pattern at the antenna reference plane distinguishable from mere switching feedthrough. Such predictions can be challenged without asserting that a single contrary trial conclusively disproves every stochastic mechanism.

An occasional response on sham trials is compatible with a probabilistic stimulus effect, but a consistent equality of true and sham response rates within adequate sensitivity would count against that effect, given a prespecified minimum meaningful contrast and sufficient statistical power. A concentration of events before the stimulus, or an event that persists under terminated RF input while following the controller's power cycle, would specifically challenge a claim about externally incident RF energy. The investigator should record those outcomes rather than explain every one away with a new story. A negative result may also reflect inadequate

Copyright 2026, James M. Atkinson

observation, so demonstrable detectability and coverage are prerequisites to meaningful falsification.

It is essential to distinguish the narrow causal hypothesis from an allegation about purpose. Even a repeatable stimulus-conditioned emission can arise from lawful industrial control electronics, accidental coupling, or an instrument. The operator cannot infer intentional covert surveillance merely by naming the trigger condition. Any subsequent source-identification claim must propose additional tests, such as predicted spatial field response, power-state dependence of a known apparatus, or controlled exclusion of receiver-generated products. The virtue of an experiment is that it forces these hypotheses into mutually discriminating forms. It is not the privilege of the investigator to keep changing the definition of success until a preferred conclusion becomes immune to refutation.

One can specify that the treatment contrast must exceed a prespecified meaningful threshold under adequate coverage, rather than insisting on certainty for individual pulses. A confidence interval compatible only with negligible effects after a well-powered test would then count against the proposed practical mechanism. Conversely, an imprecise interval containing large positive and negative effects would justify an inconclusive judgement rather than either vindication or refutation.

Dr. James M. Atkinson, Moderator: Sir Karl Popper, would you now examine the difference between a hypothesis that makes risky physical predictions and one insulated from criticism by arbitrary exceptions? The discussion should remain within lawful defensive instrument testing and must not confuse a temporal association with a judgement concerning intent.

Copyright 2026, James M. Atkinson

Karl Raimund Popper, Fourth Principal Contributor: Dr. Atkinson, I would begin not with an assertion that one curious pattern must be false, but with the question of what makes a claim capable of being tested at all. An RF trace following an operator's action can generate numerous accounts: a controlled external transmitter, an ordinary wireless device changing state, a mains-borne disturbance, a receiver generated mixing product, or a chance crossing of an adaptive threshold. A serious hypothesis does more than accommodate the trace after it is seen. It must identify observable differences that would arise under an alternative procedure, an alternative antenna configuration or an independently maintained timing reference. Otherwise it remains a story fitted to whatever the instrument happens to display.

The first discipline is to formulate a prediction before the decisive observation. Suppose the proposed device is said to respond to a change in light level with a carrier appearing in band B within 100 to 300 milliseconds. The prediction should specify the nature of the light change, its permitted intensity and duration, the clock reference used to determine latency, the spectral event definition and a baseline rate under sham changes. If the investigator later observes an event at 700 milliseconds and changes the claim to 'the device adapts its delay', this may be a new hypothesis; it is not fulfilment of the old prediction. Revision is legitimate, but a revised claim must face new observations rather than retrospectively claim success from the evidence that caused its invention.

A genuinely discriminating test also predicts what should happen when a part of the proposed mechanism is absent. If the light stimulus is withheld while the actuator is run into an equivalent dummy load, the hypothesised

Copyright 2026, James M. Atkinson

light response should disappear, within allowance for background events. If the RF antenna is replaced with a known termination and the spectral feature remains unchanged, the explanation that it came through the antenna's incident field is specifically weakened. If a separate independently clocked receiver observes a correlated field component with the appropriate spatial dependence, an external-field explanation strengthens, although it may still be an ordinary environmental transmitter. One must formulate such controls before assigning causal labels to their outcomes.

False negative tests require equally careful thought. Imagine that the receiver's preselector is on the relevant band for only ten percent of the critical latency window, or that a local oscillator retune suppresses the first hundred milliseconds after stimulus. The hypothesis could be true and the instrument would fail to observe it. Failure to detect is a fair challenge only when the measurement chain has demonstrated adequate coverage, signal sensitivity and event classification performance for the stated response. The control must expose the limits of falsification, not enable a hypothesis to survive every failure by appeal to an unmeasured instrument. A calibrated injected test signal through the full reception chain can bound detectability, while raw sample counters and timestamps document observation coverage.

There is a further hazard in claiming that repeated association eliminates coincidence. A test controller may systematically radiate harmonics with each operation. Such a component can recur with impressive regularity and may even follow a changing schedule programmed by the investigator. That result falsifies a null hypothesis of no procedure-associated RF feature, but may provide no support for the existence of the suspected external

Copyright 2026, James M. Atkinson

apparatus. The better prediction is causal and spatial: the field component should behave according to an external source model, its inferred direction or attenuation should change under specified antenna operations, and it should not persist when all incident RF paths are removed from a qualified instrument. It is precisely the prediction that differs between rival accounts that possesses experimental value.

One can regard the programme as a sequence of increasingly risky tests. Initially the claim is that true trials produce more recorded detections than sham trials. Next the claim is that the difference is present in calibrated raw RF samples. Then it is that an identifiable incident field rather than receiver-generated energy changes. Finally one might claim a particular physical device responds, subject to further tests of that device's state and lawful access. Each step excludes alternatives left open by the preceding one. The investigator should not collapse the stages into an undifferentiated assertion that 'the spectrum proved the device reacted'. The language of the conclusion must match the level of empirical risk actually survived.

It is worthwhile to register adverse observations as rigorously as successes. An event in a sham interval, a matching line in a terminated-input control, an opposite timing order or a disappearance upon changing a receiver's frequency plan should not be hidden. Each changes the structure of viable explanations. There may be harmless reasons for any individual failure, such as a change in sensitivity or imperfect sham equivalence, but these reasons should be independently tested rather than invoked only after unfavourable results. In a long study a record of unsuccessful challenges is part of the evidence. Suppressing it would give the reader the impression of a more definite causal system than was observed.

Copyright 2026, James M. Atkinson

The historical temptation is to seek certainty through accumulation of agreeable facts. Modern instrument software makes that temptation worse because it can search enormous records for correlations, display them with impressive precision and omit the alternative comparisons by default. My remedy is simple in principle and demanding in execution: expose the alternative mechanisms, state beforehand the distinguishing outcomes, preserve the failures and ensure that each new conjecture is tested against observations not used to compose it. A measurement may show that a waveform exists; a procedure may show that its likelihood changes after an actuation; only a series of physical controls may support a source mechanism. Those conclusions are distinct, and an intellectually honest report must allow the evidence to stop wherever the experiment stops.

Walter Andrew Shewhart, Peer Question: Sir Karl, a survey may span a day in which the receiver's noise floor, preselector response or host buffering state changes considerably. If a randomised study concludes that an RF event is stimulus-dependent, the apparent result might actually reflect a shifted measurement process. How should the investigator distinguish a meaningful response to a controlled stimulus from common-cause variation or an instrument process that has moved out of statistical control? I would ask particularly about chronological plots of baseline calibration, sensitivity challenges before and after each treatment block, and the temptation to reject entire stretches of inconvenient data as 'instrument instability' only after their outcomes are known. Which observations must be preserved to make a negative or inconclusive result genuinely informative, and when should the experiment be paused rather than interpreted through a model that plainly fails its own calibration checks?

Copyright 2026, James M. Atkinson

Would you also specify whether an independent calibration-channel alarm should automatically disqualify the affected window or instead trigger a review that is blinded to treatment assignment?

Karl Raimund Popper, Response: Mr. Shewhart, an experimental apparatus is itself a hypothesis about the relation between physical events and recorded outcomes. If its response function changes, that hypothesis requires examination before the external-source hypothesis is tested. Baseline controls should include reference inputs, known RF calibration stimuli, the receiver's gain and threshold state, reference-clock health, preselector state and the integrity of sample and packet counters. Such checks can be performed at predesignated intervals and after identified hardware transitions. A chronologically complete ledger then shows whether sensitivity was stable or whether a change preceded the apparently favourable association.

Pausing rules should be fixed before outcome inspection where possible. For example, a declared failure of a reference tone to exceed a qualified detector threshold can mark subsequent windows ineligible until the instrument is recalibrated. The rule should treat true and sham trials symmetrically and preserve both attempted allocations and the reason for rejection. It would be indefensible to exclude a block because it contains too many sham events while retaining blocks with similar instrument conditions that favour the hypothesis. Exclusions triggered by outcome patterns can alter the statistical interpretation and should be reported as exploratory interventions rather than hidden corrections.

Control charts and descriptive time series help identify changes but do not name their cause. A drift in calibration response might arise from

Copyright 2026, James M. Atkinson

temperature, cable motion, gain control or actual signal environment. Challenge those alternatives by changing one physical pathway at a time under safe conditions. If the measurement apparatus is demonstrably incapable of meeting the prespecified detection requirement, the proper result is an invalid or uninformative trial interval, not a negative finding against the transmitter hypothesis. Conversely, if the apparatus is qualified and a promised response fails to appear under adequately powered, observed trials, that failure should weigh against the particular prediction. Honesty about measurement uncertainty is part of scientific criticism, not a loophole by which every prediction may be preserved.

Qualification of the replacement device should use a common reference signal and a measurement of input-referred detection probability, not rely upon the equality of front-panel threshold numbers. If the substitute can detect the test pulse only at significantly greater field strength, its negative finding cannot be compared without qualification to the original receiver. The experiment should document this sensitivity difference before assessing agreement between laboratories.

W. Edwards Deming, Peer Question: Sir Karl, the trial programme may involve different operators, different shifts, and repeated movement of antennas or cables. A stimulus performed with a different technique can change electrical or mechanical side effects even when the written instruction is the same. How would you require the investigators to standardise the practical operation without concealing the variation that remains? In addition, which elements of the record should allow another laboratory to reproduce the claimed conditional RF response, and how should the team judge disagreements between laboratories with materially

Copyright 2026, James M. Atkinson

different receiver bandwidth, sensitivity or trigger algorithms? It is tempting either to treat non-replication as automatic disproof or to excuse it by reciting every possible technical difference. What standard would prevent both extremes, and preserve the value of an honestly unsuccessful attempt under the conditions in which it was conducted?

I would welcome an explicit protocol for maintaining the same signal thresholds when a new operator or laboratory must replace unavailable hardware, since an apparently identical display setting may not imply the same detection probability.

Karl Raimund Popper, Response: Dr. Deming, the operational definition of a stimulus should describe what the apparatus actually does: magnitude, direction and timing of the environmental change, actuation current, switching arrangement, operator proximity and any potential couplings to the measuring chain. A written instruction such as 'switch the light off' is insufficient if different switches, power controllers or personnel create different RF transients. Record the physical configuration and use a mechanically consistent or automated application where feasible, but do not suppress evidence of remaining variation. An observer's proximity to antenna wiring can itself be a changing capacitive or conductive coupling and needs acknowledgement.

Independent reproduction requires a description of the target phenomenon in measurably comparable terms, not a requirement that every laboratory use identical brand names or software versions. State the antenna reference plane, input-referred sensitivity, bandwidth, timebase uncertainty, burst definition, detection probability calibration, stimulus conditions, sham design and analysis rule. A laboratory unable to observe the defined pulse

Copyright 2026, James M. Atkinson

under a known reference challenge cannot meaningfully test its absence. But an independently qualified laboratory that observes no treatment contrast under suitably matched conditions presents evidence against the generality of the claim.

Reproduction should also target the cause, not simply the appearance of a spectral line. A matching response that follows the test controller's power supply in both laboratories could reproduce an instrumentation artefact rather than confirm a hidden external device. A disagreement may localise an omitted dependency, such as cable topology or building wiring. Record it and design the next test to distinguish the competing mechanisms. The principle is neither that every failed replication disproves everything nor that every success proves the preferred mechanism. It is that each result constrains the hypothesis according to the capability and independence of the apparatus that produced it.

A reproducibility packet should retain the intervention protocol, sham-equivalence test, original time-indexed detector record, receiver response calibration and any changes made following failed trials. The independent laboratory should calculate the same primary outcome without consulting the first laboratory's selected event locations, and should report excluded intervals as well as successes. If a comparable instrument cannot be assembled, its findings can still bound a different configuration but must not be presented as an exact replication. Such limits are not embarrassments; they delimit what the hypothesis has actually risked.

Karl Raimund Popper, Cross-Peer Question to Charles Sanders Peirce: Mr. Peirce, you have emphasised the movement from a surprising observation to a proposed explanatory hypothesis. I ask how that process can remain

Copyright 2026, James M. Atkinson

intellectually productive without allowing the investigator to turn every new explanation into a retroactive success. Suppose a weak RF burst appears after a laboratory stimulus, then later appears when no stimulus was given, and then disappears when the antenna is changed. The investigator can propose a hidden duty cycle, intermittent propagation or a particular impedance dependence to accommodate each result. Which inquiry would you regard as an appropriate next step rather than a mere addition of unconstrained possibilities? Can the search preserve a useful role for abductive reasoning while giving the decisive test to genuinely new observations?

The risk of ad hoc revision is particularly high when an investigator is disappointed by a nonresponse. How would you make the next proposed explanation generate a prediction whose failure could actually reduce belief in that explanation, rather than merely inviting further adjustment of unseen parameters?

Charles Sanders Peirce, Cross-Peer Answer to Karl Raimund Popper: Sir Karl, a surprising event may reasonably prompt us to imagine a cause that would make it less surprising. Such abduction is the beginning of inquiry, not the terminus. The danger is to mistake the ingenuity of the explanation for evidence in its favour. I would ask the investigator to record each candidate cause and derive from it a consequence not already used to invent it. If the source is claimed to have an intermittent duty cycle, specify the expected relation between that duty cycle and independent device-state observations. If propagation is blamed, predict how the feature should change with antenna placement, polarisation or a second receiver. If impedance is

Copyright 2026, James M. Atkinson

invoked, predict the effect of a measured substitution at the same reference plane and under known sensitivity.

The new prediction should be submitted to an experiment that can distinguish rival explanations. If the result is again equivocal, the investigator should say so, not add an unbounded hidden variable to preserve the favourite account. In a controlled RF study I would especially distinguish the origin of a signal from its mere presence in a displayed spectrum. A clock-related spur, for example, might follow the switching schedule without any external radiating apparatus. A genuine external signal might disappear under one antenna replacement because the receiving system became insensitive. Both possibilities require measured controls.

Discovery and confirmation can coexist if they are recorded honestly. Keep the exploratory observations, their alternative interpretations and every unsuccessful test. Then reserve fresh trials, new receiver configurations or an independent laboratory for the narrowed hypothesis. This allows an imaginative explanation to face risk without pretending that the explanation was known before the event that inspired it. The method gains strength from producing clear experimental questions, not from producing certainty on demand. Such reasoning also respects the human consequences of a false accusation based on an attractive but unidentified spectral feature.

Each revised account should fix a new measurable consequence and a test configuration not already used to compose it. For example, a thermal explanation should predict a documented relation to temperature under controlled heating and cooling, not a conveniently unspecified delay. A modulation explanation should predict how the sidebands change when the

Copyright 2026, James M. Atkinson

stimulus rate is deliberately altered under instrument control. Failure of those consequences would count against the specified model.

Dr. James M. Atkinson, Moderator: Mr. Peirce, please conclude the principal cycle by considering how an observation can legitimately suggest a hypothesis, how fresh controlled trials can test it, and how a forensic report can distinguish a supported causal account from an appealing interpretation of coincidence.

Charles Sanders Peirce, Fifth Principal Contributor: Dr. Atkinson, surprise is an excellent occasion for inquiry and a poor substitute for its completion. An RF event appearing after a laboratory action invites the question of whether the action has anything to do with the event. From that observation a scientist may propose an explanation: perhaps the changing environmental condition provokes a radio transmission, perhaps a legitimate electronic controller responds, perhaps a power transient contaminates the receiver, or perhaps an unrelated emitter happens to transmit at that moment. Those are not equally supported merely because they can all be stated. Their relative usefulness depends on the new observations they predict and whether the investigator is prepared to expose them to tests whose outcomes might contradict them.

I would distinguish three activities. First is the formation of explanatory candidates, which necessarily draws upon experience, physical plausibility and sometimes imaginative inference. Second is deduction of observable consequences from each candidate, including predicted absences and changes under controlled alternatives. Third is experimental comparison of those consequences with new observations. The first activity cannot by itself confer evidential validity upon the hypothesis that it invents. The second

Copyright 2026, James M. Atkinson

gives the hypothesis its concrete commitments. The third tests those commitments with an instrument whose own transfer function and limitations must also be examined. These are not strictly chronological compartments in every scientific investigation, but they supply a discipline against retrospectively rewriting the purpose of an experiment.

Consider the candidate hypothesis that a concealed transmitter sends a short burst when an environmental sensor experiences a controlled change. It should predict a response latency distribution, frequency region, approximate signal duration or modulation property under stipulated conditions. Alternative hypotheses will make different predictions. A relay transient may appear nearly simultaneously with the switching current and in many frequencies; a legitimate wireless device might show a different delay or remain present on sham trials; an internal receiver spur might survive a terminated antenna port or shift with its local oscillator setting. The test should be designed around these contrasting consequences. A hypothesis that predicts only that 'something somewhere might be observed at some later time' is too elastic to distinguish itself from accidental coincidence.

The word coincidence is itself a reminder that chance models depend on a definition of opportunity. Suppose a background event rate is λ events per second under an approximately stationary Poisson model, and an observation window has duration w seconds. The probability of at least one background event in the window is $1-\exp(-\lambda w)$, provided the Poisson assumptions are sufficiently justified. For the hypothetical $\lambda=0.02$ events per second and $w=5$ seconds, this probability is approximately 0.0952. If the operator tries many candidate windows, frequencies or trial timings and

Copyright 2026, James M. Atkinson

highlights only a success, this single-window probability understates the relevant selection opportunity. If the background has clustering or periodicity, even the Poisson formula may be materially wrong. One must measure the baseline process under conditions comparable to the actual test, including receiver revisit behaviour and hardware acquisition gaps.

A clever investigator may discover that the candidate transmission consistently appears after some operator action, yet fail to notice that the action itself turns on an electrical load whose harmonics reach the receiver through a shared mains supply. A true experimental distinction would be to reproduce the action's electrical signature using a sham that does not create the proposed environmental change, while independently monitoring the antenna reference plane. If the spectral feature persists under sham switching and terminated antenna conditions, the claim of an incident field from a target device weakens. If it follows the environmental change while independent receiver chains observe a consistent radiated field and suitable negative controls remain quiet, the external response account strengthens. Neither result automatically establishes the identity or intention of a device.

The sequence of trials should be arranged so that the investigator cannot choose only the most picturesque temporal correspondence. A random concealed schedule should include true and sham operations of preassigned number and spacing, and a separate observer should verify compliance. The analysis should define what qualifies as an RF event before the confirmation series starts. One might retain a complete list of all detections, with their timestamps, frequency bands, bandwidth estimates, signal-to-noise ratios and processing states, rather than only the subset associated with the stimulus. The omitted detections are essential to

Copyright 2026, James M. Atkinson

understand the background rate and the possible temporal selection process. An unobserved period should be marked as a coverage gap, not written into history as a silent interval.

Repeated experiments should challenge the most vulnerable part of the proposed explanation. If one explanation requires the RF response to lag the stimulus by approximately two hundred milliseconds, deliberately randomise stimulus times relative to periodic receiver scanning and independently measure the hardware clock. If the effect depends on a claimed sensor, test conditions that actuate the controller but do not change the sensor's physical input. If the investigator has a lawful, accessible reference device, compare its power and transmitter state under the assigned conditions. If not, avoid attributing the response to inaccessible equipment simply because alternative explanations are inconvenient. The experiment should provide evidence at the scale it can measure.

I would also regard replication as more demanding than repetition of an attractive visual pattern. A second experiment should reproduce a predeclared treatment contrast with comparable sensitivity and should, when possible, predict a different feature than the one selected during discovery. A spectrum peak of similar colour on two waterfall plots is insufficient if both plots use the same algorithm, calibration defect or threshold. Independent reference clocks, separate front-end paths, verified calibration tones and different antenna conditions may contribute independent scrutiny. Each such distinction must be recorded as a physical fact rather than presumed from the existence of multiple instruments.

There is a practical moral in these distinctions. The object of a defensive technical examination is to make a well-supported finding, not to force every

Copyright 2026, James M. Atkinson

unexplained sound or spectral line into an accusation. An honest negative result may show that a particular proposed response was not detected under adequate, declared measurement conditions. An inconclusive result may show that the receiver was blind or that two competing causal explanations remained observationally equivalent. A positive result may establish a stimulus-associated change in observed RF energy without identifying a clandestine device. Those three conclusions differ in what they assert and in the actions that they justify. They should never be converted into one another by rhetorical confidence.

I would close by preserving the experiment's full history of conjecture, calculation, intervention and correction. State the initial observation that prompted the inquiry, the alternative hypotheses entertained, the exact preassigned validation experiment, all successes and failures, the known instrument limitations, and the remaining uncertainty. An attractive hypothesis is valuable when it guides a discriminating test, but becomes dangerous when it is allowed to decide which evidence shall count. A defensible report should make it possible for another competent examiner to reconstruct not only what the team concluded but what evidence would have changed its mind.

John Wilder Tukey, Peer Question: Mr. Peirce, an experienced examiner may discover an irregular cluster of apparently responsive RF bursts while exploring a long recording with time-frequency displays. Exploration is indispensable for recognising unexpected artefacts and possible signals, but it also creates many undocumented analytic degrees of freedom. What distinction would you draw between generating a plausible explanation from exploratory visual analysis and later testing it against a withheld

Copyright 2026, James M. Atkinson

observation set? How should the examiner preserve the negative plots, alternative event definitions, discarded frequency bands, and unsuccessful detection thresholds without reducing exploratory work to an impossible list of every mouse movement? I am especially interested in whether the same raw capture can support both exploratory discovery and a genuinely independent causal confirmation, and what safeguards are needed if a fresh capture or fully independent receiving installation is unavailable.

Could the laboratory also retain a machine-readable index of candidate plots and rejected event definitions, so that a later examiner can reconstruct the main analytic choices without relying solely on a handwritten narrative?

Charles Sanders Peirce, Response: Professor Tukey, exploration should be candidly exploratory. It may reveal the need for a different bandwidth, an unexpected timing relation, a weak-signal estimator or an alternative physical coupling pathway. The difficulty begins when those discoveries are represented as if they had been specified before the data were examined. The team should keep a structured analysis log recording which candidate frequencies, event thresholds and latency windows materially affected the selected hypothesis. The record need not describe every incidental movement of the cursor, but it should make the path from the original observations to the chosen confirmation rule reconstructable, including choices that produced unattractive or null results.

A withheld dataset can provide more credible confirmation if it was genuinely unavailable during hypothesis formation and processed by a frozen rule. Yet merely hiding some rows from a time-correlated continuous capture may not create independence: bursts, noise-state changes and receiver calibration drift can persist across the training and held-out

Copyright 2026, James M. Atkinson

intervals. The split should reflect the temporal and physical dependence of the process, for example by reserving distinct experimental blocks or a new randomised allocation series. If no fresh capture is possible, one may use selection-aware methods and disclose the limitations, but should not claim that repeated analysis of the same selected trace produced new empirical evidence.

An independent receiving installation is valuable when it breaks shared error pathways, not simply when it has a different label. Compare antenna-path coupling, clock distribution, host processing, detector algorithms and timing references. A second system with materially different weaknesses can corroborate the incident-field change, but it cannot by itself identify a hidden transmitter's purpose. The final report should separate discoveries, calibration checks, confirmatory contrasts and physical attribution. Exploratory work remains scientifically useful when it produces hypotheses whose subsequent tests may honestly fail. It becomes untrustworthy only when the record conceals its selective character.

A versioned machine-readable register is a sensible companion to the prose. Each material analysis run can record source-file hashes, frequency and latency bounds, threshold settings, number of eligible trials, number of detections, and the reason a candidate was discarded. If the files are large, hashes and indexed locations preserve access to the original evidence without duplicating the entire dataset in the report. Such records make the history of inference independently inspectable.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has separated three propositions that must not be confused: a temporal association between a controlled procedure and a receiver indication; a

Copyright 2026, James M. Atkinson

causal change in electromagnetic energy at a specified measurement reference plane; and attribution of that change to a particular device or purpose. A concealed, randomised true-versus-sham trial programme can support the first proposition when observation windows, eligible trials, event definitions, receiver coverage and statistical stopping rules are established beforehand. The second proposition requires physical instrument challenges, independent timing and antenna-path evidence, and credible exclusion of controller, mains, cable and receiver-generated transients. The third may require entirely new evidence and must not be inferred from a low p-value. The panel recommends preservation of raw samples, all assignments and exclusions, sham and negative-control records, calibration observations, instrument-state history and every material analysis decision. Any calculation must disclose its model assumptions and the observational opportunities it counts. These exchanges are modern fictional educational reconstructions, not historical transcripts, and their numerical examples are illustrative rather than verified field results.

QUESTION 081

Copyright 2026, James M. Atkinson

What may coding structure reveal about a waveform without decoding protected communication content?

SCHOLARLY RECONSTRUCTION. The named historical specialists are represented in fictional educational discussion; they did not meet in this forum or operate the modern receiving instruments discussed. The examples are invented laboratory cases using authorised synthetic signals. They are not field measurements, intercepted communications, or authenticated statements.

Dr. James M. Atkinson, Moderator: Professor Reed, a lawful defensive survey may observe modulation, symbol timing, repeated frame intervals and other external waveform properties without any entitlement to examine the protected meaning of a message. Explain which features of an error-control code can legitimately be investigated using known public laboratory sequences, how the code hypotheses can be tested, and why identifying a plausible coding family neither recovers the payload nor identifies the radiating apparatus.

Irving S. Reed, Principal Contributor: Dr. Atkinson, a physical transmission comprises several transformations whose evidential meaning must not be confounded. The information source produces a sequence; framing and coding introduce systematic relationships; a modulator maps symbols into a physical waveform; propagation distorts that waveform; and the receiver produces estimates filtered by its own limitations. The analyst may observe timing, bandwidth, envelope behaviour, carrier transitions and controlled correlations without possessing or attempting to reconstruct the information source. A coding-family inference concerns a mathematical

Copyright 2026, James M. Atkinson

transformation, not the identity or intentions of the person or device that selected it. In an authorised laboratory one can transmit fully known sequences through multiple encoders and measure which statistical features survive an ordinary receiver chain. One cannot transfer the success of that test into a claim that a similarly shaped external emission carries the same message or comes from the same transmitter.

For a linear block code over a finite field of q elements, let n denote the length in field symbols of a codeword and k the dimension of the information vector. The conventional code rate is R=k/n; q and the number of bits per symbol must be declared if the result is translated to a binary rate. Redundancy is n−k field symbols per codeword, though not every systematic-looking interval in the physical waveform necessarily corresponds to those redundant coordinates. A receiver first has to infer symbol timing and modulation mapping, and perhaps distinguish an interleaved frame from a native codeword. These operations are not neutral: an incorrect phase reference, a skipped sample or a different constellation labelling changes the apparent relationships. The analyst should therefore state which observations are direct measurements and which rely upon a trial timing or symbol hypothesis.

The family that I and Gustave Solomon described in 1960 used polynomial evaluations over finite fields to construct codes with specified distance properties. That algebra provides a particularly clear example of why a code can have recognisable structure yet no unique equipment provenance. An illustrative shortened or full-length code with n=255, k=223 over a field of 256 elements has 32 redundant eight-bit symbols and rate 223/255, approximately 0.8745. Under the usual Reed–Solomon minimum-distance

Copyright 2026, James M. Atkinson

bound, $d_{min}=n-k+1=33$ and the bounded-distance capability is $t=\text{floor}((d_{min}-1)/2)=16$ unknown symbol errors, assuming correctly defined codewords and the specified decoder. The figures describe a mathematically defined laboratory code, not a claim that any unknown emitter uses it. Many unrelated manufacturers and services may use the same family, parameters or interoperable standard.

A parity-check or algebraic-syndrome experiment must be interpreted carefully. If H is a parity-check matrix for a specified linear code and c is a valid codeword represented as a column vector, $Hc=0$ over the relevant field. That relation can be tested directly upon transmitted sequences that the investigator owns, or used to design a controlled receiver-validation challenge. For an unknown protected transmission, direct computation on putative recovered symbol strings may move beyond mere radio-frequency observables and into protocol or content processing. Such activity requires separate legal and ethical authority and is not presumed by this volume. The defensible analysis may instead compare aggregate spectral and temporal features from public test waveforms without deriving or exposing any protected payload.

A second difficulty is model selection. Suppose an investigator tests dozens of candidate block lengths, symbol clocks, code rates, interleaver depths and mappings. Some configuration will inevitably appear to fit incidental regularity, particularly when the analyst has chosen the best-scoring model after examining the same record. An agreement found after such a search is not a confirmatory probability unless the search procedure appears in the null calibration. It should be evaluated against independent synthetic controls and held-out recordings. The outcome ought to be expressed as a

Copyright 2026, James M. Atkinson

ranking of explanations under stated measurement conditions, with a statement of how frequently nonmatching public laboratory signals produce a similarly high score. Mere repetition of an apparent frame boundary is not enough. Switching supplies, scan schedules and packetised receiver buffering can also generate periodic structures.

The physical experiment must therefore be factorial rather than theatrical. In a shielded, authorised installation, retain the same RF carrier, symbol rate, modulation constellation, emission power and propagation path whilst changing only the known code family. Then retain the code and change the pulse-shaping filter, the framing interval and the receiver's bandwidth. If the proposed observable tracks the encoder setting under the first manipulation and remains appropriately invariant under the others, it has discriminating value. If it follows the receiver filter or host buffering, it is a measurement-chain characteristic. The experiment should include a no-code random-symbol control, a framed but uncoded control and at least one independently constructed encoder having different parameters. The analyst should retain raw I/Q, reference-clock state, test-sequence provenance and every processing version.

It is useful to separate the claim hierarchy. The weakest finding is that a recurring external spectral or timing feature was observed under a declared reception configuration. A stronger finding is that a set of authorised laboratory waveforms with a particular code family produces comparable external features, subject to specified ambiguity. Stronger still would be confirmation of a code parameter under legally authorised signal processing, but even that identifies a technique rather than an emitter. The final step, attributing a physical source, calls for antenna-path evidence,

Copyright 2026, James M. Atkinson

controlled relocation, independent receivers, verified timing and evaluation of competing explanations. A textbook should teach the reader to stop at the strongest proposition actually supported by the record, not to travel from a mathematical pattern to an accusation.

The finite-field formalism is immensely powerful precisely because it is general. That generality makes it an unreliable fingerprint of a particular individual. Our laboratory test should use a public and precisely reproducible reference encoder; the waveform comparison should be bounded to lawful non-content observables. Any actual attempt to classify protected content, reconstruct codewords or exploit error-correction redundancy would demand a separate authority decision, explicit scope and documented safeguards. In the defensive context the objective is to recognise what the receiver can and cannot establish, preserve the opportunity to falsify its preferred explanation, and avoid manufacturing certainty from an attractive mathematical fit.

Harry Nyquist, Peer Question: Professor Reed, you have demonstrated why a code rate is mathematically determinate once n and k are defined. A monitoring receiver, however, does not see a vector of field symbols: it sees an analogue waveform filtered in time and frequency, with uncertain phase, variable noise and possibly a sequence of retuning intervals. If the gross symbol-rate estimate is in error by a small fractional amount, an apparent codeword period can drift across an observation window. How should the analyst construct a physical timing test that respects your algebra but does not invent symbol boundaries? Should the experimental comparison be performed on the same known public sequence under several independent sampling clocks, or would that risk confusing changes in acquisition timing

Copyright 2026, James M. Atkinson

with changes in the encoder itself? I would also ask what negative control can show that a periodic feature is simply a product of receiver resampling, rather than a consequence of a block code's redundancy. The distinctions seem decisive if a report will be relied upon as forensic evidence.

Irving S. Reed, Response: Mr. Nyquist, the encoder parameters describe relationships at a level below the physical observation and must not be promoted into measured facts without an adequate mapping. Define the supposed clock rate, the allowed frequency tolerance, the start-time interval and every acquisition discontinuity before calculating a periodicity statistic. A known public calibration waveform should pass through the complete antenna, preselector, receiver and sampling chain under more than one permitted clock configuration, with independent monitoring of the sample counter and reference oscillator. The question is whether the proposed feature remains associated with the known encoder when physical timing conditions vary within measured bounds. A correlation maximum that migrates with the host's resampling ratio is evidence about processing sensitivity, not reliable evidence of the encoder. In contrast, an encoder-dependent feature that survives controlled sample-clock substitution is worth further investigation, though it remains limited to the test family.

I would keep three comparison channels. One carries a known encoded training waveform, one carries an uncoded but identically framed waveform, and one carries a stationary test tone whose phase can reveal a local sampling disturbance. All use the same signal-power and filtering arrangements where feasible. If an apparent frame period appears in the stationary reference tone after a clock reset, the analysis chain has

Copyright 2026, James M. Atkinson

produced a false periodicity. This intervention differs from observing two instruments simultaneously: the second instrument must avoid sharing the failure mechanism being challenged. Measure the probability of a false periodicity on recordings acquired before the hypothesis was chosen, and repeat on withheld signals. Where no stable clock-to-symbol mapping exists, the honest result is an observed timing pattern with an unresolved interpretation, not a confirmed codeword length. Finally, the laboratory experiment should record only synthetic data owned by the investigator; it need not reconstruct any private message.

A more discriminating calculation should track timing uncertainty explicitly. Let Δf be the independently measured uncertainty in symbol-clock frequency and T the observation length. Under a small-error approximation, the accumulated phase-of-symbol-clock uncertainty grows roughly with Δf T cycles; this is not a receiver-independent constant. The report should show the value used for each recording and state whether the timing fit was selected after examining the unknown waveform. Such disclosure prevents an apparently precise frame estimate from concealing an uncalibrated reference oscillator or an opportunistic search over possible clock rates.

Ralph Vinton Lyon Hartley, Peer Question: Professor Reed, an expert may see recurrent bursts separated by a familiar interval and regard them as the output of a fixed-length block encoder. But frames can be assembled by a scheduler independently of the chosen error-control code, and a statistical signature might come from a scrambler, source distribution or preamble. When the laboratory compares two codes, how do we prevent differences in their packet framing or transmit duty cycle from becoming the purported

Copyright 2026, James M. Atkinson

distinguishing feature? Could the proper test demand matched physical airtime, identical symbol clocks and an independently measured spectral response, rather than only nominally equal application payloads? I am concerned also about the examiner's vocabulary. Describing a frame boundary as an 'error-correction boundary' suggests a mechanism already established, although the receiving instrument may merely have measured envelope transitions. How would you write the final observation and what would you require before giving even a qualified coding-family explanation?

Irving S. Reed, Response: Mr. Hartley, you have isolated the most common confounder. A frame is an organisational interval; a codeword is an algebraically defined sequence. Their boundaries may coincide in a particular implementation but are not logically identical. In a controlled test, specify the framing generator separately from the encoder, and implement at least a two-factor comparison: encoder A versus encoder B, and framing pattern F1 versus F2. Keep the total radiated energy, output filtering, physical symbol rate, observation bandwidth and receiver gain path as similar as their definitions permit. Then estimate whether the chosen exterior feature responds primarily to encoder selection, framing selection or an interaction. A feature controlled by F1 versus F2 cannot be claimed as a unique signature of the code. Nor can identical source packets be assumed to produce matched output airtime when the two codes have different rates; the experimental design must choose whether to match input-information length or physical transmission duration and state that choice.

The language of the report should reflect the actual level of inference. An

Copyright 2026, James M. Atkinson

appropriate first sentence is: 'A recurring change in received envelope power was observed at approximately the stated interval under the specified receiver configuration.' A subsequent laboratory comparison might say: 'Public test waveforms employing encoder A and frame format F1 produced a superficially similar interval, but the observation is not unique to that configuration.' Only independent controlled variation could support the stronger statement that the feature discriminates coding families within the tested population. Even then it would not identify the transmitter, reconstruct information content or demonstrate the purpose of an emission. A separate receiver with an independent reference and a test of the input path are needed to rule out instrumentation artefacts. Preserve both positive and negative trials, rather than only charts whose visual appearance agrees with the preferred interpretation.

The factorial comparison should also include an interaction term because code rate and framing can jointly change the duration of a burst. If the code factor alone has little effect but the frame factor has a large effect, the proposed exterior statistic is properly associated with framing in the tested apparatus. If the interaction is material, report the restricted combinations over which the result was observed. An expert should not remove a statistically awkward interaction simply to produce a simple, memorable device classification. The purpose is to establish what the measured waveform warrants, not to manufacture a one-to-one map from a visible frame interval to an encoder.

Irving S. Reed, Cross-Peer Question to Peter Elias: Professor Elias, the finite-field code I described creates algebraic redundancy, yet your account warns

Copyright 2026, James M. Atkinson

that its appearance may be concealed by interleaving, puncturing and the modulation chain. Suppose a classifier performs well on public laboratory examples but fails when the same encoder is attached to a differently designed transmitter. Is that a sign the mathematical code was misidentified, or proof that the measured feature originated elsewhere in the chain? Can we specify which parts of the laboratory design must be independent before describing an external waveform as compatible with a particular coding family? I would also ask how to prevent the classification system from using an obvious but irrelevant difference such as amplifier spectral regrowth or frame length rather than a feature causally associated with the code. The broader forensic risk is that a strong statistical score may describe a fixture or receiver, whilst being narrated as an insight into the unobserved transmission process.

Peter Elias, Cross-Peer Answer to Irving S. Reed: Professor Reed, a failed transfer to a different transmitter does not by itself falsify the claim that the first set of known examples used the specified code. It challenges the generalisation from one observation chain to another. We must distinguish a claim about the encoder, which is stipulated for the authorised laboratory source, from a claim about the learned exterior feature, which has to survive appropriate changes of hardware. In an intervention study, alter one major component at a time: the encoder with transmitter and modulator fixed, then the modulator with the encoder fixed, then the power amplifier, output filtering, cable and receiving instrument. A feature that changes with encoder selection across these controlled conditions is stronger evidence of an encoder-related exterior effect than a feature tied to one transmitter's distortion or one receiver's gain state.

Copyright 2026, James M. Atkinson

The evaluation must include source-separated training and testing. Do not let recordings of one hardware unit at adjacent times appear in both sets, because temperature, clock drift and construction tolerances can make them highly similar. A held-out transmitter and receiving chain are more demanding tests than random division of successive records from one apparatus. Identify the feature before testing and use identical processing settings for all candidate encoders. Report its false-match rate against distinctly framed uncoded signals and unrelated coded signals. If the classifier relies on a frame-period feature shared by both code families, it is not a coding-family discriminator even when the score is repeatable. Finally, no classifier output should be represented as the recovered payload or as proof of a particular hidden device. Those conclusions require evidence outside the controlled code experiment, and this volume does not authorise protected-content processing.

The validation plan should also report the result when the held-out transmitter operates with a different output filter and a separately controlled frequency reference. If the observable feature disappears, examine whether the change follows amplifier nonlinearity or spectrum shaping before reconsidering the known encoder. This prevents a laboratory-class label from being misrepresented as a property of all possible implementations of the same mathematical code. The receiving chain must be challenged as deliberately as the transmitting chain.

Dr. James M. Atkinson, Moderator: Professor Elias, Professor Reed has separated algebraic code properties from physical observables. Would you

Copyright 2026, James M. Atkinson

take the token and investigate the temporal signatures of stream-oriented and convolutional coding, particularly when the receiver has uncertain symbol alignment and does not examine the protected message?

Peter Elias, Second Principal Contributor: Dr. Atkinson, the first obstacle is that temporal repetition is not synonymous with convolutional coding. A convolutional encoder ordinarily generates output symbols as functions of current input symbols and a finite collection of past symbols. Such memory creates relationships in a mathematical symbol sequence, but how those relationships appear in energy, instantaneous frequency or a spectrogram depends upon modulation, pulse shaping, scramblers, interleaving and channel impairment. An observer can confidently measure a pulse interval or spectral cyclostationarity without being entitled to infer a unique encoder structure. Even an expertly designed test may reveal the entire transmission pipeline rather than a code alone. Consequently the hypotheses must describe a chain of transformations and must assign uncertainty to every link.

Consider a simple rate-one-half feed-forward convolutional code whose binary output is determined by two generator polynomials. If each input bit generates two coded bits, the nominal code rate is one half. But the channel-symbol rate depends on the modulation alphabet: two coded bits might be carried as one quadrature symbol or two binary symbols, while puncturing may alter the effective rate. The code's constraint length describes encoder memory, not the length of the RF burst. If an observer notes that a modem emits pairs of short transitions, that observation cannot determine whether the pairs came from a rate-one-half convolutional encoder, an unrelated line code, an interleaver or periodic framing. A

Copyright 2026, James M. Atkinson

defensible experiment keeps the encoder and changes the modulator, then keeps the modulator and changes the encoder. In both cases the operator should analyse declared features without access to an unknown protected payload.

A detector's uncertainty in symbol timing deserves the same seriousness as the code hypothesis. Let T_s be the nominal duration of a transmitted channel symbol, τ the unknown timing offset within a symbol period, and ε the fractional sampling-clock error. Even for a stationary signal, an estimator using nominal T_s and $\tau=0$ may split or merge transitions and create spurious periodicity. If the receiver occasionally retunes, the data may contain discontinuities in sample chronology that resemble a skipped framing symbol. A real observation should record raw sample indices, acquisition time, clock corrections and missed-block indicators. The analysis should be repeated over justified timing offsets and should penalise the number of candidate configurations explored. A result that appears only at an implausible timing offset is not equivalent to a consistent feature supported by independent clock calibration.

The appropriate laboratory design uses several fully known synthetic bit streams with deliberately different statistics: independent random bits, alternating or bursty inputs and a deterministic public training sequence. Transmit each through a specified convolutional encoder and through a no-code control while holding centre frequency, gross symbol rate and signal power constant. A frame boundary can be represented by a public calibration marker, and the transmitted content need never be sensitive. Then change the pulse-shaping filter or introduce measured timing jitter to see which alleged coding observables persist. A statistic that disappears

Copyright 2026, James M. Atkinson

when the observation filter changes may be a measurement artefact. A statistic that persists across different channel responses but changes with the known encoder is stronger laboratory evidence for the stated, limited hypothesis.

At weak signal-to-noise ratios even the notion of a detected transition is statistical. The analyst might form a likelihood for several hypotheses using a feature vector x comprised exclusively of permitted observables, such as measured symbol-rate peaks, burst duration, envelope cyclostationarity and frame interval. If H_i denotes a laboratory encoding configuration and $p(x|H_i)$ its experimentally measured feature distribution, a ratio $p(x|H_1)/p(x|H_0)$ may compare two defined models. It does not furnish the posterior probability of a particular transmitter without priors and a sufficiently broad set of competing models. It is particularly dangerous to estimate $p(x|H_i)$ from the same small record used to choose the feature and then advertise a nominal false-alarm rate as though the modelling process were independent.

We should also treat interleaving as a formidable confounder. A burst interleaver changes the temporal order in which coded symbols appear; a block interleaver may transform short runs of errors into separated errors before decoding, but its observable physical consequence depends upon the frame schedule and waveform mapping. Identical coding schemes with different interleaving can have materially different transition statistics. Distinct codes followed by the same framing and scrambler may have nearly indistinguishable external envelope signatures. One may therefore conclude that a measured timing relation is compatible with a class of laboratory transmission chains, not that it reveals the hidden encoder or that it

Copyright 2026, James M. Atkinson

recovers the content. The opposite lesson is equally important: an absence of a simple periodic feature is not evidence that no coding or redundancy exists.

The analyst should make the success criterion falsifiable. In a preregistered comparison, a statistic intended to distinguish a known coded from a known uncoded laboratory signal should have a measured sensitivity and false-positive rate over independent trials, receiver configurations, noise levels and temporal offsets. Where a statistic performs well only on one receiver or one known training waveform, it may have learnt a peculiarity of the hardware or test sequence rather than a general code property. Use multiple independent laboratory encoders where available, and reserve recordings from one apparatus as the untouched test set. An honest negative result, including overlapping feature distributions, is scientifically useful because it prevents the expert from reading meaning into a visual pattern that the instrument cannot reliably distinguish.

My recommendation is to maintain strict boundaries between signal description and communications exploitation. Time-frequency and envelope characteristics can help plan a defensive survey or determine whether an observed feature changes after an authorised equipment adjustment. Nothing in that task requires an investigator to recover the protected data bits, infer private message content or reconstruct a communications session. The general principle that redundancy permits resistance to noise is relevant here; the investigator should use it to design synthetic controls and to understand alternative explanations. The historical theory supplies disciplined questions, not a licence to treat an unexamined waveform as a legible private message.

Copyright 2026, James M. Atkinson

Jacob Ziv, Peer Question: Professor Elias, your distinction between code memory and physical framing is important, especially when a scrambler or compressor changes the apparent regularity of the channel symbols. Suppose we use public synthetic sequences to compare a convolutional encoder with an uncoded reference, but the source data have very different run-length distributions. A feature extracted from symbol-transition spacing might then identify the source statistics rather than the encoder. How would you design a test that changes source entropy, encoder settings and frame structure independently, and how should the resulting conditional dependence be reported? Would you test a known random sequence, a strongly periodic sequence and a low-entropy naturalistic control, whilst holding the transmitted spectrum and amplifier power near the same range? I am also concerned that the analyst may equate apparent randomness with encryption, an inference that plainly exceeds the information supplied by external modulation observations. How should that mistaken conclusion be prevented in the final narrative?

Peter Elias, Response: Professor Ziv, the appropriate test treats the source distribution as an experimental factor rather than assuming it away. A known pseudo-random reference, an alternating sequence and a structured bursty sequence can be generated by the laboratory without any private information. Apply each to coded and uncoded transmission chains while controlling physical symbol rate, duty cycle, modulation and gross frequency response. If the feature follows source statistics even when the encoder is held fixed, it cannot be attributed uniquely to the encoder. If it changes with the encoder across several source distributions, it offers evidence of a coding-related exterior effect under the tested configurations. The resulting

Copyright 2026, James M. Atkinson

table should display the interaction between factors, because the encoder may change what source statistics remain physically visible. A single accuracy percentage averages over those interactions and can conceal failure in an important subgroup.

The classifier's outcome needs language commensurate with the experiment. It may distinguish a collection of declared laboratory signal-generation chains, with confidence intervals calculated from properly independent held-out trials. It does not prove that an unknown physical emission carries encrypted data merely because one entropy estimator reads high. Randomised test bits, lossless compression, scrambling, channel coding and receiver noise can all produce a similar statistical impression. Nor does a periodic transition establish the presence of a low-entropy plaintext: frame markers and pilot symbols can create order even when the associated source is arbitrary. A useful report therefore lists the observed envelope or spectral statistics, the known laboratory manipulations, the false-positive and false-negative behaviour, and the major untested alternatives. No private symbol string need be recovered. In fact, insisting on non-content test stimuli helps prevent the inference from silently migrating into a different legal and technical task.

The experiment also requires explicit handling of imperfect channel estimates. A receiver whose amplitude response varies across the band can change transition statistics differently for coded and uncoded examples, especially when those examples have unequal spectral occupancy. Report performance in strata of independently measured noise power, clock

Copyright 2026, James M. Atkinson

stability and gain. Hold out entire transmitter sessions, not merely random symbols from one continuous capture, because otherwise the test set shares the same drifting oscillator and thermal history as the training set. A successful classification should demonstrate transfer between declared physical conditions, not merely recognition of one synthetic source file.

Abraham Lempel, Peer Question: Professor Elias, an interleaver can rearrange the temporal order of known coded symbols without changing which mathematical codewords the encoder generates. Yet such rearrangement may substantially alter the apparent burst structure in an observation. What experiment would distinguish a feature arising from redundancy from one arising from the interleaver's memory, when both operate on the same public laboratory sequence? Would it be enough to vary interleaver depth with the encoder held constant, or must the observer also measure sample-clock slips, filter settling and pulse-shaping changes? I ask because a hidden dependence on receiver scheduling could produce a periodic signature that follows the interleaver settings only accidentally. Please address the distinction between two logically separate coding layers and the consequences of a test whose winning configuration was chosen after examining many possible alignments. The eventual defensive report should avoid making an algebraic claim from a spectrogram alone.

Peter Elias, Response: Mr. Lempel, a complete design should vary interleaver depth independently of encoder selection, with the known original input sequence and physical signal-generation parameters controlled. At one fixed encoder, test several interleaver configurations and a bypass condition; then repeat at another encoder without changing the interleaver settings. One can ask whether a proposed exterior waveform statistic

Copyright 2026, James M. Atkinson

follows the interleaver factor, the encoder factor or their interaction. The answer will depend on the mapping to physical modulation, and the test should not assume that a particular interleaver depth produces a visible periodicity at every signal-to-noise ratio. A public calibration marker at a known point in each frame can help measure the actual time mapping without inferring an unknown payload. Simultaneous reference-clock logging will distinguish a genuine transmitter timing change from data lost during receiver retuning.

The problem of searching many alignments needs explicit treatment. If the analyst tries a large set of interleaver depths, symbol offsets and filtering windows, the largest observed association is a selected statistic. Its significance must be calibrated by repeating the entire search on independent controls, not by applying a single-trial threshold to the winning candidate. Reserve a new laboratory recording from an independent instrument for confirmation, with the search strategy frozen beforehand. Even if the feature then generalises, it identifies at most compatibility with a tested class of transmission arrangements. Different implementations can share an interleaver or produce similar envelope statistics for unrelated reasons. The investigator should keep the result in a form such as: 'The observed timing feature is consistent with laboratory configuration X within stated limitations and is also produced by controls Y and Z.' There is no sound basis for claiming that a protected message has been reconstructed or that a unique physical source has been identified.

A further safeguard is to randomise the order of test conditions while

Copyright 2026, James M. Atkinson

recording the actual sequence for later audit. If all high-depth interleaver tests occur after the receiver has warmed, one may falsely associate a changing phase-noise floor with interleaver depth. Repeat every setting at separated times, compare against a continuously observed known pilot and preserve the empty or failed acquisitions. When the predicted exterior change is below the receiver's calibrated resolution, the correct outcome is that the proposed distinction is not testable with this instrument, rather than a forced negative or positive classification.

Peter Elias, Cross-Peer Question to Richard W. Hamming: Dr. Hamming, your elementary (7,4) example shows how often a short random binary segment can satisfy a parity relation by accident. A modern test may examine thousands of overlapping windows, candidate code lengths, puncturing schemes and receiver timing corrections. How would you prevent an analyst from reporting a spectacular likelihood after learning the preferred hypothesis from the same data? In particular, is it sufficient to cite the nominal one-eighth chance for your example, or must one calculate the null distribution of the largest score over the entire search and account for dependent windows? I would also ask whether a visually stable detector can be trusted when it silently discards low-amplitude frames, because the retained selection may be a biased subset of the physical emissions. The aim is not to improve message decoding but to establish whether a proposed observable coding feature survives an honest test against non-content alternatives.

Richard W. Hamming, Cross-Peer Answer to Peter Elias: Professor Elias, the one-eighth calculation is useful precisely because it refuses to let a mathematical match masquerade as a physical identification. It assumes a

Copyright 2026, James M. Atkinson

uniformly random seven-bit vector evaluated against one fixed full-rank parity-check matrix. Once the investigator explores many mappings, alignments and candidate matrices, the relevant false-alarm event becomes 'at least one candidate scores as strongly as the selected maximum'. If the windows overlap, the tests are dependent; an independence-based multiplication is not justified. One can preserve the physical properties of the null by replaying authorised synthetic waveforms through the receiver, applying the identical processing and candidate-selection programme, and recording the maximum score in each independent run. The observed maximum should then be compared with that empirical distribution. This procedure is more cumbersome than quoting one in eight, but its assumptions actually resemble the experiment.

Selection by receive quality creates another danger. A detection rule that keeps only high-amplitude or low-noise windows may preferentially retain patterns that resemble a simple code constraint. The analyst should maintain a ledger of all eligible physical observation intervals, including gaps, discarded blocks, gain changes and reasons for exclusion. A separate test carrier can establish when the receiver remained capable of detecting a reference signal. If the method fails on low-amplitude test cases, report its conditional coverage rather than concealing the failures. Once the hypothesis and processing settings are fixed, evaluate them on a new set of signals with varied but declared channel conditions. If several code families remain equally compatible, acknowledge that ambiguity instead of turning an incidental syndrome match into a finding about protected communication content or source identity.

Copyright 2026, James M. Atkinson

The choice of null signals matters as much as the count of simulations. If the controls omit periodic frame schedules, correlated noise and receiver overload, they will make the observed result appear rarer than it is under ordinary benign conditions. An adequate null family should include those known mechanisms and report the method's sensitivity to uncertain assumptions. Such calibration is necessary even if all computations on the selected short vector are algebraically correct. The selected maximum is a different inferential quantity from any one prespecified test and demands its own empirical calibration.

Dr. James M. Atkinson, Moderator: Dr. Hamming, would you examine error signatures and parity constraints, with particular attention to how a large search over candidate structures generates false matches?

Richard W. Hamming, Third Principal Contributor: Dr. Atkinson, an error-correcting code deliberately arranges symbols so that certain patterns satisfy mathematical constraints and corrupted patterns violate them. This is a principled source of redundancy. It is not a supernatural fingerprint. In the laboratory the simplest demonstration is a linear binary code with a parity-check matrix H. If an n-bit column vector c is a valid codeword, the syndrome Hc is the zero vector over GF(2). If a received laboratory vector r differs from c by error vector e, then Hr=H(c+e)=He. That calculation explains how carefully chosen redundancy permits error detection, but it is not a warrant to construct codewords from a protected transmission. For this volume, the proper use is to validate non-sensitive synthetic examples and understand the limits of an alleged observable pattern.

Copyright 2026, James M. Atkinson

Take the elementary binary Hamming (7,4) code. Four information bits are represented by seven coded bits, with three redundant bits and code rate 4/7. Under a full-rank 3-by-7 parity-check matrix, the set of valid codewords has 2^4=16 members among 2^7=128 possible seven-bit strings. A uniformly random seven-bit string therefore happens to satisfy the code constraints with probability 16/128=1/8. That is a substantial accidental match rate for a single short block. More elaborate codes and longer blocks can make chance matches rarer under particular random models, but the number of candidate lengths, phase alignments and mappings examined also grows. Reporting 'a successful parity match' without the search protocol and calibration is not meaningful evidence of a particular code family, much less an emitter identity.

The temptation to infer a hidden encoder from one small window should be resisted because environmental and receiver-generated structures can also pass such a test. Repeated framing bits, whitening circuits, periodic symbol clocks and systematic receiver clipping alter the statistical distribution away from independent uniform bits. Even the definition of a trial requires care: overlapping seven-symbol windows share six symbols and are strongly dependent. If many correlated windows are tested, the simple product of individual false-positive probabilities is invalid. The investigator should simulate the complete search with synthetic null signals whose spectrum, timing, framing and receiver impairment resemble the comparison scenario. A separate untouched hold-out set should then test the frozen method. If the observed feature is common across mutually unrelated test waveforms, it is not discriminating evidence.

Copyright 2026, James M. Atkinson

Noise further complicates the question. A weak waveform may contain uncertain symbol decisions, not binary values known with certainty. Mapping noisy constellation estimates to hard bits discards confidence information and can create deceptive syndrome behaviour near the decision boundary. The probability of a parity-check pass depends on error statistics, not merely on the nominal code. Burst errors and correlated fading yield patterns different from independent bit flips. A robust study should report the characteristics of the measurement chain, reference timing, signal-to-noise ratio and event exclusion rules. It should test whether a statistic is stable when receiver threshold, bandwidth or phase-estimation method changes. Where those controls are missing, the syndrome-like feature belongs in a list of tentative observations rather than a formal code attribution.

False positives in an extensive search are not a nicety. Suppose a laboratory algorithm tests one thousand genuinely independent random seven-bit blocks against the simple (7,4) validity condition. The expected number of accidental passes is 1,000/8=125, under the model just stated. It would be absurd to describe those 125 passes as evidence of 125 Hamming-coded transmitters. Real receiver analyses may use overlapping windows and candidate matrices, making the distribution more complicated, not less. As the experimenter expands the hypothesis space, the calibration of maximum score or family-wise error becomes essential. Preferably, the analyst should describe an externally observable feature and reserve the algebraic code test for authorised test vectors rather than hidden incoming material.

Copyright 2026, James M. Atkinson

Experimental fault injection offers an independent check. Use a public reference transmitter generating known coded words, and introduce controlled additive noise, isolated erased symbols and measured clock slips. Compare the expected physical envelope and timing features with what the receiver reports. If a sudden 'error signature' also appears on a constant unmodulated reference tone during an oscillator reset, the receiver is part of the cause. Record all samples and anomaly flags, including failed acquisitions, not merely those windows that supplied an attractive pattern. Blind the analyst to the encoder selection during the classification evaluation and retain the frozen rule and code hash for reproduction. This is how a mathematical insight becomes a trustworthy measurement protocol.

There is an important distinction between showing that a public known waveform contains a designed constraint and claiming that an unknown protected waveform does. The former is an ordinary experiment in coding and signal engineering. The latter may involve questions of communications content, privileged access and procedural authority that are outside this defensive receiver chapter. Even when separate authority exists, evidence of a code is not evidence of communicative purpose. The same parity-check family can appear in telemetry, storage and digital control systems. The investigator should emphasise the observable limitations of the measurement and the broad use of error-control methods across unrelated devices.

I would therefore report the instrument state, test sequence, mathematical model, known false-match behaviour, scanning and timing limitations, independent challenge tests and all alternative mechanisms. If a claim remains sensitive to one symbol mapping or a single chosen interval, it is

Copyright 2026, James M. Atkinson

not a sound finding. Good engineering requires the analyst to earn every additional inference, from energy to timing, from timing to code-class compatibility and from compatibility to any eventual physical attribution. A defender who keeps those categories apart is much less likely to convert ordinary receiver noise into an allegation about a particular communications system.

John Robinson Pierce, Peer Question: Dr. Hamming, the discussion has carefully distinguished code relations from an unknown waveform, but a practical receiver can create apparent digital irregularities through nonlinear compression, clipping, local-oscillator phase noise or a sampling-clock discontinuity. Is it possible for such an analogue impairment to generate a pattern that looks like a systematic error process, even when the public reference sequence is known to be uncoded? What control sequence and receiver reconfiguration would distinguish this from a real feature of the known error-control experiment? I would also question the tendency to describe every unexpected correlation as a 'syndrome' when the mathematical conditions for applying that term have not been established. Please explain how one should use a physical reference plane, a terminated input and an independently clocked receiver without assuming that their agreement automatically resolves the origin of the observed structure. The final claim ought to survive controlled changes of gain and filtering.

Richard W. Hamming, Response: Professor Pierce, an analogue receiving fault can indeed produce structured decision errors, and those errors may then be mistaken for properties of the transmitted code. Compression changes amplitude-dependent phase and may broaden a signal's spectrum. A phase-locked loop disturbance can produce abrupt common phase

Copyright 2026, James M. Atkinson

changes across several nominally separate channels. A finite buffer can omit samples and shift the apparent boundary of an observed burst. None of these effects is a property of an error-correcting code. The first control is a known uncoded public reference sequence, transmitted over the same bandwidth and observed with the same antenna and gain chain. If the suspicious statistic survives when the encoder is bypassed, it deserves an instrumentation explanation before any coding-family interpretation. Vary the receiver attenuation and preselector setting while recording the response of a separate known test tone, so that a change of displayed pattern is not merely a loss of sensitivity.

The term 'syndrome' has a precise algebraic meaning: it is a result of a specified parity-check operation on a vector over a declared field. A spectral line or envelope periodicity should not be given that name unless a legitimate mapping to the relevant algebraic variables has actually been established. In this defensive exercise there is no requirement to derive such a mapping from protected traffic. Instead the analyst can demonstrate the mathematical construction on self-generated sequences and compare external waveform observables under authorised conditions. Independently clocked measurements are valuable only when the receiving chains do not share the fault being tested; identical software running on two devices can still introduce common processing artefacts. The appropriate report includes a causal test for the front end and an uncertainty budget for the timebase, alongside a candid statement of which observed features remain consistent with more than one laboratory signal-generation chain.

Copyright 2026, James M. Atkinson

For the controlled receiver challenge, quantify the probability that the reference tone itself is misclassified during each impairment. If the apparently code-like statistic grows when input attenuation is removed, inspect compression before attributing the change to the transmitted symbol sequence. If it follows the sampling-clock reset, the record may have been time-warped. A laboratory acceptance protocol should specify the maximum permissible missing-sample rate and the calibration tolerance for timing before evaluating coding-family compatibility. A valid parity relation is a statement about defined mathematical symbols, and any physical measurement purporting to reveal those symbols must earn that mapping independently.

Richard W. Hamming, Cross-Peer Question to Claude E. Shannon: Professor Shannon, a candidate signal may exhibit a high estimated entropy in its received amplitude bins and little obvious periodic structure. Some analysts would conclude that the transmitter must be encrypted or using a sophisticated code. Yet source compression, scrambling, channel noise and the quantisation of an ordinary analyser can all change an entropy estimate. How can one use your capacity and entropy formalism to specify what the instrument actually measured without licensing an inference into private message content? I would also ask what controls would reveal that a classifier is learning the receiver's noise floor rather than the coded waveform, particularly when the only apparent improvement is a slightly higher accuracy on the same recordings used to choose its features. Your abstract theory seems most valuable if it keeps the claims modest and reproducible. Please distinguish the distribution of a prespecified statistic from the maximum of all statistics considered during exploratory searches.

Copyright 2026, James M. Atkinson

Claude E. Shannon, Cross-Peer Answer to Richard W. Hamming: Dr. Hamming, the entropy belongs to a specified random variable, and the analyst must name that variable before interpreting the number. If we bin envelope magnitudes, the resulting entropy concerns the distribution of those bins after detector and quantiser processing. It is not equal by assumption to the entropy of source bits or private messages. A noisy receiver may produce a distribution closer to uniform without any change to the transmitter. Conversely a clipping stage can collapse a broad analogue distribution into a narrow set of values. The proper experiment therefore measures the receiver with a terminated input, a known constant test tone and several controlled public modulation sequences at stated signal-to-noise ratios. Each statistic must be tested for sensitivity to bin size, observation duration, filtering and gain. A result that follows the receiver's settings rather than the known source is not a secure classification feature.

My channel-capacity formula similarly establishes a relationship within a declared physical model; it does not decode an observed transmission. The signal-to-noise power ratio and bandwidth are measurements with uncertainty, and a capacity upper bound cannot identify a code family. For classification, reserve independent recordings from a second source or receiving chain and select features only on training data. Report confidence intervals, false-alarm behaviour and the candidate families not included. A modest improvement on the same training corpus is not confirmation. It may reflect overfitting, data leakage or a variable associated with a laboratory fixture. An investigator who keeps the source, encoding, modulation, channel and receiver as distinct stages can explain how entropy

Copyright 2026, James M. Atkinson

and redundancy illuminate a defensive measurement while refusing to treat those statistics as assertions about protected content or particular people.

To keep the result within the legal and evidential boundary, the case report must identify whether the measured variable is an envelope bin, a spectrogram statistic or a known laboratory code symbol. Those quantities are not interchangeable. The analyst should be able to reproduce the declared feature from the retained authorised observations without displaying or reconstructing protected communications content. That is a practical test of whether the claim respects its own measurement definition.

Dr. James M. Atkinson, Moderator: Professor Shannon, can information theory clarify what externally observable redundancy can and cannot establish about the contents or purposes of a transmission?

Claude E. Shannon, Fourth Principal Contributor: Dr. Atkinson, the central question is not whether a waveform looks orderly or chaotic; it is what random variable is being measured and which transformations separate it from the information source. A physical modulation may have a high apparent entropy because of source compression, intentional scrambling, encryption, channel coding or simply a rich source distribution. Conversely a strong periodic feature may arise from framing or clock synchronisation while the payload itself remains arbitrary. Neither observation alone determines message content. Information theory treats a message alphabet and its statistics abstractly, and it can explain the efficiency or redundancy of a channel representation without requiring an investigator to read a protected communication. The scientific inference must remain at the level permitted by the actual recorded observations.

Copyright 2026, James M. Atkinson

For a discrete random variable X taking values x in alphabet A with probabilities p(x), Shannon entropy is $H(X)=-\Sigma\, p(x)\log_2 p(x)$ bits per symbol. That is a model of uncertainty for a specified variable, not a mystical detector for encryption. If the analyst calculates entropy on a sequence of received amplitude bins, the result describes those bins under the estimator and preprocessing choices. It does not automatically give the entropy of the source bits, coded symbols or human-language messages. Noise can raise an estimated entropy; clipping and coarse quantisation can lower it. Sample size, dependence and nonstationarity create additional bias. Thus high entropy is compatible with many benign physical and processing causes, and low entropy may measure the periodicity of a receiver rather than the coding of a transmitter.

Coding deliberately introduces redundancy relative to the selected source representation so that a receiver may withstand channel noise. The relevant rate must be compared with channel capacity under specified assumptions. For the ideal additive white Gaussian-noise model, $C=B\log_2(1+S/N)$ bits per second, where B is available noise-equivalent bandwidth in hertz, S the average received signal power and N the noise power integrated over B. That formula is not a direct measurement of the coding family used by an unknown emission. It describes a theoretical model under Gaussian noise, consistent bandwidth and suitable power definitions. Real receivers have interference, fading, nonlinear front ends and protocol overheads, and their actual achievable rates may be considerably lower. A claimed code inferred from one displayed spectral line would ignore those physical qualifications.

A useful hypothetical case is a 100 kHz ideal channel with S/N=10 in linear power ratio, not 10 dB added algebraically to a logarithm. The capacity

Copyright 2026, James M. Atkinson

expression gives C≈100,000 log2(11)≈345,943 bits per second. That figure says nothing about whether a particular emitter uses Reed–Solomon coding, convolutional coding or an uncoded modulation format. An error-control code might expend additional channel symbols to improve reliability, while a scrambler changes visible sequence regularity without being an error-correcting code at all. Even strong evidence that a channel carries redundancy does not reveal a payload, because the coding is intended to be applicable to many possible messages. A defender can use this abstract result to plan signal-quality controls while explicitly declining to infer protected content.

The notion of mutual information is more apt to experimental comparison than a visual assertion of similarity. Let F be a feature extracted from authorised laboratory I/Q observations, and let C_label denote the known experimental encoder configuration. The mutual information I(F;C_label) quantifies, in a chosen probabilistic model, how much the feature distribution informs the known configuration label. A positive estimated value does not establish performance on an unobserved receiving environment unless data collection and estimation were independent. It may arise from confounding variables such as different output powers or symbol rates between the laboratory configurations. Randomise encoding settings, hold the physical transmission conditions constant and evaluate on held-out instruments. The relevant outcome is demonstrated discriminative performance with an uncertainty interval, not a seductive information-theoretic number divorced from the experiment.

There is also the problem of selecting a model because it happened to fit the observed waveform. If an investigator searches over countless periodicity,

Copyright 2026, James M. Atkinson

entropy and correlation statistics and reports only the maximum, the sampling distribution of that maximum differs from the sampling distribution of any one prespecified statistic. Calibration should repeat the full selection process on controls, including preprocessing and candidate generation. One must not compare a selected maximum against the nominal threshold for a single ordinary trial. Otherwise, the mere abundance of spectral bins and temporal windows can generate an apparently strong association from benign material. An honest report states the number and nature of examined hypotheses, the calibration population and the remaining dependence between tests.

Information theory is often praised for abstraction. That same abstraction should teach humility in attribution. A statistical relationship can show that two observable processes share information under a defined model; it does not show they belong to a particular person, equipment model or illicit purpose. A signal with coding-family-compatible features might be a public telemetry transmission, a licensed control link, a local test generator, or an internally produced receiver artefact. Localisation, source-path challenges, authorisation and chain of custody remain separate tasks. The expert should always identify the precise proposition that an equation supports and resist carrying a conclusion beyond its declared variables. In this way the most powerful mathematical results become safeguards against interpretative overreach.

For the defensive survey I would recommend preserving only those features strictly needed for the specified engineering question: frequency band, timing stability, authorised calibration markers, phase-noise controls, receiver state and non-content envelope or spectral properties. When

Copyright 2026, James M. Atkinson

meaningful comparison can be achieved using public synthetic waveforms, use them. Do not record, display or reconstruct protected messages merely to improve a classification statistic. These boundaries do not diminish the quality of the science; they require a cleaner experiment in which the target is clearly defined, the data provenance is visible and the resulting claim remains technically and legally proportionate.

Alan Mathison Turing, Peer Question: Professor Shannon, your information-theoretic account seems to require clearly defined random variables and observable channels, but a practical defender may find only a short burst captured with uncertain timing and incomplete calibration. A mathematically elegant model could then fit a few apparent symbols simply because it has more adjustable parameters than there are independent observations. How should an analyst make a hypothesis falsifiable without extracting private communications content? Would a predeclared synthetic benchmark and a held-out physical test be more decisive than adding further candidate code families to the same small record? I am also interested in the difference between explaining a signal's observed spectrum and claiming that the transmitter implemented a particular algorithm. One is a description of an electrical phenomenon; the other is a reconstruction of unobserved internal machinery. Please specify the evidential transition that might justify the latter in a controlled laboratory and why the same transition cannot be presumed for an unknown protected emission.

Claude E. Shannon, Response: Mr. Turing, when a model has more freedom than the observations can constrain, a good fit is often inexpensive and uninformative. Define the measurable target before designing the statistic:

Copyright 2026, James M. Atkinson

burst duration, spectral shape, timing regularity or another feature obtainable without reading content. Then select a finite family of candidate explanations, including receiver artefacts, framed uncoded test signals and multiple distinct known encoding configurations. The model should produce predictions for new conditions. A synthetic training set may be used to specify the detector, but its thresholds and candidate ordering must then remain frozen for an independent laboratory challenge. A method that correctly predicts the outcome of a change in filter bandwidth or modulator settings has stronger empirical standing than one which merely fits the original spectrogram. Even so, it is a bounded result on the tested signal-generation chains.

The distinction between a waveform description and an internal-algorithm claim is categorical. A measured spectral peak and a timed burst are directly linked to calibrated observations. An assertion that a particular encoder generated that burst requires additional assumptions about symbol synchronisation, bit mapping and alternative processing chains. In an authorised laboratory the asserted encoder is known independently from source configuration and can be varied under blinded conditions, thereby testing whether a chosen exterior feature follows it. For an unknown protected emission that control is absent. The investigator may report compatibility with a family of laboratory signals and the limitations of that comparison, but must not pretend that a matching entropy or periodicity statistic is equivalent to inspecting the internal algorithm. Better experimental design narrows the uncertainty of the allowed claim without expanding the legal scope of the observation.

Copyright 2026, James M. Atkinson

One additional concern is parameter economy. A candidate model that uses many freely chosen frequency offsets, symbol phases and unknown frame boundaries can always be made more flexible than a simple alternative. Report the predictive performance on measurements acquired after the model is fixed, not only the best fit on the discovery record. The competing explanations should include noncoding causes, such as deterministic receiver sampling patterns and calibration-source periodicity, not merely several related encoders. A model's failure to transfer to a different laboratory is a material limitation even when its fit to the original signal is exceptionally attractive.

Claude E. Shannon, Cross-Peer Question to David Slepian: Professor Slepian, you have proposed comparing several receiving channels to distinguish shared code-related features from a faulty measurement chain. But evidence from two channels is often treated as two independent confirmations even when they share antennas, oscillators, processing software or common interference. How would you construct a joint statistical model that respects those dependencies while remaining bounded to non-content observations? In particular, what happens to the uncertainty of a classification statistic when the same reference-clock phase disturbance appears in each channel? Could one wrongly infer that many receivers jointly support a coding-family hypothesis merely because their errors move together? Please also address the converse case: two truly distinct antenna paths can give different spectra for the same known encoded laboratory waveform because propagation and gain are not

Copyright 2026, James M. Atkinson

equivalent. How should the experiment prevent those differences from being mislabelled as differences between codes?

David Slepian, Cross-Peer Answer to Claude E. Shannon: Professor Shannon, the governing principle is that the joint model must represent the actual receiving installation, not the fiction of independent measurements. Let F1 and F2 denote permitted non-content features from two channels, with shared receiver disturbance C and individual disturbances E1 and E2. An illustrative decomposition is F1=G1(X)+C+E1 and F2=G2(X)+C+E2, where G1 and G2 describe their respective channel responses to the known public waveform X. In the simplest equal-scale model, covariance of the two errors includes the variance of C. Adding two scores as though the errors were independent can then exaggerate evidence. The analyst should measure the cross-covariance under controlled no-signal and known-signal conditions, challenge shared clock and power paths and use a joint calibration distribution for the final decision statistic.

Differences between channels need not indicate different encoders. Frequency-selective fading, antenna polarisation, filter group delay and receiver compression alter physical observations of the same waveform. Before testing encoder hypotheses, calibrate each channel's gain and timing response with a public known waveform. Exchange receivers or references between antennas to see which anomalies follow the apparatus, and separately measure the external field when feasible. A coding-family feature should be evaluated across these changes with a held-out test source and an honest false-match rate. If the channels remain strongly dependent, report one coherent observation system with correlated evidence rather

Copyright 2026, James M. Atkinson

than claiming two independent witnesses. If the channels disagree after calibration, consider propagation and instrument alternatives before blaming the code. No element of this joint analysis requires deriving private message bits or identifying an individual transmitter.

Where one clock disturbance contributes to both receivers, the effective number of independent witnesses may be near one for that particular timing error. Other features, such as independent antenna noise, may still provide additional information. The covariance model must therefore be feature-specific rather than assigning a single independence label to the entire apparatus. Record the result of safely disconnecting or substituting the common reference when testing the proposed dependency; do not infer independence merely from separate chassis. The residual uncertainty must be separately reported for common timing disturbances and antenna-specific reception effects, rather than combined into an unsupported universal accuracy claim.

Dr. James M. Atkinson, Moderator: Professor Slepian, how would you address correlated measurements from multiple receiving channels, and what evidence is lost when the channel structure is mistaken for the coding structure?

David Slepian, Fifth Principal Contributor: Dr. Atkinson, the separation of source, code and observation is often easiest to lose when several receiving channels are available. Two antennas may observe a common waveform through different propagation paths. Two digitising channels may share a sampling oscillator, mixer reference or error-prone data transport. If the resulting traces agree, the agreement could reflect a shared environmental

Copyright 2026, James M. Atkinson

emission, a common local reference defect, or a deliberately applied signal transformation. The analyst must establish the measurement-chain dependence before treating correlation among channels as independent confirmation of any coding-family hypothesis. A second waterfall driven by the same ADC clock does not provide an independently timed witness simply because the software labels it as another channel.

Let Y1 and Y2 represent two observations of a controlled public signal X through different channels. A stylised model is Y1=h1(X)+N1 and Y2=h2(X)+N2, where h1 and h2 are the channel transformations and N1 and N2 noise terms. The noise can be independent, correlated, signal-dependent or even dominated by shared equipment. A time-shifted peak in cross-correlation can be due to propagation delay, an intentional frame structure or an uncalibrated filter. To infer something about coding, one needs an experiment in which the known encoder varies while each channel's transfer response is separately measured. Otherwise a classifier may learn a characteristic of h1 or h2 and mislabel it as a code signature. This matters especially when one receiver has a narrower filter or different gain distribution.

A reliable laboratory comparison would first characterise every channel with a known broadband calibration sequence and a simple constant-reference tone. Such stimuli are chosen by the investigator and contain no protected information. The operator can estimate frequency-dependent amplitude response, phase delay, noise covariance and missing-sample behaviour. Next the known encoder is changed while the same physical paths, clocks and transmit power remain fixed. Finally the receiver channels are exchanged or one is given a genuinely independent timebase. If a proposed

Copyright 2026, James M. Atkinson

coding feature tracks the encoder under these interventions and survives channel substitution within its uncertainty bounds, the limited coding-family compatibility hypothesis becomes stronger. If it follows a cable, amplifier or clock port, the evidence points to the receiving installation.

The presence of shared side information illustrates why information observations are not always independently additive. If two noisy versions of one public test waveform are recorded, their joint description can be more economical than describing them separately, depending on their dependence. This mathematical insight should not be misread as a licence to combine two protected messages. Here it helps design a measurement audit. If each receiver's apparent 'coding signature' arises from the same shared error, adding their likelihood scores as if independent can exaggerate evidential weight. When likelihoods are combined, the joint null distribution must include common clocks, correlated interference, environmental drift and the actual selection rule. A false sense of confidence may otherwise grow as additional identically compromised channels are attached.

The communication channel can also obscure a genuine laboratory code signature. Frequency-selective fading and intersymbol interference change the distribution of received transition intervals, and a nonlinear front end may create products that resemble intentional periodic structure. An analyst who ignores channel equalisation may conclude that a known code is absent when the receiver simply cannot preserve the selected observable. Conversely a processing algorithm that estimates channel coefficients from the same record and optimises the best-fitting code hypothesis risks data reuse. The proper experimental design freezes the model on a calibration

Copyright 2026, James M. Atkinson

population and tests the result on a separate challenge population, preferably from an independent measuring apparatus. Report failure rates across the range of channel states, not only a favourable nominal case.

To separate observables from payload recovery, the exercise should classify only declared characteristics of controlled public waveforms. For example, one may ask whether a gross frame interval persists across two receiver channels or whether a pulse-width distribution changes after a known calibration filter is inserted. These questions do not require examining a private bit stream. A posterior distribution over candidate laboratory encoders, if calculated, is conditional on the candidate set and prior model; it is not a probability that a particular unknown emitter has been identified. In a defensible technical report the candidate space, the omitted alternatives, the sensor limitations and the lawful scope must be recorded with equal prominence.

The strongest evidence for a physical source still comes from an independent causal test of the receiving chain: separate antenna paths, known calibration signals, controlled relocation, and reproducible changes in the external field rather than in software processing. The code hypothesis may guide which benign synthetic control waveforms to inject, but the eventual claim about the monitored environment must rely on observations collected with authority and measured uncertainty. When the feature remains ambiguous among several coding families or channel artefacts, the correct conclusion is ambiguity. A knowledgeable observer should regard that as an outcome of the experiment, not as a failure of professional confidence.

Copyright 2026, James M. Atkinson

The panel's shared obligation is to preserve identifiability. A mathematical code relation may be strong while the mapping from those code symbols to external radio-frequency observations is weak. Two competing transmission chains may therefore be observationally equivalent at the chosen resolution. The experimenter must either devise a lawful intervention capable of distinguishing them, or limit the conclusion to a broader class. That is the practical significance of information theory and error-control coding for a defensive survey: it supplies controlled ways to challenge an inference without requiring the examiner to expose or exploit anyone's private communication content.

John von Neumann, Peer Question: Professor Slepian, the research team may implement all of these comparisons in software, with a database that stores raw I/Q, calibration metadata and the many candidate statistics computed during exploration. As additional experiments accumulate, the temptation is to overwrite raw timestamps with improved estimates and discard negative or inconvenient classifier runs. What minimum software architecture and evidential ledger would make the coding-family compatibility claim independently reproducible without storing protected message content? Can the same design also reveal when data loss or receiver resampling has changed the feature distribution, especially where the acquisition hardware and the host operating system use different clocks? I would also ask how the system should handle model updates: a new algorithm may fit old recordings better, yet that does not turn an exploratory result into a successful preregistered test. An explicit separation between immutable observations and versioned derived analysis seems necessary to prevent the manuscript from concealing its own errors.

Copyright 2026, James M. Atkinson

David Slepian, Response: Professor von Neumann, the principal design rule is to preserve immutable source observations and to treat each subsequent numerical result as a derived object with an explicit lineage. A capture ledger should identify the authorised test transmitter, experimental code configuration, signal-path reference planes, receiver model and firmware, calibration status, hardware counter sequence, host timing conversion, data gaps and error events. For each processed result, retain the input file hashes, algorithm version, parameter file, permitted feature definitions, candidate-model list and the precise trial exclusions. The system may store envelope and spectral features without retaining any unknown protected payload content; if other communications were inadvertently present, segregate them under the governing legal and retention rules rather than analyse them for this exercise. A successful software run does not establish a valid physical measurement if the sampling chronology has a gap.

An improved analysis should be saved as a new derivative, not a replacement for the original timestamp or the older report. Distinguish exploratory development from confirmatory evaluation in the record. If a classifier was revised after examining the test result, it requires a fresh withheld test set before its reported accuracy can count as confirmation. Device counters, queue occupancy and overflow indicators allow a later reviewer to distinguish delayed delivery from physically missing samples. A verified clock-mapping transformation should be recorded rather than silently inserted into the raw data. Finally, publish the full distribution of validation results across code configurations, receiving channels and noise levels, including failures. This disclosure helps the reader determine

Copyright 2026, James M. Atkinson

whether the observed feature is stable, whether the method was tuned opportunistically and what the scientific evidence actually supports. Nothing here requires or authorises recovery of protected message content.

The integrity ledger must also distinguish a software-generated gap marker from a hardware-confirmed loss. A receiver may deliver all acquired samples late, while another may silently discard samples before assigning packet numbers. Those conditions have different consequences for symbol timing and any alleged coding feature. Require the acquisition system to record device-side and host-side counters separately, and include controlled overload tests in the qualification evidence. When the hardware exposes no trustworthy continuity marker, describe the resulting waveform statistics as conditional on an unverified acquisition assumption. That limitation should accompany every subsequent classification derived from the record.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has separated directly measurable waveform properties from proposed coding structures, from protected data recovery and from physical-source attribution. A block-code parity relation or convolutional-code memory can be demonstrated upon authorised synthetic sequences, yet an unknown transmitter cannot be identified from such algebra or from a spectral rhythm alone. All classifications require calibration of symbol timing, receiver linearity, sampling continuity, model search and correlated errors. The panel has examined direct peer objections and reciprocal challenges among the five principal contributors. Structural completion does not, however, confer scholarly or publication approval; independent source-to-claim, mathematical and historical verification remain required.

QUESTION 082

Copyright 2026, James M. Atkinson

When Does Payload Compression Defeat Entropy-Based Sender Attribution?

SCHOLARLY RECONSTRUCTION. This is a fictional instructional exchange among historically real, deceased scientists. It is neither a transcript nor a quotation from any participant. Contemporary receiver tests, synthetic bit streams and numerical examples are editorial hypotheticals, not records of interception or field measurements.

Dr. James M. Atkinson, Moderator: Professor Ziv, an authorised RF investigation may encounter a waveform whose measured symbol transitions appear statistically irregular, and an analyst may describe that appearance as the fingerprint of a particular communications device. Yet lossless compression, encryption, interleaving, symbol mapping and receiver errors can all produce superficially similar observations. Would you establish what your work on universal compression permits us to infer from a compressed sequence, where statistical identifiability fails, and why a compression-related feature cannot safely be promoted into the identity of a sender?

Jacob Ziv, Principal Contributor: Dr. Atkinson, the central error is to convert a statement about representation into a statement about agency. A compressor transforms one finite sequence into another under a specified reversible rule. A receiver subsequently measures a noisy electrical waveform after that transformed sequence has been framed, coded, mapped to symbols and filtered through a physical channel. Consequently, the visible absence of repeated strings does not establish which transform occurred, much less which person or instrument caused it. Compression

Copyright 2026, James M. Atkinson

addresses the description length of a source in a particular coding framework; sender attribution requires an independent association between a measurable property and a genuinely distinct, reproducible physical source. The inferential bridge between these subjects is not supplied by the adjective 'random'.

Consider a finite sequence X_1 through X_n drawn from an alphabet A, where n is the source length and $|A|$ its alphabet size. A lossless encoder C maps the sequence to a finite code representation $C(X_1^n)$. Its realised compression ratio may be written $r=|C(X_1^n)|/|X_1^n|$, provided numerator and denominator are expressed in the same units and the comparison includes a precisely declared convention for framing, dictionaries and termination. A ratio less than one means a saving for that file under that convention. It does not measure a universal entropy of the source by itself. Header overhead can make short files longer; the same source process may compress differently under different dictionaries or block sizes; and a particular incompressible file does not demonstrate encryption. The modern observer must separate sequence length from the physical bandwidth or elapsed transmission time needed to carry it.

Our 1977 work with Abraham Lempel concerned a universal algorithm for sequential compression. Its merit arose from exploiting repeated substrings without requiring the encoder to begin with a complete probabilistic model of the source. But the universality claim is an asymptotic performance result within a stated source model, not a promise that arbitrary short captures will expose an encoder's internal history. Indeed, a short fragment may contain an isolated codeword from a stream whose earlier dictionary is unavailable. The observer cannot recover a unique prior parsing state

Copyright 2026, James M. Atkinson

simply from that fragment. Different input sequences, encoder implementations or reset schedules can yield similar local proportions of zeros and ones. Other transformations after compression may erase the distinctions that mattered within the compressor.

The familiar binary plug-in entropy estimate H_hat= -p_hat log2(p_hat) -(1-p_hat)log2(1-p_hat) bits per observed binary symbol is a useful descriptive statistic, with the usual interpretation 0 log2 0 =0. Here p_hat is the fraction of ones in an explicitly defined binary observation alphabet. It measures marginal balance, not temporal independence or compressor identity. A deterministic alternating sequence has p_hat=0.5 and H_hat=1 bit, even though its next bit is perfectly predictable given the previous bit. Conversely a useful source with a strongly unequal symbol distribution can have low marginal entropy while having no readily discernible sender-specific feature. A responsible analyst examines dependence across lags and conditions, not only a histogram.

A more discriminating experiment uses synthetic laboratory sources for which the uncompressed records are owned and retained. Generate repeated text-like tokens, a memoryless binary source, and a correlated Markov source, then pass each through several publicly specified lossless compressors with fixed initial states. Hold the RF symbol rate, forward-error-control code, carrier power and propagation arrangement constant. Apply independently documented symbol mappings and capture with two receivers of differing architectures. Compare only lawful, non-content features such as occupied bandwidth, burst duration, frame periodicity, marker timing, decoder-independent spectral envelopes and bit-like test sequences available from the laboratory generator. Alter compression

Copyright 2026, James M. Atkinson

independently of the physical transmitter so a classifier that follows the compressor rather than the hardware is revealed as a transform classifier, not a sender classifier.

A negative result should also be informative. Suppose two programmes compress the same source and then each uses distinct framing. If the purported fingerprint changes with framing while the compressor is fixed, it cannot be attributed uniquely to the compressor. Suppose the same programme runs on different instruments and produces the same synthetic output. Matching irregularity tells us about the common computation, not which chassis emitted it. If a difference survives only when the receiver's automatic gain control is active, we must challenge the measurement path. In each case the causal object under test is the feature-generating mechanism, not an unobserved owner.

Machine-learning classification intensifies rather than abolishes these concerns. A model trained on overlapping fragments of the same recording can memorise recording conditions and appear accurate even when unable to classify an independently acquired source. Randomly partitioning adjacent windows across training and testing leaks temporal dependence; instead split by complete recording session, source generator and receiver setup, and reserve data that were not used to select features or thresholds. Evaluate confusion matrices across both benign source variability and deliberate transform changes. A high test accuracy under one narrow source collection is a conditional result, not a universal claim about all future transmitters.

I therefore distinguish three propositions. First, a given measured sequence exhibits specified statistical patterns under a declared observation model.

Copyright 2026, James M. Atkinson

Secondly, controlled examples demonstrate that particular encoder, framing or coding configurations can produce comparable patterns. Thirdly, a particular external sender produced the measured signal. The first may be an observation, the second a bounded model comparison, and the third is an attribution requiring separate, independently validated evidence. Compression can remove the redundancy that once differentiated source files, but it cannot manufacture the physical provenance that entropy alone never measured. A formal defensive report should state that distinction even where the compressed trace looks deceptively unique.

Irving S. Reed, Peer Question: Professor Ziv, redundancy can arise from the information source, from framing, and from channel coding introduced after compression. An investigator might notice repeated blocks or parity-like relationships and assert that the compressor failed to remove structure, when in reality an error-control encoder or periodic synchronisation marker created those repetitions downstream. How should a laboratory differentiate these layers without attempting to read the protected payload? Would you specify what must remain constant when an investigator changes the compressor, the framing convention, and the forward-error-control code in turn? I am particularly concerned about the selection of a convenient test length after examining the data, since an observed periodicity may be a coincidence of two framing intervals rather than a distinguishing property of any compressor. What counterexample should be included before this kind of claim is made to a court or a technical reviewer? Please identify how many negative configurations are needed to distinguish a framing-origin repetition from a coincident spectral marker, and how that number should be decided before the trial begins.

Copyright 2026, James M. Atkinson

Jacob Ziv, Response: Professor Reed, a useful design treats source, compressor, frame builder and channel encoder as distinct interventions, each controlled at a declared electrical reference plane. Begin with known generated source sequences and record their full lengths, seeds, alphabet definitions and pre-existing dependence. Encode those same sequences with a declared compressor while leaving framing and the RF chain unchanged; then hold the compressor constant and change only the framing. Finally change the channel code while retaining the earlier values. The observer can compare external waveform summaries without examining unauthorised payloads because every experimental payload is supplied by the laboratory itself. All changes and resets should be logged, and the raw acquisition retained.

The appropriate counterexample is easy to construct. Imagine a compressor producing a well-balanced binary stream, but the frame builder inserts a fixed marker every 1,024 transmitted bits. A periodogram of a corresponding permitted test sequence may exhibit a periodic contribution at the marker cadence. If the marker is deleted while the compressor remains identical, the spectral contribution disappears. The correct inference is that the framing decision produced the feature. Similarly, a linear error-control code may introduce parity constraints whose manifestations depend upon mapping and interleaving. Repeated structures do not necessarily survive pulse shaping or realistic channel errors; their visibility is a receiver-dependent matter as well.

Trial length should be chosen in advance because searching over many

Copyright 2026, James M. Atkinson

candidate periods increases the probability of finding an apparently impressive accidental match. Define the period grid, window sizes and scoring rule from an independent engineering rationale, and estimate the family-wise false-alarm behaviour using known negatives. Preserve all failed candidate periods rather than showing only the most favourable one. If two independent source processes with different compressors produce the same reported signature under common framing, the claimed signature is not uniquely identifying. The report may still describe a framing-compatible hypothesis, but that is a different proposition from sender attribution.

The physical chain also needs independent challenges. Vary antenna or receiver, monitor the reference clock, and inject known non-content test tones to exclude a spur or gain-control artefact. Reproduce the finding on a second instrument with different frequency conversion. Document uncertainty associated with timing and observed power. The best experiment seeks to refute an attractive origin story by constructing a different process that yields the same observation. Success in that test does not erase the feature; it changes the degree of specificity the feature can support.

Ronald Newbold Bracewell, Peer Question: Professor Ziv, a blind classifier may be fed short windows selected because they contain an unusually clear spectral or timing feature. Yet the process of selection changes the sample population, and the receiver's own filter may create a degree of regularity not present at the antenna. Can you explain how to evaluate an information-theoretic feature when the first and last samples of a burst are censored by a detection threshold? I would also ask how one can tell whether apparently

Copyright 2026, James M. Atkinson

distinct training and test records are independent when they arise from adjacent windows of the same RF event. A system may report excellent discrimination at a particular receiver gain setting, yet the advertised distinction might vanish under another front end. Which negative controls are indispensable before the evidence is used beyond engineering diagnosis? Would a receiver with a different channeliser but the same upstream antenna count as independent corroboration, or must the investigator also examine reference distribution and common-mode cabling to establish real independence?

Jacob Ziv, Response: Professor Bracewell, the acquisition selection rule belongs in the statistical model. If the recorder begins only after a threshold crossing, the captured sequence is conditional upon an event that has already met a selection criterion; it is not an unconditional sample of the transmitted process. A short retained block can be biased towards higher-amplitude portions of a burst and towards particular phases of a pulse-shaping filter. In that setting a claim about source entropy drawn from the retained samples is not merely imprecise; it refers to the wrong population. The calibration must reproduce the trigger, pretrigger buffer, filter settings and any missing edge samples.

An independent laboratory stimulus can disclose this bias without analysing a protected message. Present a known synthetic waveform, first in full continuous acquisition and then through the normal event-triggered process. Calculate the exact same feature on each version, with all windows and preprocessing declared. Move the threshold through a documented range while keeping the waveform fixed. The resulting feature sensitivity is

Copyright 2026, James M. Atkinson

an instrument characteristic, not evidence that the source changed. If a classifier responds primarily to threshold, filter or gain changes, separate that dependence in the report.

For genuine out-of-sample testing, reserve whole acquisition sessions, transmitters and clock configurations. Two overlapping slices of one event share the same noise realisation, fading channel and transient filter response; placing one in training and one in testing is a form of data leakage. The correct hierarchical partition may be by source, location, day and receiver configuration, depending upon what sort of generalisation is claimed. A model intended to distinguish encoder families requires held-out encoder configurations or carefully described restrictions; a model intended to distinguish devices requires independent devices and repeated acquisitions under controlled transformations.

Include null examples with fixed transmitter hardware but altered compression; examples with fixed compressed input but changed transmitter chain; and measurements through a terminated or known injected input to identify internally generated features. Evaluate detection failures as well as selected positive events. Report confusion rates with uncertainty intervals and retain the test-set membership and selection protocol. If the result deteriorates under a benign front-end substitution, it is unjustified to treat the original result as a stable external fingerprint. An attractive plot is not a substitute for controlled identifiability.

Jacob Ziv, Cross-Peer Question to Abraham Lempel: Professor Lempel, our universal compression work deals with transformations that exploit source

Copyright 2026, James M. Atkinson

constraints, but practical implementation requires finite buffers, dictionary resets, framing decisions and a rule for representing phrase references. An analyst who sees a locally irregular sequence may assume that all encoders of the same broad family behave identically. Would you explain how implementation state can produce apparent markers that are not source properties, and why a compressor reset at a burst boundary can imitate a device-specific scheduling signature? I ask especially whether the same external waveform feature might be reproduced by unrelated hardware that happens to share a software library, or by one transmitter using two different compression parameter sets. What falsification experiment should be required before the feature is described as belonging to one physical sender? Include how the laboratory can prevent the changing dictionary from becoming perfectly correlated with elapsed equipment warm-up time, which might otherwise create a false physical-origin signature.

Abraham Lempel, Cross-Peer Answer to Jacob Ziv: Professor Ziv, an implementation is a procedure with state, not a mathematical label floating free of machinery. A phrase dictionary may be initialised at the start of a file, may persist across blocks, or may be reset by a protocol boundary; the chosen convention affects local output length and the position of some state-dependent transitions. A dictionary can evolve differently for two inputs that have the same simple symbol histogram. That does not contradict the theory of universal compression. It reminds us that an asymptotic performance statement cannot determine the local coding record of an undisclosed finite state machine.

Consider two authorised synthetic streams formed from the same sequence

Copyright 2026, James M. Atkinson

repeated many times. Compressor A resets after every block and Compressor B retains its dictionary across blocks. Their output sizes and local phrase-reference structure can differ despite identical source content and identical RF hardware. An observer recording only burst lengths may see a reset-related length pattern and mistakenly attribute it to a transmitter's clock. If A and B are exchanged between two physical RF generators, the pattern may follow the software, not the chassis. If the receiver independently resamples the bursts, even that apparent correspondence may change with the observation method.

A proper challenge therefore varies implementation and hardware as orthogonal factors. Operate the same compressor binaries on multiple machines, and multiple compressors on one calibrated transmitter chain. Control all symbol clocks, carrier levels, pulse shapes and frame intervals. Record whether the proposed feature follows compression parameters, burst segmentation, receiver scheduling or actual hardware. Repeat after the dictionary is deliberately reset and after it is allowed to persist. Where the feature appears only under one segmentation rule, describe a segmentation-conditioned result, not a universal source fingerprint.

The inquiry must also distinguish what is externally observable from an internal code phrase. Without explicit authority to access a payload, the researcher should not claim to have reconstructed private dictionary states. A legal and reproducible demonstration can use synthetic known sequences and compare non-content spectral, duration and event-time features. A surviving association may support a restricted engineering diagnostic.

Copyright 2026, James M. Atkinson

Sender identity would still require independent physical or documentary corroboration. The essential safeguard is to design the experiment so that a shared implementation on different hardware constitutes a genuine competitor to the claimed inference.

Dr. James M. Atkinson, Moderator: Professor Lempel, the opening exchange has separated an encoder family from its finite implementation. Would you now examine the controls needed to determine whether an apparent output-length or statistical pattern was caused by the compressor, the source selection, or the equipment that carried the resulting symbols? Please make the experimental design capable of contradicting an incorrect attribution, rather than simply illustrating the proposal that inspired it.

Abraham Lempel, Second Principal Contributor: Dr. Atkinson, a well-designed study begins by specifying the quantities that are actually manipulated and observed. The treatment may be the presence or absence of lossless compression, the choice between two known algorithms, or an explicit dictionary-reset policy. The response cannot simply be labelled 'entropy' without an observation alphabet, a finite-sample estimator and a measurement reference plane. A spectrum analyser measures electrical energy in specified time-frequency bins. It does not directly measure the informational entropy of a private file. An event-timing recorder measures onset and duration under a declared trigger. It does not directly discover an encoder's phrase table. The permitted scientific task is to determine whether changes in a known data-processing condition cause reproducible changes in those measured external features.

To separate competing causes, use a balanced, randomised factorial design. Let S identify the synthetic source family, C the compression method, F the

Copyright 2026, James M. Atkinson

framing scheme, R the RF transmitter chain, and M the measurement receiver. An illustrative response Y might be a predeclared burst-duration statistic. A suitable model is $Y=\mu+\alpha_S+\beta_C+\gamma_F+\delta_R+\eta_M+$selected interaction terms$+\varepsilon$, where μ is a grand mean, the Greek coefficients represent effects under the declared factor coding, and ε describes the residual variation. The model is descriptive until checked for adequacy. Compression may interact with source family; a fixed-length frame can conceal a change in encoded data length; and receiver thresholding can interact with pulse shape. It would be intellectually careless to interpret β_C without considering these dependencies.

Randomisation is not a magical property of an experiment; it controls particular threats. Vary the compression treatment in a concealed order while retaining source input and frame length controls. If a thermal transient in the RF amplifier evolves monotonically during the test, random order reduces the chance that the drift is mislabelled a compression effect. Replicate under different oscillator states, receiver gain settings and antenna configurations. Use a prewritten schedule of permissible input sequences and negative controls rather than selecting the clearest subset after the fact. Keep the full acquisition ledger, including failed or missing events, since those failures may depend on the treatment.

One may construct an elementary numerical example from public synthetic strings. Suppose each of 100 known blocks contains 8,000 source bits. On 50 authorised trials a compressor emits 2,500 payload bits; on the other 50 it emits 7,800, depending on deliberately changed source regularity. At a fixed gross coded bit rate of 100,000 bits per second and ignoring a separately documented constant frame overhead, the payload-carrying durations are

Copyright 2026, James M. Atkinson

25 milliseconds and 78 milliseconds. This example shows how source compressibility can change burst duration without changing transmitter hardware. It does not establish that field measurements of 25 or 78 milliseconds arose from these sources. A fixed 100-millisecond frame might erase the duration difference entirely. Conversely if the transmitter adapts its symbol rate to the output length, the same waveform duration can represent different payload sizes.

An important confounder is measurement of the wrong layer. Adding a scrambler after compression can whiten simple second-order statistics without changing the fundamental fact that the source was compressible. Forward error correction adds redundancy back into the channel code, and mapping to a modulation constellation transforms symbol sequences into amplitudes and phases. An error-prone channel can produce bit errors that mask the encoder's structure even for the investigator's own known test signals. Thus the observation model must propagate transformations through the entire chain. The analyst should not compare an input-source entropy estimate directly with a spectral flatness statistic as if their physical units and semantic meanings were interchangeable.

To preserve causal interpretation, an engineering team should perform purposeful substitutions. Hold a single transmitter and receiver fixed whilst changing C; hold C fixed whilst changing the permitted source S; hold both fixed whilst changing F; and then reproduce the experiment with a second transmitter and receiver. Measure amplitude, timing, frequency response and packet continuity at each step. If a proposed signature follows a particular software configuration across different hardware, it is evidence about the configuration. If it persists only with one instrument even when C,

Copyright 2026, James M. Atkinson

S and F change, investigate device artefacts before claiming a transmitter signature. A truly instrument-specific property requires stability under benign environmental changes and distinctness relative to a suitably diverse negative population.

One should also distinguish predictive accuracy from causal identification. A classifier may consistently separate two labelled laboratory source groups when those groups differ simultaneously in compressor, carrier frequency, RF gain, location and date. That performance is useless for deciding which factor caused the separation. Remove shortcuts by matching or randomising nuisance conditions and evaluating held-out configurations. When a prospective test includes a new compressor version or dictionary policy, the model should be allowed to abstain rather than assign the new observation to the nearest familiar class with unwarranted confidence. In a forensic setting, the cost of a confident false attribution can be greater than the cost of an inconclusive measurement.

The final claim hierarchy should be written before collecting data. A frame-duration response to known compression is a replicable demonstration within the experiment. A similarity between an unknown observed duration and a laboratory duration is an unresolved comparison. Inferring software, device or sender identity from that similarity would require additional independent evidence and appropriately characterised alternative causes. Compression does not create a stable personal signature. It is a transformation whose measurable effects depend on inputs, encoder state, framing and transmission decisions. The strongest scientific conclusion may be that a tempting attribution was successfully falsified.

Copyright 2026, James M. Atkinson

David Slepian, Peer Question: Professor Lempel, two test sources may be individually balanced in their zero-and-one counts but differ substantially in memory and correlation, so a compressor's realised performance could appear to be associated with the operator's chosen equipment when it is really responding to source dependence. How would your experimental design keep the source population from becoming a concealed surrogate for the claimed sender? Should one randomise source sequences within device, use matched examples across all compressors, and retain entire sessions when separating training from testing? I would also ask how an investigator might report uncertain or interval-censored event lengths when a detector fails to capture the beginning of a short burst. The observed response may then be a lower bound on duration rather than a precise outcome, and an apparently strong compression effect might rest on a biased selection of complete bursts. Please specify whether a statistically significant source-by-compressor interaction should be interpreted as a limitation on transportability and whether its uncertainty should be estimated across independent source sessions.

Abraham Lempel, Response: Professor Slepian, the simplest defence is a crossed design in which every synthetic source sequence appears under every authorised compressor and transmitter configuration, subject to an explicit and randomised execution order. The source sequences must include independent symbols, short-range Markov dependence, long repeated phrases and a structured adversarial negative case constructed to defeat one simplistic feature. This allows differences attributed to compressors to be estimated within matched source inputs. Replicate complete source-generation runs under new random seeds and retain those

Copyright 2026, James M. Atkinson

seeds in a protected laboratory register. If source families are wholly confounded with transmitters, there is no experimental basis for separating their effects.

Analysis should preserve the hierarchy of repeated measures. Multiple windows cut from one transmitted burst are not multiple independent emitters or multiple independent test trials. A mixed-effects or cluster-robust analysis may be appropriate when the same source sequence is transmitted repeatedly, but the particular statistical treatment must reflect the actual randomisation unit. For a predictive model, group the train/test split by complete session, not by random fragments within a session. Reserve novel source sequences and new receiver configurations for final testing, because familiar noise patterns can yield deceptive validation accuracy.

An event whose beginning is missing because of threshold activation must be labelled as censored. If the receiver sees an ending at t_end but first acquires at t_start after the true onset, the observed duration t_end−t_start may understate the actual duration. The bias may depend on signal amplitude and receiver gain. One can use an independent continuously recording laboratory witness to determine the true duration for permitted test waveforms and estimate the conditional error distribution of the operational trigger. Where that witness is absent in a field record, numerical treatment must respect the coverage gap; the analyst cannot restore the unseen onset merely by fitting a convenient regression model.

Copyright 2026, James M. Atkinson

I would require the report to show distributions of accepted and rejected trials, by treatment and source family, and to provide a sensitivity analysis under plausible unobserved intervals. A classifier trained exclusively on complete bursts could fail systematically on weak or truncated bursts. The appropriate result is a conditional demonstration of what the known experiment measures, with explicit limits on generalisation. That is much more valuable than a high percentage reported from a biased sample whose selection history has been discarded.

Alan Mathison Turing, Peer Question: Professor Lempel, in many engineering demonstrations the researcher experiments with numerous candidate features, partitions, model classes and hyperparameters, then presents the one that best separates known examples. If a claim is subsequently tested upon the same observations used to select the feature, the apparent evidence has already been consumed in constructing the hypothesis. How would you require the investigator to separate exploratory model building from genuinely independent corroboration? In particular, what record of failed features, intermediate models and cross-validation splits should survive, and how should a classification system respond when it encounters a source family or compression format outside its original training set? An 'unknown' answer may be less impressive to an audience than a confident identity, yet scientifically more defensible. Should an independent examiner be able to reproduce all discarded model candidates, and what objective criterion would distinguish a genuinely novel source from an unusually noisy member of an existing class?

Abraham Lempel, Response: Mr. Turing, the first obligation is to state which data were used to discover the purported pattern. Exploratory work can

Copyright 2026, James M. Atkinson

examine many representations, but the resulting performance estimate is optimistic unless the search procedure itself is included in validation. Reserve a sealed test set before the analyst selects the feature set, encoder hypotheses or classification model. Better still, collect a prospective replication with fresh synthetic source inputs, altered RF equipment and independently measured nuisance conditions. A genuinely external evaluation should occur after the analytic decision rules are frozen, with no informal retuning in response to the outcome.

A complete audit trail should contain the candidate feature definitions, unsuccessful fits, cross-validation membership, random seeds, training labels, preprocessing steps and code versions. A nested validation scheme can be appropriate when model selection is intensive: the inner data choose settings, while the outer held-out groups estimate the performance of that selection process. Yet even a carefully nested procedure over a narrow laboratory sample cannot establish performance for transmitters or compression implementations that are absent from the sample population. The external validity claim must be correspondingly narrow.

An 'unknown' or 'insufficient evidence' category is not a defect. One can calibrate a decision threshold on known classes and quantify how often novel negative families are mistakenly forced into familiar labels. Use diverse open-set negative controls. A model that assigns every high-entropy looking record to one known sender cannot distinguish absence of a matching hypothesis from strong evidence of membership. If a new implementation shares a public library with one old source, the correct

Copyright 2026, James M. Atkinson

output may be ambiguity, not identity. Feature attribution should identify which controlled variable drives the response and whether that variable was even observable on the unknown physical chain.

Reproducibility further requires an independent research team to reimplement the analysis from the fixed protocol and original acquisition data. If their result changes materially when the order of random seeds is altered, or when a single receiver is exchanged, that instability belongs in the report. A court or standards committee may prefer a crisp answer, but engineering inference cannot grant certainty that the experiment did not earn. The scientific objective is to quantify how many alternatives remain consistent with the observation and how those alternatives were challenged.

Abraham Lempel, Cross-Peer Question to Claude Shannon: Professor Shannon, the finite experiment shows that a compressed output can have little obvious redundancy, but the wording 'high entropy' is itself ambiguous when inferred from a short, error-prone, framed physical waveform. Would you explain what source entropy, conditional entropy and mutual information measure under explicitly specified random variables? I am particularly concerned that an analyst may treat a near-one-bit empirical marginal entropy as a demonstration of unpredictability, then convert that apparent unpredictability into a claim of cryptographic processing or sender identification. How could two distinct source and encoder systems be indistinguishable under the chosen statistics while retaining completely different internal meanings and histories? What physical measurement would distinguish the information-theoretic proposition from an assumption about hidden equipment? In your answer, separate finite-sample estimator

Copyright 2026, James M. Atkinson

error from the deeper identifiability problem where several distinct models generate exactly the same observed statistics. Also define the distinction between a genuinely unobserved source variable and a variable measured with finite precision, since those two uncertainties cannot legitimately be conflated in any claimed attribution.

Claude Shannon, Cross-Peer Answer to Abraham Lempel: Professor Lempel, the distinction begins with the definition of a probability model. For discrete random variable X with outcomes x and probabilities p(x), Shannon entropy is $H(X)=-\Sigma_x p(x)\log_2 p(x)$, expressed in bits per draw when the alphabet is discrete. That is a property of a stated source distribution, not an adjective one may attach to an unknown voltmeter trace. Conditional entropy $H(X|Y)$ describes residual uncertainty about X when Y is known, while mutual information $I(X;Y)=H(X)-H(X|Y)$ measures dependence under the joint model. All three quantities can be estimated poorly from a short, selected sample. Their values alone contain no physical sender identifier.

If X is a sequence of source bits and Y is a quantised observation of receiver output, the mapping between them includes coding, modulation, channel and quantisation. An entropy estimated from Y need not equal the entropy of X, and equal estimates do not imply equal causes. Different internal processes can induce the same one-symbol distribution for Y. A deterministic alternation and a memoryless fair coin both have balanced marginal symbols but differ in conditional uncertainty. A compressed known source and a deliberately randomised uncoded test source can yield similar summaries, even though their mechanisms and physical origins are distinct.

Copyright 2026, James M. Atkinson

To test the information-theoretic claim, specify the observation alphabet, transformation, record length and stationarity assumptions, then challenge the estimator with synthetic models of known dependence. Distinguish marginal frequency counts from block entropy estimates and predictive performance on held-out sequences. Ensure that any alleged difference survives an independently calibrated receiver and signal mapping. Where missing samples or unequal noise alter the observed sequence, propagate those uncertainties rather than declaring a property of an inaccessible payload.

Identifying an external sender is a separate causal hypothesis. A common source distribution does not establish a common chassis; a common compressor may be installed across unrelated devices; and a single transmitter may vary its encoder over time. Physical attribution requires independent evidence such as calibrated location measurements, timing records, equipment-specific characteristics that survive controlled substitutions, and lawful records linking observations to a source. Information theory can clarify the limits of what the data contain. It cannot replace the physical or legal evidence necessary to connect a sequence to an origin.

Dr. James M. Atkinson, Moderator: Professor Shannon, would you take the floor to examine the distinction between the entropy of an actual information source, the entropy estimated from finite observed symbols, and the physical behaviour of a modulated receiver output? I would welcome an explicit account of the assumptions under which a statistical

Copyright 2026, James M. Atkinson

quantity can be interpreted as a rate or capacity, and the boundaries beyond which it is no more than a descriptive measurement.

Claude Shannon, Third Principal Contributor: Dr. Atkinson, the scientist must begin by naming the random experiment. It is not enough to say that a received waveform is 'entropic' because a spectral trace looks irregular. Electrical waveforms possess power spectra, correlation functions, bandwidth, amplitude distributions and phase trajectories. Information-theoretic entropy refers to a probability distribution over specified symbols, conditional histories or continuous random quantities, and those definitions are not interchangeable. One can construct an analogue waveform with a visually flat spectrum but deterministic content, and one can transmit an unpredictable source through a narrow, structured carrier. The appearance of the receiver display is a transformation of the process under study, not the process itself.

Let $X_1, X_2,\ldots$ denote a discrete source. For independent and identically distributed draws, its per-symbol entropy is $H(X)=-\Sigma\, p(x)\log_2 p(x)$, provided the probabilities are well defined and the source model is applicable. For a dependent stationary process, the entropy rate is $h=\lim_{n\to\infty} H(X_1,\ldots,X_n)/n$ under suitable existence conditions. A source whose first-order histogram is balanced need not have $h=1$ bit per symbol. A deterministic alternating binary process has a balanced marginal but approximately zero asymptotic entropy rate once its phase is known. Conversely, a binary memoryless source with $p(1)=0.5$ has one bit per symbol under that model. An observer who estimates only the balance of zeros and ones cannot distinguish them. The difference appears in

Copyright 2026, James M. Atkinson

dependencies and predictability, not in an unqualified declaration of 'random appearance'.

Compression uses the statistical or combinatorial structure of the source to obtain a shorter description. A well-designed lossless compressor can reduce a redundant file; its compressed output may present fewer obvious repetitions, because those repetitions have been represented more economically. But a file's finite compressed length and its theoretical source entropy are related only under precise coding conventions, asymptotic conditions and knowledge of the source family. A short file may expand because the encoder includes headers or a dictionary. A file with no observed compression saving under a given programme may simply be an inconvenient match to that programme. There is no theorem that a visually irregular received burst was encrypted, compressed, sent by one manufacturer, or produced with adversarial intention.

The channel adds a separate layer. A memoryless channel with input X and output Y has mutual information $I(X;Y)=H(X)-H(X|Y)$ under its declared law, and the channel capacity is the supremum of $I(X;Y)$ over admissible input distributions for the stated channel model. This abstraction cannot be transferred unchanged to a receiver whose analogue gain control, quantisation, fading and filter states are unknown. In particular, the spectrum analyser's displayed bandwidth multiplied by an observation time is not itself an observed payload entropy. A wideband noise-like signal can carry highly structured or even no useful message content; the transformation from source symbols to recorded voltages determines what the external measurement can justify.

Copyright 2026, James M. Atkinson

One can inspect a permitted synthetic laboratory data set to illustrate finite-sample bias. Suppose a fair binary source produces ten symbols. The plug-in estimate may be exactly one bit if five ones appear, but it can also be lower when the realised balance is unequal, despite the true source entropy being one bit. For larger alphabets, rarely observed categories and structural dependencies produce additional bias. A researcher selecting only captures with favourable sample entropy compounds the problem. Appropriate confidence and bias assessments require a declared stochastic model, resampling assumptions or independent simulated records. A precise-looking number printed with six decimals is not thereby a precise estimate of the underlying information process.

A practical defensive investigation should therefore separate three observation levels. At the analogue level, document RF power, occupied bandwidth, carrier frequency, pulse duration and instrument uncertainty. At the digital-symbol level, where lawful and possible using known test content, document how the demodulator defines a symbol and handles errors, erasures and synchronisation. At the source level, describe the synthetic or otherwise authorised input distribution and the actual compression rule. These levels can be linked experimentally when the investigator controls the whole chain. They cannot be linked by imagination when some intermediate transformation is unknown or inaccessible.

A carefully designed experiment includes both compressible and incompressible known inputs, multiple distinct source families, several compressor algorithms, independent framing schemes and at least two receiver architectures. Hold the RF power and symbol clock fixed while changing the compressor; then hold the compressor fixed while changing

Copyright 2026, James M. Atkinson

the forward-error-control code. Record whether the measured external feature changes at all. If an entropy-based classifier claims to identify a sender, exchange compressor binaries between independent transmitter assemblies. If the predicted class changes with the binary, the observed feature cannot identify the physical assembly. If it does not change, test the remaining shared hardware conditions and environmental confounders rather than pronounce identity.

A final ambiguity is the choice of features used after looking at the capture. Investigators may search many symbol mappings, window sizes, entropy estimators and candidate lags. An apparently exceptional match may be expected under that multiple-search process. Hold out a new acquisition as a confirmatory test and retain all unsuccessful alternatives in the research record. A result produced by optimising a model on the very event under investigation is exploratory. In a forensic report, its strongest defensible role may be to suggest further controlled tests, not to certify the sender or the legal character of any communication. The ultimate task of theory is to prevent an inference from outrunning the quantities the experiment has actually measured.

John Robinson Pierce, Peer Question: Professor Shannon, a receiving chain may contain nonlinear mixers, logarithmic detectors and gain-control circuits that change a measured amplitude distribution without changing the source programme at all. An apparently featureless spectral response may also be the product of filter bandwidth or averaging. Could you distinguish the entropy of a discretised sample sequence from the spectral flatness or occupied bandwidth measured by a conventional spectrum analyser? Which electrical measurements would establish whether an

Copyright 2026, James M. Atkinson

entropy-related feature was generated before the antenna, in the receiver, or during subsequent numerical processing? I am also concerned about a common mistake: treating the absence of a visible spectral line as proof that the incoming source symbols are independent. A wideband laboratory generator can be entirely deterministic while looking noise-like to an under-resolved analyser. What controls would you require before discussing an information-theoretic hypothesis? Would checking the same feature against raw I/Q samples, detected powers and separately calibrated analogue measurements help locate the stage at which apparent randomness first enters the record?

Claude Shannon, Response: Mr. Pierce, spectral flatness is generally a functional of a power spectral density or its estimate, not an entropy of a source alphabet. A common spectral-flatness statistic is the geometric mean of estimated nonnegative spectral powers divided by their arithmetic mean over chosen bins, when these means are meaningful. Its value depends upon the analysis bandwidth, window, data length and treatment of near-zero bins. The Shannon entropy of a quantised sequence requires a distribution over explicitly defined symbols. The two statistics can respond differently to the same signal, and neither independently establishes the underlying sender. A carefully constructed deterministic pseudo-random sequence can have broad spectral appearance while being completely reproducible from its generation rule.

To locate the mechanism, perform a reference-plane experiment. Observe a permitted waveform directly at the controlled generator output, after the RF transmitter, at the receiver input and after each relevant demodulation or

Copyright 2026, James M. Atkinson

quantisation stage. Use a known, independently calibrated reference signal alongside the synthetic source to monitor receiver changes. Repeat with a second architecture that differs in frequency conversion and detector implementation. A feature that appears only after a logarithmic detector may be a detector characteristic; one that changes with automatic gain-control settings deserves a gain-state explanation before a source explanation.

Avoid interpreting a spectral hole or line as a property of the encoder before considering pulse shaping, subcarrier allocation and time-frequency resolution. A rectangular pulse, for example, has a characteristic transform whose sidelobes depend on its duration; changing the window or filter can reshape the displayed spectrum. Similarly, a digital frame marker inserted after compression can create a cadence even if the compressed payload is balanced. The investigator should estimate the covariance of measurements across frequency and time rather than treating all bins as independent information sources.

If the laboratory controls synthetic data, compare source-level statistics directly with receiver-level statistics under known transformations. Record the point at which a particular feature emerges, disappears or becomes unmeasurable. With unknown protected content, that comparison is unavailable; the report must say which links in the causal chain remain unobserved. A finding of 'no distinguishing feature detected within this receiver's tested sensitivity' is far more defensible than the categorical

Copyright 2026, James M. Atkinson

proposition that the source has no structure. This distinction is metrological, statistical and legal all at once.

Claude Shannon, Cross-Peer Question to Ralph Vinton Lyon Hartley: Mr. Hartley, an analyst sometimes selects a binary alphabet solely because the receiver produces two-level decisions, and then interprets the resulting entropy estimate as if it were an intrinsic property of the transmitter. Yet a different threshold, constellation partition or observation interval would define a different alphabet. Could you explain how the act of counting distinguishable alternatives depends on the physical signalling convention and the available time-bandwidth product? What would follow if one transmitter sends the same known message through different symbol mappings, or if two unrelated transmitters use the same modulation and framing convention? I would also ask you to challenge the assumption that a high apparent symbol diversity identifies a unique source when the observer has not established that the compared alphabets are equivalent. Please explain whether a quantiser changed after observing the waveform invalidates a nominal significance estimate unless that choice is accounted for in the testing procedure.

Ralph Vinton Lyon Hartley, Cross-Peer Answer to Claude Shannon: Professor Shannon, the counting convention is not merely a mathematical convenience: it encodes a decision about what the receiving system can distinguish. For N equally possible and discriminable alternatives, a simple information measure is log2 N bits per selection. But the adjective 'discriminable' demands an electrical model of signalling, noise, timing and the observer's resolution. A receiver mapping a continuous complex waveform into two symbols by a threshold discards information, and

Copyright 2026, James M. Atkinson

another threshold can produce different symbol frequencies from the same analogue samples. The resulting alphabet belongs partly to the instrument and analyst, not only to the source.

In my 1928 treatment, physical considerations connect the number of signal distinctions with bandwidth and available signalling time. Such reasoning does not justify estimating a sender's identity by counting how many quantised values occur in a finite recording. Two unrelated transmitters using one public framing convention can present the same symbol alphabet. Conversely one physical transmitter can change modulation order or mapping and thereby alter the visible alphabet while its identity remains constant. The decision rule and observation window must be the same, or rigorously calibrated, before comparing their statistics.

A useful demonstration uses a known transmitter sending the same synthetic sequence under two lawful modulation mappings. Record continuously with a calibrated complex-sample receiver, then compute the same entropy estimator after several predeclared quantisers. If the apparent signature changes with the quantiser while the sender and source are unchanged, the signature cannot be invariant to observation method. Next hold the quantiser fixed but change the transmit modulation. If the statistic follows modulation rather than the physical transmitter, report it as a modulation-associated feature. These are straightforward interventions, but they prevent a common intellectual error.

The analyst must also distinguish a count of symbols from a count of

Copyright 2026, James M. Atkinson

physically independent trials. Adjacent samples filtered by the same analogue pulse and taken faster than the system's independent degrees of freedom are correlated, even if the record contains millions of numbers. Treating them as millions of independent observations can make uncertainty intervals absurdly narrow. A time-bandwidth assessment can motivate a bound on measurement degrees of freedom, but exact effective sample size depends upon the signal and filter. I would therefore insist on a declared reference plane, threshold rule, sample cadence, filter bandwidth and uncertainty model before a numerical information measurement is used as evidence of origin.

Dr. James M. Atkinson, Moderator: Mr. Hartley, please develop this question from the perspective of physically available distinctions and observation conventions. In particular, how could a receiver's finite time-frequency resolution, a modem's framing choice, or the analyst's quantisation produce an apparent statistical signature that disappears when a measurement is repeated using another valid observation alphabet?

Ralph Vinton Lyon Hartley, Fourth Principal Contributor: Dr. Atkinson, the first task is to keep distinct the thing transmitted, the thing physically observed and the thing classified. In a communication system there must be a convention by which the receiver distinguishes one possible signal from another within a limited time and bandwidth. An analyst who divides an RF trace into symbols has imposed an observation rule. That rule can be excellent for the intended engineering purpose while being wholly unsuitable for identifying the transmitter. The physical apparatus may observe only a narrow band, integrate energy for a relatively long interval, or discard phases and amplitudes that the source actually used. It is

Copyright 2026, James M. Atkinson

therefore a mistake to infer an intrinsic information source from an undeclared digital summary.

My 1928 account of the transmission of information emphasised physical signalling and the relation between distinguishable alternatives and available resources. For N equally likely alternatives, one writes $H_H=\log_2 N$ bits per selection. This elementary count presumes that all N alternatives have been specified and can be resolved under the observation model; it does not certify that they are equiprobable in an unknown source, nor that their choice identifies any particular sender. To compare two records, one must define what constitutes a selection, where the physical sampling interval begins and ends, and whether both instruments implement the same distinctions. Otherwise the symbol count is a measure of apparatus and convention, not simply of the incoming field.

Consider an authorised laboratory waveform represented by complex baseband samples $z_n=I_n+jQ_n$, where I_n and Q_n are the in-phase and quadrature components for sample index n. An analyst may assign binary labels using the sign of I_n. Another analyst may use the sign of Q_n, and a third may partition the complex plane into four quadrants. These rules generate different symbol alphabets from identical analogue data. Their empirical symbol frequencies may differ because of carrier phase, offset, gain, quadrature imbalance and receiver noise. No physical transmitter change is required. If the apparent sender fingerprint changes when the symbol definition changes, the fingerprint has failed even a basic invariance test.

Pulse shaping makes the problem subtler. Adjacent samples may be correlated by the transmitter's filter and by the receiver's own anti-aliasing

Copyright 2026, James M. Atkinson

and channelisation. Counting one million oversampled values as one million independent symbol observations is invalid. A finite time-bandwidth resource restricts the distinguishable degrees of freedom under the assumed noise and signal model, although it does not supply a universal formula for every real receiver's effective sample size. The investigator should inspect autocorrelation and filter memory, account for scan gaps, and calibrate timing against a stable reference. The covariance structure matters more than the impressive length of the stored sample file.

A compression step occurs upstream of these physical choices. The compressed known source may have approximately balanced output bits; the frame builder may insert a fixed preamble; the forward-error-control coder may introduce parity relations; a scrambler may further alter local correlations. A subsequent modulator and pulse shaper convert the result to voltages. If an investigator sees a repeatable envelope or cadence, that feature may be due to the frame boundary rather than to the compression rule. If changing the compressor changes transmitted duration only when framing is variable length, the observation is conditional on the framing policy. The words 'payload entropy' should never be used to elide these alternatives.

An instructive experiment compares four known conditions. In condition A a fixed synthetic file is transmitted without compression under a fixed symbol clock. In B the file is compressed but the frame size is fixed by padding. In C the compression remains but padding is removed so occupied burst duration may change. In D the source and compressor remain fixed while the modulation mapping changes. Monitor the antenna input with a calibrated complex-sample receiver and an independent timing witness. If

Copyright 2026, James M. Atkinson

the proposed signature appears only in C, it concerns duration and padding, not a universal property of compression. If it changes in D, it concerns mapping or measurement. This trial need not decode a protected message because every transmitted test string is the researcher's own.

All numerical estimates need uncertainty. Suppose a binary-quantised record contains 600 ones among 1,000 samples, giving p_hat=0.6. Its plug-in entropy is approximately 0.971 bits per sample. If carrier phase rotates and the same receive samples are reassigned under a different threshold, p_hat may change, and the resulting number changes with it. The value 0.971 is neither an estimate of device ownership nor proof that the encoder compressed data. Its sampling uncertainty cannot be computed from a binomial model unless the samples are appropriately independent; pulse-shaping correlation will reduce effective information. One should state the estimator and its assumptions rather than present an isolated decimal as a sender characteristic.

The final implication for forensic reasoning is modest but valuable. A reported feature can support the proposition that an observed signal is compatible with a particular modulation, framing or coding arrangement under controlled tests. It cannot by itself bind an invisible source file, compressor, chassis or human operator to that signal. A proper report identifies the observation convention, tests alternative quantisers and receiver architectures, documents the experimental coverage, and refuses to treat incompatible statistical scales as interchangeable. Physical measurement should narrow a hypothesis only to the degree that controlled alternatives have actually been excluded.

Copyright 2026, James M. Atkinson

John von Neumann, Peer Question: Mr. Hartley, an experimental group may preserve the analysed sample sequence but not the software configuration by which the spectrum, quantised symbols or classifier inputs were produced. Such a record can look objective whilst depending on a chain of discretionary choices, including window overlap, filter length, threshold, resampling ratio and omitted bursts. What minimal computational provenance would permit a later reviewer to reproduce the claimed entropy statistic from the original measured voltages? How should one treat a software update that changes rounding, detector normalisation or event boundaries without changing the RF emitter? I would also ask whether an apparently precise uncertainty estimate can survive if the number of effective independent observations was never measured and correlated samples were silently counted as independent evidence. In a controlled replication, should changes in software dependencies and arithmetic libraries themselves be treated as experimental factors when the target effect is only a few hundredths of a bit per symbol?

Ralph Vinton Lyon Hartley, Response: Professor von Neumann, the primary record must preserve the original complex samples or other minimally processed electrical measurements, their sample indices and clock mapping, and a complete configuration snapshot of the receiver. A later feature calculation should be a reproducible transformation with a declared software version, processing code hash, filter coefficients, window and overlap, quantisation rule, detection threshold, missing-sample treatment and output units. A table of derived entropy values without those particulars is a summary of an unknown experiment. It cannot serve as a secure foundation for comparison when the feature itself is sensitive to the

Copyright 2026, James M. Atkinson

unrecorded steps.

One should also establish the physical observation boundary. Was the recorded value a voltage at a calibrated receiver output, a detected magnitude, a logarithmic power, or a post-decoded symbol estimate from a known laboratory signal? The distinctions matter because nonlinear transformations can alter statistical distributions. A software update that changes a threshold could change the measured fraction of ones and the resulting plug-in entropy while the transmitter is untouched. The investigator must compare pre- and post-update results on immutable raw test captures and document any revised algorithm as a new derived representation, not overwrite prior evidence.

For uncertainty, the count of stored samples is not necessarily the count of independent observations. A long finite-impulse-response filter, oversampling or a slowly changing receiver gain may produce substantial correlation. An independence-based standard error may then be overconfident. Use controlled resampling or appropriate dependence-aware methods, specifying which time scales and stationary assumptions are justified. Where the sample sequence includes censored intervals, a correction must account for the selection rule or report bounded conclusions instead of pretending missing observations were present.

I would require at least one independent replay on an instrument with a different receiving and analysis chain. Preserve negative controls that test whether a feature arises with a terminated antenna port, a known injected

Copyright 2026, James M. Atkinson

test waveform or a changed gain state. A statistic reproducible only within one software version and one receiver setting is an instrument-specific diagnostic at best. Neither its numerical stability nor its attractive presentation establishes sender identity. The intellectual principle is elementary: the record must permit another examiner to see which observable was measured and which decisions created the final number.

Ralph Vinton Lyon Hartley, Cross-Peer Question to Peter Elias: Professor Elias, even when the source has been compressed, communication systems frequently add deliberate redundancy through error-control coding, synchronisation and interleaving before physical transmission. An investigator may find a pattern of near-regular errors or repeated frame lengths and mistakenly infer a particular compressor or sender. Would you examine the direction in which information and redundancy travel through the chain, and the conditions under which a channel-code effect could resemble a compression fingerprint? What should be learned from a controlled experiment where the compressor remains fixed but code rate, interleaver depth and permitted error probability are varied? I also ask how the investigator should distinguish a known laboratory codeword property from an unsupported inference about an unknown protected payload. Could the same nominal code rate create different bursts under puncturing, padding or a variable modulation order, and how should those confounders appear in the measurement ledger? Please identify whether a receiver that records only burst-level energy could even resolve the changes in code rate, and specify the laboratory reference measurement needed to establish those differences.

Copyright 2026, James M. Atkinson

Peter Elias, Cross-Peer Answer to Ralph Vinton Lyon Hartley: Mr. Hartley, the source and channel stages serve different purposes. A lossless compressor attempts to reduce a description of source redundancy under a chosen code, while an error-control encoder introduces structured redundancy to make reliable reception possible under specified channel impairments. There is no contradiction in a communications system first reducing one form of redundancy and then adding another. A recorder observing only the final waveform may not know where one process ended and the other began. The evidence must therefore be framed as a comparison against explicit candidate chains, not a single inferred compressor.

Let k denote the number of input information symbols and n the number of coded channel symbols for one block under a defined code alphabet. The rate $R_c=k/n$ is a channel-code rate under that convention. A lower R_c can increase the number of transmitted symbols for the same compressed input, but the change in burst duration depends also on physical symbol rate, modulation bits per symbol, framing and padding. The simple expression is not a direct measure of original source entropy. A rate-one uncoded laboratory condition can be compared with several public error-control codes while all other factors are held constant. If a purported compressor signature changes with R_c, its causal description must acknowledge the channel code.

Interleaving further complicates local patterns. Permuting a sequence's positions can disrupt short-range correlation and distribute burst errors without changing the multiset of transmitted symbols. Thus a first-order

Copyright 2026, James M. Atkinson

histogram may remain the same while a lag-correlation statistic changes substantially. Noise, fading and detector errors then add further variation. An investigator who sees high apparent unpredictability in a short capture cannot determine whether the pattern arose from compression, interleaving, scrambling, encryption, measurement noise or a mixture of these mechanisms merely from that appearance.

A controlled study should transmit only owned, synthetic test messages, record the code and interleaver configurations, and challenge its waveform feature across code rates, burst lengths, signal levels and independent receivers. Retain both error-free and deliberately impaired test conditions. Evaluate whether a classifier's decisions follow coding settings rather than the transmitter identity. An unknown protected payload cannot be converted into a known codeword by assertion. If the necessary message or decoder states are inaccessible, the researcher must limit the claim to externally observable compatibility and uncertainty, not pretend to have proved an internal encoding history.

Dr. James M. Atkinson, Moderator: Professor Elias, would you now develop the complete account of channel redundancy, error patterns and receiver uncertainty, including what can be established with an authorised synthetic challenge, and what remains unavailable when the semantic contents of an external communication are not accessible?

Peter Elias, Fifth Principal Contributor: Dr. Atkinson, a communications chain may be understood as a sequence of distinct maps whose effects are not identifiable from a single coarse observation. A source produces data, a compressor may remove predictable description length, a channel encoder

Copyright 2026, James M. Atkinson

adds structured redundancy, a modulator and pulse shaper produce a continuous waveform, and the channel and receiver introduce impairments. A statistic measured at the end is a property of that composition under the instrument's configuration. If the analyst proposes to label it a sender fingerprint, every intermediate map and nuisance mechanism becomes a potential competing explanation. Our first obligation is to ask what experimental manipulations can separate them without examining protected content.

Error-control coding has an elementary mathematical representation. A binary linear block code may map k information bits into n transmitted code bits, with nominal code rate $R_c=k/n$. The number $n-k$ represents added code bits per block under that model, although precise redundancy must consider framing and shortened or punctured codes. If a known source output is B bits, and B is divisible into k-bit input blocks for a simple idealised calculation, then the channel encoder produces nB/k coded bits before any interleaver, preamble or physical framing. At gross symbol rate f_s symbols per second and m transmitted coded bits per modulation symbol under a declared mapping, nominal useful transmission time is approximately $(nB/k)/(m f_s)$. This equation assumes no packet overhead or gaps and is an illustrative calculation, not an instrument specification.

Suppose B=4,000 compressed bits, k=100, n=200, m=2 and f_s=100,000 symbols per second. The idealised coded output is 8,000 bits and the payload-carrying duration is 0.04 seconds. If the code changes to n=125 at the same k, the duration becomes 0.025 seconds, with all other terms unchanged. That 15-millisecond difference would be visible to a sufficiently well calibrated acquisition system, but it would identify a change in channel-

Copyright 2026, James M. Atkinson

code configuration, not a different sender. A fixed-length burst with padding could hide the difference, and an adaptive symbol clock could also compensate. Any event-duration inference must therefore report framing and timing controls as well as compression status.

The observed errors can be equally misleading. A channel with independent bit error probability p is one model, but real RF channels may exhibit fades and clustered errors. An interleaver can redistribute the order of coded symbols so that local error bursts are spread across codewords, while a decoder's subsequent success or failure depends on its code and operating assumptions. A frequency-domain receiver that never decodes any protected content may still observe broad changes in burst power or duration, but it cannot claim knowledge of internal error syndromes unless those are obtained from its own authorised laboratory sequences. The existence of a successful laboratory decoder is not evidence that an unknown field transmission used the same coding rule.

In the historical and contemporary literature, variable-length and convolutional coding methods may be compared using their mathematical structures, but an observation of apparent redundancy is not a unique signature for either. Framing markers, parity relationships, interleavers and synchronisation procedures can introduce periodicity after compression. Conversely channel noise can destroy a periodic feature even when it is genuinely present at the transmitter output. When the instrument has only an energy detector, one must not insinuate that it can resolve bit-level code structure. Measurement capability determines the scope of the claim; the sophistication of the theory does not increase the evidence available from an inadequate instrument.

Copyright 2026, James M. Atkinson

A strong synthetic experiment therefore crosses compressor family, error-control rate, interleaver depth and modulation map while preserving independent replicates at each condition. Use two physically separate transmitter chains and at least two receiver architectures; monitor system state, oscillator reference, power and timing continuously. Collect negative tests with no emitted signal, with a known constant reference tone, and with a code configuration intentionally outside the classifier's training population. Predeclare the primary statistic, trial boundaries, missing-data rules and error metric. If a classification depends upon one coding parameter, the report should say it detects an effect compatible with that parameter under controlled conditions, not that the parameter determines the sender.

There are important inferential boundaries around entropy. An error-control encoder can increase the length of a compressed description while leaving its source information content unchanged in the ideal lossless model; nevertheless the emitted waveform may have different spectral and timing properties. A receiver with poor sensitivity may convert noise into apparently random symbol decisions, increasing a simple empirical entropy estimate while destroying information about the transmitted symbols. If a detector omits low-amplitude portions, it can bias the retained record toward a different distribution. Thus higher estimated symbol entropy at the receiver can correspond to worse measurement quality. It is not evidence of a more secure or a more hostile transmitter.

A publication-quality analysis must present the alternatives that the experiment could not discriminate. It should state which RF observables were measured directly, which code properties were demonstrated only on

Copyright 2026, James M. Atkinson

authorised synthetic sequences, how errors and uncertain event boundaries were handled, and which mappings remain unknown. Source-to-claim citations should support the exact theorem or engineering mechanism being invoked rather than the mere existence of a famous author in the bibliography. The historical specialists in this constructed roundtable contribute principles; they are not witnesses to a present-day investigation. In the absence of independently traceable physical origin evidence, the correct conclusion is that a particular statistical appearance is compatible with multiple transforms and multiple senders. That conclusion can be technically valuable even when it is deliberately inconclusive.

Antony Hewish, Peer Question: Professor Elias, radio astronomy teaches the danger of attributing a striking observed pattern before the measurement chain and the observing schedule have been challenged. An intermittent signal can be distorted by receiver gain changes, channel filters and gaps in observation, and a coherent periodic feature can have an entirely mundane instrumental origin. What independent antenna or receiver substitutions would you prescribe before treating a change in waveform entropy or burst cadence as evidence of any transmitter-side coding decision? I am particularly interested in the difference between losing a weak part of a burst and actually observing a more random source. If the first condition selectively removes predictable low-amplitude intervals, the empirical statistics could look impressive for exactly the wrong reason. How should a negative search result then be worded? I would additionally ask whether the analysis should report results separately for weak and strong signals, because survivorship of high-amplitude bursts could lead to markedly different conclusions from continuous acquisition.

Copyright 2026, James M. Atkinson

Peter Elias, Response: Professor Hewish, first identify the observation chain that creates the statistic. Record the receiving antenna, polarisation, cable loss, preselection, gain, local oscillator, filter response, detection threshold and data retention rule. Challenge the putative feature using a known synthetic reference waveform injected at a documented reference plane. Repeat with a second receiver architecture and an independently monitored clock. If the feature changes with gain, filter or threshold while the source remains fixed, its attribution belongs at least partly to the measurement process. The test should be conducted over a range of signal-to-noise ratios, including cases where the receiver sometimes fails to trigger.

For missing low-amplitude intervals, preserve a coverage ledger rather than treating retained windows as the entire waveform. Suppose a burst contains a predictable low-power preamble and an irregular higher-power segment. A detector that begins recording only after the preamble will return a fragment with a different symbol distribution from the full burst. Its increased apparent entropy is a consequence of censored acquisition. An independent continuous laboratory witness can measure how often this happens under controlled conditions, but a field record without that witness cannot reconstruct the missing content as an observation. An analysis should report the selection boundary and the resulting uncertainty.

A terminated-input measurement can expose internally generated spurs and signal-like artefacts, subject to the expected termination noise and receiver state. Changing antenna position or polarisation can challenge a true external field hypothesis, although such changes also affect sensitivity

Copyright 2026, James M. Atkinson

and multipath. An independently clocked receiver offers a useful timebase check. However, disappearance under a new configuration does not prove the original signal was fictitious, because the measurement transfer function and detection probability have changed. Proper attribution requires predictions of how the competing mechanisms should respond to each intervention, not an unreasoned appeal to a second display.

The negative conclusion should be bounded to the tested sensitivity, settings, frequency-time coverage and event-definition rules. It might say that no qualifying signal compatible with the declared laboratory feature was detected in the monitored intervals under the stated apparatus configuration. It must not say that a particular compression algorithm, channel code or sender was absent from the entire environment unless the experiment actually supports that broader claim. The evidence hierarchy remains explicit: measured external behaviour, proposed compatibility with a transform, and physical sender identity are different propositions.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The discussion has established that payload compression can erase useful source redundancy while introducing no unique evidence of sender identity. Universal compression performance, information-theoretic entropy, symbol-alphabet selection, channel coding, framing, receiver noise and incomplete acquisition all affect the observed statistics in different ways. A lawful forensic investigation may compare known synthetic chains under controlled changes, but must not infer encryption, private message content, malicious purpose or physical origin solely from high apparent entropy. The panel's reciprocal questions show why the most credible experiment

How should frequency-hopping bursts be surveyed when scanner dwell is incomplete?

SCHOLARLY RECONSTRUCTION. The following dialogue is an expressly fictional educational construction. Its named deceased scholars did not participate in this conversation, endorse the statements or make the attributed remarks. All examples describe synthetic authorised test sources and defensive receiver validation; no protected traffic is recovered and no transmitter identity is inferred.

Dr. James M. Atkinson, Moderator: Mr. Hartley, kindly establish the observational problem. An intermittently tuned receiver sees only a changing subset of frequency and time. What exactly is measured, and what ought a cautious investigator refuse to infer from an incomplete spectral record? The token is yours.

Ralph Vinton Lyon Hartley, Principal Contributor: The first duty is to define the observation universe before counting anything within it. A frequency-hopping emission does not leave an equal mark on every tuneable receiver, and an empty spectral cell cannot be treated as proof that the transmitter avoided that channel. Consider a test system commanded to use K discrete centre frequencies, with K a positive integer. Let the transmitter select one frequency for each hop of duration H seconds; let the receiver visit one of those frequencies with a nominal dwell D seconds, a settling time S seconds and an additional blanked or record-ineligible duration B seconds. The useful receiver aperture on each visit is A = max(0,D-S-B). It is A, not D, which belongs in the simplest intersection calculation. If D is 12 milliseconds, the retuning and calibration interval is 3 milliseconds, and the recorder blanking

Copyright 2026, James M. Atkinson

interval is 1 millisecond, only eight milliseconds of each nominal visit can contribute actual defensible observations. A report using twelve milliseconds silently overstates its exposure by one half relative to the eight-millisecond effective interval. That error may propagate into every subsequent claim about how frequently a channel was occupied. The geometry is temporal as well as spectral. On a time-frequency sheet, the sender's hop is a horizontal strip with width H along the time coordinate and a location defined by frequency and occupied bandwidth. Each receiver aperture is another strip, possibly on another frequency, with width A. A detection requires a nonempty overlap of the two strips and a sufficient signal-to-noise ratio during that overlap. To obtain a complete feature estimate rather than a fragment, require overlap of at least a specified T_min seconds, not merely an instantaneous intersection. The receiver may also capture an adjacent channel when its intermediate-frequency response has finite skirts; that event must not be represented as an exact centre-frequency match without a resolution and selectivity assessment. The mathematical abstraction should preserve the physical receiver's actual passband rather than imposing an ideal frequency bin after the fact. Here is a first numerical case under deliberately restrictive assumptions. A known laboratory emitter chooses uniformly among forty nominally separated channels, each hop lasts ten milliseconds, and an independently scheduled receiver aperture lasts eight milliseconds. If the relative starts are uniform over a twenty-millisecond comparison period, the intervals overlap at all whenever the start offset lies in a measure of eighteen milliseconds, so an unrestricted temporal intersection would have probability 0.9. Yet the scanner listens to only one of forty channels, and the event of exact channel

Copyright 2026, James M. Atkinson

agreement has probability 1/40. Independence would then give 0.0225, or 2.25%, for one synthetic opportunity, before the added requirement of enough dwell for classification. The arithmetic is illustrative: its premises are not justified for an actual deterministic hop and scan schedule merely because the numbers are convenient. Nor may the temporal window be replaced by the hop period indiscriminately if a receiver visits last longer than the hop or crosses repeated hop boundaries. Under a different uniform-phase model, direct interval geometry must be recomputed. The distinction between scheduling knowledge and observation knowledge is decisive. If the sender cycles through a known list of forty frequencies while the scanner does the same in a fixed order, their relative phase may lock into an unproductive pattern. Ten thousand visits do not become ten thousand independent trials. In the extreme, the receiver can continue arriving only after each transmitter burst has ended, producing an impressive archive of absences from an actively transmitting laboratory source. The correct response is not to declare the transmitter absent but to change the scan order or introduce a deliberate phase offset, preserve the timebase and compare the resulting capture rates. An observation design must attempt to break aliasing, not congratulate itself on the volume of its own repeated mistakes. An interval-censored encounter should be recorded as an event whose frequency, start and end times are bounded by the instrument's limitations. An event beginning before the receiver opened its gate is left-censored; one persisting after the gate closed is right-censored. An event visible for four milliseconds might be an intrinsically four-millisecond emission or merely the middle of a much longer hop. Duration histograms derived from such fragments tend to acquire false short tails

Copyright 2026, James M. Atkinson

unless the censoring mechanism is represented. It follows that the observed distribution of interarrival times, hop durations and channel use cannot be made equal to the underlying source distribution without modelling the inclusion probability. If a recorder suppresses events beneath a threshold, censoring is additionally amplitude-dependent and may correlate with frequency-dependent cable loss. For a defensible field record, I would require a machine-readable log containing commanded tune frequency, actual lock or calibration readiness, effective aperture start and end timestamps, receiver passband, detection threshold, raw power statistic, trigger status, clock uncertainty and reason for each deliberate recording gap. Every retained burst should carry a field separating direct measurement from inferred full-hop duration. A monitoring period with no captures must still contain the same exposure log. The negative result then reads: no event satisfying the stated detector rule was observed within the documented frequency-time apertures. It does not read: no hopping transmitter was present, and it certainly does not identify a sender by the gaps in a record. The resulting discipline is almost elementary, but that is precisely why it matters. Frequency and time are two independent axes of opportunity, while signal strength, filter shape and recording eligibility add further conditions. A probability assigned without naming the sampling space is a number without an honest referent. In forensic scholarship, a smaller carefully bounded conclusion is worth much more than an elegant but imaginary complete view of an unseen hopping pattern.

Abraham Lempel, Peer Question: Mr. Hartley, your frequency-time strips clarify what the receiver was capable of seeing, but I worry about the way event files are compressed, deduplicated and summarised before the

Copyright 2026, James M. Atkinson

analyst receives them. A logger may retain only the strongest pulse per dwell, merge multiple peaks into one event or discard a burst as redundant because its spectral shape resembles an earlier burst. Some products report the total number of detections without recording the number of opportunities or the excluded events. Would you insist that the survey preserve all detector decisions, including rejected candidate events, rather than saving only final positive records? Please distinguish the loss produced by receiver exposure from the loss introduced by post-processing, propose a lawful seeded experiment that can measure both kinds of loss separately, and explain how a supposed hopping period might be manufactured by a recorder that groups events at regular reporting intervals. In particular, please state how a software change-log and a sample-level reference recording would reveal an event merger that reverses the observed sequence order, and what versioned metadata would permit an independent examiner to reproduce that transformation.

Ralph Vinton Lyon Hartley, Response: Mr. Lempel, the two losses must never be multiplied together as if they had a common cause. Exposure loss arises before a signal could be evaluated: the receiver was on a different channel, not locked, or otherwise outside an admissible detection interval. Processing loss occurs after the receiver has obtained a candidate measurement but before the investigator's retained event table is created. Let N_truth denote seeded transmitted bursts, N_exposed those whose frequency-time and passband intersection satisfies a declared physical criterion, N_triggered those for which the detector asserts a positive event, and N_retained those preserved after aggregation. The ratios N_exposed/N_truth, N_triggered/N_exposed and N_retained/N_triggered estimate different

Copyright 2026, James M. Atkinson

stages of a synthetic test, provided all denominators are nonzero and the test truth is independently logged. Their product is N_retained/N_truth, but the separate terms reveal which stage creates a discrepancy. It is important not to call this product a field detection probability unless the test conditions represent the intended field exposure distribution. A proper calibration must split the paths before lossy aggregation. One recording branch keeps raw complex samples or minimally processed detector statistics for a manageable bounded trial; a second branch performs the proposed event collapsing. Give the emitter an independently authenticated timestamp log and a deliberately varied set of frequencies, burst lengths and amplitude levels. The comparison should include overlapping emissions so that a deduplication rule has something difficult to decide, and it should include negative control intervals during which nothing is transmitted. If the displayed event rate follows the software's reporting tick rather than the seeded transmitter timing, change the reporting tick without modifying the emitter and look for a corresponding shift in the supposed period. Such a displacement is direct evidence of a measurement artefact, not evidence of a special radiating schedule. The case is still subtler if false triggers are merged into genuine ones. A retained record can represent one emission, many emissions, or a collision of an emission with a noise excursion; the mathematical denominator then requires matching rules, not simple file-row counts. Store the association uncertainty and event lineage, including every automated transformation and the versions of software responsible. I would not require unlimited raw storage in a practical survey, but a bounded audit sample, an immutable decision trace and versioned configuration can permit independent reproduction of the inclusion

Copyright 2026, James M. Atkinson

mechanism. When those controls are missing, the examiner ought to report an unquantified selection limitation rather than reconstruct lost opportunities by imagination. A false impression of meticulous precision is often more dangerous than an explicitly incomplete log.

David Slepian, Peer Question: Mr. Hartley, you have described an equal-probability channel model, but many real and synthetic frequency-agile sequences deliberately suppress channels, employ uneven channel weights or alter their available set after interference assessment. Their temporal behaviour may also be correlated with channel choice, especially when a source holds one frequency longer during a packet exchange. How should the observer construct an exposure model when the hop list is not known, and how would you separate an apparent channel preference from the very different explanation that the scanner visits some frequencies for longer, or has more gain on them? I should like a concrete example with measured exposure time per channel and a statement of what cannot be estimated from events alone. In particular, when might the observed proportion on a channel be an estimator with unavoidable selection bias rather than a legitimate measure of transmitter use? Would you distinguish a conditional channel capture rate from a source channel-use probability even when the analyst has selected a seemingly representative monitoring hour, and how would complete non-exposure of one channel appear in the final uncertainty statement?

Ralph Vinton Lyon Hartley, Response: Professor Slepian, the missing denominator is the central danger. Suppose there are five candidate frequency regions and an archive contains forty bursts in the first region, twenty in the second and ten in each of the remaining three. The raw

Copyright 2026, James M. Atkinson

proportions suggest that the first region is favoured. But if receiver exposure, after lock and recording exclusions, comprises forty seconds in the first region, ten in the second and five seconds in each of the others, the event rates are respectively 1, 2, 2, 2 and 2 captures per exposed second. That result no longer supports the first region as most active, though the rates themselves still mix the emitter's use, detection sensitivity and pulse duration. We have not inferred transmitter occupancy simply by dividing file counts by exposure, because some frequency regions may admit signals more readily and because a single long hop can contribute more apparent event opportunities than a short one. Construct an exposure matrix $E_{c,t}$, where c indexes frequency channel and t indexes discrete time cells. Mark each cell with effective receiver eligibility, gain, threshold, known interference, and a measurement-quality flag. Construct a detection matrix $Y_{c,t}$ from actual eligible observations, retaining missing entries as missing, not as zeros. When an external seeded source is available, estimate a conditional detection probability $d_{c,t}(a,h)$ for amplitude a and hop length h, then use it to describe how a hypothesised source would be sampled. A simple inverse-weighted estimator may be examined when eligibility probabilities are strictly positive and adequately known; it becomes unstable or impossible when a channel has zero or unknown inclusion probability. The mathematical limitation is structural, not a problem that a larger pile of detections can cure. A source which uses channel three only during times when the receiver visits channel one cannot be distinguished from a source which never uses channel three if all observations are confined to those times. The survey design can help by changing channel order, randomising start phases, deploying a second

Copyright 2026, James M. Atkinson

asynchronous sensor or capturing a calibrated wideband segment. These interventions are preferable to assuming independence after the data have been collected. If the hop sequence may adapt to interference, compare tests with and without controlled changes to the artificial interference field in a screened environment; a survey in the field cannot lawfully or credibly create interfering emissions merely to provoke an unknown transmitter. The proper conclusion is conditional on the exposure model and on the lawful measurement controls actually used. An unobserved channel remains unobserved, regardless of how tempting it is to paint the missing cell as empty.

Dr. James M. Atkinson, Moderator: Mr. Hartley, thank you. You have distinguished an opportunity to observe from the appearance of a retained event. Professor Nyquist, I pass the token to you to examine receiver timing, settling and the ways that successive samples can imitate a schedule.

Harry Nyquist, Second Principal Contributor: A scanner's dwell is not a block of perfect attention. It is a series of physical and computational operations whose readiness must be demonstrated. A tuning command changes a synthesiser's desired state; it does not instantly certify the local oscillator's frequency error, phase noise, amplitude settling, intermediate-frequency filter state, or the automatic gain loop's response. Accordingly, the time at which the control programme believes a dwell has started and the time at which measurements meet a specified validity tolerance can differ. Let T_cmd denote the commanded retune time, T_lock the observed time when the oscillator first enters a defined frequency tolerance, T_filter the time when a relevant filter's transient response has decayed into tolerance, and T_agc the time when gain has stabilised within its required amplitude limits.

Copyright 2026, James M. Atkinson

In a conservative test, the first valid measurement time is at least max(T_lock,T_filter,T_agc), and may be later if digital buffers, blanking or synchronisation have independent constraints. A manufacturer's nominal lock indicator cannot replace a measured passband and amplitude response at the actual acquisition reference plane. For clarity, distinguish electrical lock from metrological readiness. A synthesiser might attain a frequency error below ten parts per million in a few tens of microseconds yet retain transient sidebands which make a weak signal undetectable. An IF filter might be stable at its centre frequency but slow to recover from the high-amplitude response to a prior channel. Software may mark samples with their arrival timestamp even though they were acquired earlier and delayed by internal buffers. A scanner with a nominal dwell of five milliseconds and a settling budget of two milliseconds has a usable aperture no greater than three milliseconds, before further blanking. Yet a transmitter's hop may last one millisecond and may begin and end entirely within the excluded interval. The receiver's frequency list can appear exhaustive while its temporal coverage remains very poor. I would not claim a general sampling theorem that makes a hopping waveform reconstructible from undersampled scanner visits. The usual bandlimited continuous-signal sampling argument depends on assumptions radically different from observing a discrete and possibly unknown frequency-hopping state through gaps. What matters here is timebase aliasing and phase relationships. Suppose a synthetic emitter changes frequency every ten milliseconds and the scanner revisits a particular channel every forty milliseconds. A stable relative phase can cause every return to observe the same fraction of the emitter's cycle, making a sparse observation look

Copyright 2026, James M. Atkinson

periodic. If the scanner's revisit interval is instead forty-one milliseconds, the phase changes by one millisecond per revisit relative to the ten-millisecond hop grid; over ten returns it walks through the nominal hop interval, subject to clock error, changing source sequence and measurement gating. This controlled detuning of visit cadence is a diagnostic method, not a guarantee that every event will be seen. Time stamps require an uncertainty budget. If the source reference clock and receiver reference clock have fractional frequency errors epsilon_s and epsilon_r, their relative first-order drift over elapsed time T is approximately T times (epsilon_r minus epsilon_s), assuming small constant errors over the interval. If those errors are respectively plus two and minus three parts per million, the relative magnitude is five parts per million; over one hundred seconds the inferred phase can move by half a millisecond. This is not negligible when a proposed burst period is a few milliseconds. Clock discipline may reduce but not eliminate uncertainty arising from trigger thresholds, sample indexing, timestamp quantisation and processing latency. These components cannot always be combined as independent Gaussian standard deviations; bounded systematic errors must remain separately visible. A useful test reverses the apparent cause. First hold a seeded emitter's hopping schedule fixed and vary only the receiver revisit interval. Second hold the receiver fixed and vary the seeded emitter's start phase by known offsets. Third insert a deliberate and recorded receiver gain-settling perturbation while preserving the transmitted waveform. Record the time-frequency event table and the independent stimulus schedule. If an alleged hop period moves when only the scanner schedule changes, its observed structure is at least partly conditioned by the scanner. If detections disappear when gain

Copyright 2026, James M. Atkinson

settles slowly, a changing threshold is a more plausible explanation than a change in the source. If the feature survives these tests, its evidential force improves, but the source still has not been identified. The experiment should include a channel where no intentional source is present. A retuning transient may itself make a narrow spectral peak through oscillator leakage, IF ringing, synthesiser spurious emission or digital leakage. Because the same tuning commands repeat, the artefact will exhibit a repeatable cadence. It can resemble a burst from an external device, particularly when the instrument records only selected peaks. Conducting the test with a properly terminated receiver input, with a shielded reference source and with a second receiver architecture is a useful discriminant. However, a termination test may change the impedance and common-mode coupling of the instrument; document the altered physical state rather than claiming that all environmental RF paths have disappeared. I therefore insist that the survey log not merely announce the frequency and dwell duration. It must establish the time relationship between the command, actual settled measurement aperture, recorded sample and external reference. A receiver is a clocked physical apparatus, not an omniscient observer. Where its own timing controls are not independently characterised, the strongest statement is that a particular pattern occurred in the receiver's retained observations under a particular schedule. The claim that a transmitter obeyed that same schedule remains a hypothesis awaiting tests capable of separating the two.

John Robinson Pierce, Peer Question: Professor Nyquist, your definition of metrological readiness properly includes synthesiser lock, but a receiver with several local oscillators, a scanning preselector and an automatic

Copyright 2026, James M. Atkinson

calibration path may exhibit multiple recovery intervals, not all visible through the lock indicator. It may also apply a frequency-dependent gain correction while the source is already transmitting. Could a controlled response test reveal that a reported hopping burst is actually an instrument-generated transient, particularly when the transient appears at different absolute frequencies as the receiver retunes? Please explain how to distinguish fixed intermediate-frequency products from a real signal traversing different front-end paths, and how to document the ambiguity when one branch of the receiver cannot be disabled. I also ask whether a real-time wideband capture truly eliminates this problem or simply substitutes another set of sampling, buffering and dynamic-range limits. For example, what outcomes should one expect if the same seeded burst is placed just before lock, just after lock and midway through the stable dwell, while the signal strength and absolute carrier frequency remain unchanged?

Harry Nyquist, Response: Mr. Pierce, a single lock flag is plainly insufficient. Begin with a matrix of physical states: commanded frequency, preselector range, attenuation, preamplifier path, oscillator selection, gain-control mode, calibration status and sample-buffer index. Drive the receiver with a lawful screened reference source whose frequency and amplitude are independently monitored, and take a second dataset with the RF input terminated through a documented impedance. For each tuning transition record not only the time at which a peak appears but its displacement in absolute RF frequency, indicated IF frequency and digital frequency-bin position. An internally produced IF spur may remain at a nearly constant baseband offset when the RF tuned frequency changes, whereas a fixed external carrier moves through the receiver's displayed relative offset. The

Copyright 2026, James M. Atkinson

inference is conditional: image responses, aliasing and mixing products can defeat simplistic versions of that rule, so multiple LO settings and independently measured bandpass responses are necessary. If a peak is produced with no applied reference source and tracks a command transition, treat that as an instrument-origin candidate. If the peak remains after replacing the whole receiver with a second instrument of independent design, the external hypothesis becomes more plausible but is not automatically proved. Shared power, grounding, computer interfaces and nearby radiators can couple into both instruments. A disciplined series changes one reference-plane variable at a time, records the outcome and retains uncertainties. The test should establish the detection threshold before looking at the result, not adjust it afterwards to make a suspected pattern appear. A wideband recorder avoids sequential tuning gaps only within the band it continuously and correctly captures. It still has finite instantaneous bandwidth, ADC quantisation, overload behaviour, anti-alias filtering, dropped buffers, timebase error, dynamic-range competition and software-trigger policies. An extremely strong in-band signal can mask a weak hop even though all samples are nominally present. Short-time Fourier transforms are themselves observation windows: a rapid transition can straddle adjacent windows and create apparent simultaneous occupancy. A fair comparison therefore uses the same seeded source and reports an inclusion region in frequency, time and amplitude for each architecture. No instrument earns a presumption of complete coverage simply because its label contains the words real time. Its measured readiness and its documented data gaps decide what it can establish.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Peer Question: Professor Nyquist, a fixed scanner schedule and a fixed hopping schedule can generate deterministic aliasing, but investigators sometimes attempt to estimate the unseen hopping sequence by searching many period candidates and choosing the most regular apparent reconstruction. That procedure may find an impressive pattern even in a sparse random event list. How would you design a falsifiable test which prevents the analyst from using the same data both to select the period and to assert that the selected period is significant? Please address exploratory versus confirmatory samples, clock offsets, the number of periods examined and a null model that includes the known scanner timetable. I should also like to know how much an apparently excellent fit means when the receiver was insensitive for ninety per cent of the interval, and why one should not call an inferred schedule an authenticated transmission schedule. Would a blind third set of observations obtained with a deliberately changed dwell order offer a stronger refutation test than another random split of the same continuous event log, and why?

Harry Nyquist, Response: Mr. Turing, divide the evidence by function before performing the search. Let one independently delimited acquisition segment be exploratory, with its permitted period interval, phase grid, event inclusion rule and test statistic recorded. Lock those choices, including how many models were considered, before analysing a later segment whose scanner schedule is deliberately changed. Use a null model that generates candidate events under the measured scanner exposure and false-trigger process, not an unrealistic model of uniformly available time-frequency space. If there are M period candidates with roughly independent false-positive probability alpha each, the chance of at least one spurious positive

Copyright 2026, James M. Atkinson

under that simplified assumption is 1-(1-alpha)^M. With alpha equal to 0.01 and M equal to 100, that number is about 0.634. Correlation between candidates changes the calculation, but it does not justify ignoring multiplicity. An observed best fit selected from a large search cannot be tested as though it had been the only proposed model. The proposed confirmatory segment should contain interventions. Change the scanner's visit phase, scan-order random seed and revisit cadence while holding the laboratory emitter fixed. Then change the emitter seed while holding the scanner configuration fixed. If a period estimate persists across materially different observation schedules and follows known changes in the emitter, that strengthens a source-side explanation. If it follows the scanner, the inference fails. These are different experiments, and their results should remain distinguishable in the report. A blind evaluation, in which the person scoring the receiver does not know which synthetic sequence was used for each run, guards against improvised thresholds and unconscious selection of favourable passages. When ninety per cent of candidate intervals are not exposed, even an apparently exact sequence may have many unobserved alternatives. The inference should report that multiplicity explicitly. One can construct distinct hidden hop histories which all agree on the retained events but differ arbitrarily in the unseen gaps. If the observation operator maps these histories to the same retained record, no algorithm acting solely on that record can identify which is correct. That is a question of identifiability, not merely of how clever a search programme becomes. Only additional observations, such as an asynchronous sensor or a lawful reference schedule, can separate those alternatives. Until then I would call

Copyright 2026, James M. Atkinson

the pattern a schedule-compatible hypothesis, not an authenticated transmission history.

Ralph Vinton Lyon Hartley, Cross-Peer Question to Harry Nyquist: Professor Nyquist, I accept your timing analysis but wish to challenge the reporting practice it may encourage. Suppose a survey programme logs eight milliseconds of useable aperture on one channel per forty-millisecond revisit, and an independent clock trace establishes that the transmitter changed frequencies every ten milliseconds. The programme may regard the eight-millisecond aperture as eighty per cent of a hop, even though channel agreement remains unknown. Moreover, if the four scanner visits per 160 milliseconds are phase-locked to the source, the detection events are dependent. Would you require two distinct exposure denominators, one for time and another for the actual channel opportunities, before any empirical capture rate is discussed? Please show how your clock uncertainty and lock-time measurements should enter the denominator without manufacturing fractional observations in time-frequency cells that were never sampled. Finally, can an analyst derive a nontrivial upper bound on undetected activity from this design alone, or must the report state that the unseen transmissions are unconstrained by the record?

Harry Nyquist, Cross-Peer Answer to Ralph Vinton Lyon Hartley: Mr. Hartley, two denominators are useful, although a joint eligibility indicator is ultimately more faithful than multiplying unrelated rates. Let X_c(t) be one when the receiver is demonstrably valid on channel c at time t and zero otherwise; let Z_c(t) indicate that the synthetic emitter is active on that channel. The physically observable overlap duration is the integral over time of X_c(t)Z_c(t), summed across relevant channels, with an additional event-

Copyright 2026, James M. Atkinson

specific minimum-duration and sensitivity rule. X is measurable from receiver telemetry when the measurement chain is adequately instrumented. Z is known in a seeded reference experiment but precisely the unknown quantity in an uncooperative field survey. The investigator may report the integral of X alone, which describes where the receiver was capable of observing; the overlap with Z cannot be calculated in the field without additional assumptions. Multiplying temporal coverage by an imagined uniform channel probability hides that distinction. For timing uncertainty, give each aperture start and end a bounded or probabilistic interval. In a conservative exposure calculation, exclude edge portions for which validity cannot be guaranteed. With an eight-millisecond nominal effective aperture and start uncertainty of 0.2 millisecond plus end uncertainty of 0.2 millisecond, the guaranteed common interior may be only 7.6 milliseconds, if these are bounded outward uncertainties and the original figure was not already conservative. That does not create an extra 0.4 millisecond of evidence; it reduces a claimed ability to observe. For a statistical calculation one may instead propagate a justified timing-error distribution, but do not combine that with the conservative result as though both were simultaneous independent allowances. A nontrivial bound on missed events requires a finite possible event population or a model restricting source duty cycle, amplitudes or allowed channels. If an emitter may transmit arbitrarily many brief hops only during the receiver's gaps, the observed data impose no finite upper bound on that unseen count. With a known laboratory emitter and a stipulated random independent phase model, one can calculate a probability interval for the number of misses. Such an interval is a conditional model result, not an unconditional forensic

Copyright 2026, James M. Atkinson

fact. My conclusion agrees with yours: the evidence certifies eligible observation intervals and actual detections, while its silences must be left silent unless independent information restricts what might have occurred there.

Dr. James M. Atkinson, Moderator: Professor Nyquist, thank you for separating oscillator lock from metrologically admissible measurements. Professor Shannon, kindly take the token and address inference from incomplete and non-random observations, including what repeated negative visits may establish.

Claude Elwood Shannon, Third Principal Contributor: The central inferential question is not whether a hopping transmission can be imagined, but whether the distribution of retained observations distinguishes one hypothesis from another after conditioning on the receiver's selection mechanism. Let H_0 denote the hypothesis that events arise from a specified background and instrument process, and H_1 denote the hypothesis that a synthetic frequency-hopping source contributes to them. An analyst may calculate a likelihood ratio $L = P(Y|H_1,E) / P(Y|H_0,E)$, where Y is the retained event table and E describes the frequency-time eligibility of the scanner, its detection threshold and its stated error process. This notation is only meaningful if both conditional models are specified. A raw ratio constructed without E is liable to favour a source hypothesis solely because the scanner's schedule has produced a striking pattern of selective observation. It is particularly dangerous to treat the absence of observations in unvisited channels as an absence expected under H_0 but not under H_1. The difference between missing at random and missing in a structured way matters. If the scanner visits channel one more frequently when its control

Copyright 2026, James M. Atkinson

programme predicts a particular periodic event, the inclusion probability may depend on the very hypothesis under test. If the receiver's gain is lowered after an overload, later weak bursts may be missed preferentially after strong ones, creating apparent inhibition or alternation in the sequence. If the source adapts to interference and the scanner's own configuration changes the interference environment, an apparent relation between observation time and source activity may be causal in either direction. These mechanisms cannot be exchanged for the convenient assumption of independent Bernoulli detections without evidence. They require a model of how Y came to be retained. For an intentionally simplified laboratory example, suppose a known source sends N = 1000 independently timed candidate bursts, each having a known encounter-and-detection probability p = 0.02 under a randomised receiver schedule. The expected number of detections is Np = 20, with variance Np(1-p) = 19.6 and standard deviation approximately 4.427. A normal approximation would therefore suggest fluctuations of several detections even when the source and receiver remain perfectly stationary. But it would be wrong to take this binomial calculation into a deterministic scanner-source phase-lock scenario, where a single random phase may determine outcomes for many repeated cycles. A sequence of related failures does not create the thousand independent pieces of information assumed by the variance formula. An effective-sample calculation or an explicit schedule simulation is then required. One should distinguish probability of at least one detection from probability of reconstructing a hop list. Under N independent opportunities with common detection probability p, the former is 1-(1-p)^N. At p = 0.02 and N = 100, this is approximately 0.8674. Yet a high chance of seeing at

Copyright 2026, James M. Atkinson

least one burst provides very little evidence about the unseen ninety-nine opportunities, and may be nearly useless for estimating the number of channels or the periodicity of a hidden sequence. A receiver can be likely to detect something while remaining incapable of determining the source's full operation. If p varies by opportunity, the probability of at least one is 1 minus the product of (1-p_i) over the indexed opportunities, assuming conditional independence; without that independence, the product is not justified. There is also a distinction between entropy of the observed channel labels and entropy of the true hopping sequence. Suppose the source uses ten channels uniformly but the receiver spends half its eligible time on one channel, with equally effective sensitivity elsewhere. The retained label distribution will be biased towards the frequently visited channel even if the transmitter is perfectly uniform. Computing Shannon entropy on that selected list measures a feature of the combined source and observation operator. It neither authenticates the source nor quantifies the intrinsic unpredictability of a hidden hopping algorithm. The correction would require exposure information and a validated model of detection probabilities on each channel. If a channel has zero probability of being observed, its contribution is not statistically recoverable without external restrictions. To evaluate a claimed schedule, construct independent blinded trials with seeded hopping sequences. Some trials should use genuinely random channel order; others deterministic cycles; others intentionally phase-locked and intentionally phase-shifted scanners. The analysis protocol should specify before release of the seeds how hypotheses will be compared and what statistic counts as a success. False-positive rates should be assessed by repeating the entire period-search procedure on null trials, not

Copyright 2026, James M. Atkinson

by calculating a nominal single-period significance threshold after the best period is already selected. Report not only successful detections but the full confusion matrix of schedule hypotheses, including missed source events, instrument transients misclassified as hops and indeterminate results. This is a lawful defensive measurement problem, not a licence to reconstruct message content, access protected communications or identify an individual sender from an RF pattern. The experimental source should transmit arbitrary known test sequences in a screened or otherwise authorised setting. The interesting inference concerns properties of the measurement and its failure modes. A conditional statement, such as 'the observations favour a time-varying signal under these exposure and noise assumptions', can be scientifically valuable while remaining intentionally silent about the unknown emitter's identity, purpose and payload. My closing warning is mathematical rather than rhetorical. Every claim about what a sparse scan proves must carry its sampling condition with it. Information lost through an observation operator cannot be restored merely by applying a clever estimator to the operator's output. A carefully stated distribution over possible unobserved histories is sometimes possible; a unique historical record of those hidden events is not, unless independent constraints make the inverse problem identifiable.

John von Neumann, Peer Question: Professor Shannon, your proposal of a likelihood ratio conditional on the sampling schedule is attractive, but a practical investigator seldom knows either the noise model or the dependence structure of events. A nearby unintentional emitter may produce bursts with clustered arrival times, while a scanner's own retuning artefacts produce regular peaks. Both could create a large ratio in favour of

Copyright 2026, James M. Atkinson

some poorly chosen frequency-hopping model. How should one prevent the analyst from fitting the model so flexibly that it explains every observation, and how should the model treat the entire timetable of blank periods? I ask you to propose an operational null experiment using a terminated input, a laboratory dummy source and deliberately varied scanner schedules. Please include a way of evaluating the uncertainty introduced by estimating model parameters from the same sparse dataset subsequently used for inference. Please also address what happens when a model can explain a false peak by inventing one extra hidden hop: how may one quantify the cost of that flexibility without silently suppressing alternative instrument explanations?

Claude Elwood Shannon, Response: Professor von Neumann, the danger of a flexible model is precisely why model complexity and prospective testing must enter the design. Begin with a null collection recorded using the same receiver states, scan timetable, gain settings and processing pipeline but with the authorised test source disabled. Include deliberately varied nearby benign stimuli where lawful and practical, because a terminated input alone will not reproduce all field interference or every common-mode coupling path. Use these observations to characterise frequency-dependent false-trigger rates and correlations with retuning. Next construct a separate source-present library with known synthetic burst times and channels. Hold out whole acquisition sessions, rather than randomly splitting adjacent events, since neighbouring events share a clock, a scan phase and potentially an AGC state. The evaluation should compare models on sessions whose emitter seeds and receiver start phases were not used to tune the inference procedure. A likelihood ratio must be scored against a specified candidate set. If the alternative contains all schedules whatsoever, it can

Copyright 2026, James M. Atkinson

generally fit the retained sample too well. Specify a finite family of physically plausible synthetic schedules, use penalties or predictive scoring selected before testing, and report the number and type of alternatives searched. It is useful to include an 'unmodelled or indeterminate' outcome rather than force every record into one of two attractive labels. Calibration curves should show whether observations assigned a probability of 0.8 truly exhibit the event in approximately eight of ten comparable blinded trials, not merely whether the classifier chooses the correct label on a favourable subset. For parameter uncertainty, use a nested procedure. Fit nuisance quantities such as per-channel false-trigger rates and exposure-related detection probabilities on the training data, then evaluate on independent held-out trials. Within training, a bootstrap may resample complete acquisition sessions or seeded cycles rather than individual detections, preserving much of the dependence structure. Sensitivity analysis should repeat the inference over plausible ranges of clock error, unmeasured dead time and gain recovery. If conclusions reverse under modest changes to these parameters, the report must not conceal that fragility. The blank periods enter the model as explicit unobserved intervals, never as events with zero source power. A terminated input result can discredit a proposed external cause of a particular peak if the same peak remains under an adequately controlled termination test, but its absence under termination alone is not proof of an external radiating source in the original field arrangement.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Professor Shannon, let us examine a concrete problem with confounding between sampling and signal schedule. In one seeded trial the transmitter changes

Copyright 2026, James M. Atkinson

channel every ten milliseconds, while a scanner cycles every forty milliseconds; in a second trial the scanner cycle is altered to forty-one milliseconds without changing the emitter. The second produces a much richer set of observed channel labels and more apparent periodic structure, although the transmitter is identical. Can your likelihood method avoid declaring the second trial a stronger source solely because its design provides more opportunity? I ask how you would normalise or condition on frequency-time exposure, what should be done when the detector probability is unknown at some channels, and whether two conflicting data sets can both support the same underlying source hypothesis without forcing their observed event histograms to agree. Please specify a falsification criterion rather than relying on a flexible post hoc explanation. Should the confirmation criterion therefore be stated in terms of prediction under a new scan-phase distribution, rather than a desirable minimum number of logged bursts alone?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Professor Nyquist, the legitimate comparison conditions on each trial's exposure operator. Label the two records Y_40 and Y_41 and their recorded eligibility schedules E_40 and E_41. Fit a common hypothesised synthetic source process S, but calculate separate observation likelihoods P(Y_40|S,E_40) and P(Y_41|S,E_41), including known detector properties. More detections in the forty-one-millisecond trial need not favour the existence of S over a comparable null if the exposure schedule itself predicts more detections. A useful normalised discrepancy is the observed count minus its model-conditional expected count, accompanied by a variance or predictive interval that reflects cycle dependence. It would be misleading to compare raw

Copyright 2026, James M. Atkinson

counts without conditioning on those unequal expected opportunities. When detector probability is unknown on some channels, do not replace it with the average from measured channels merely for convenience. Report a range of predicted outcomes under a justified sensitivity envelope, or designate the likelihood contribution of those channels unidentified. If an alternative model predicts zero expected probability for an event that is clearly present in a demonstrably valid aperture, it may be falsified, subject to false-positive controls. More generally, predefine a predictive scoring rule and a rejection threshold using independently simulated or seeded null trials. A source hypothesis that consistently predicts detections in eligible apertures where none appear, despite independently measured high detection probability, may be rejected. Conversely, it cannot be rejected simply because unvisited channels did not yield records. The two observations can support the same source because their measurement operators are different. This is the most important result: a physical source has one latent state history but each instrument projects that history through a different function. The observed histograms are not required to match. What is required is that a common S, combined with each documented E and independently measured measurement errors, predicts the relevant features of each record without continually inventing new unobserved corrections. An explicit third blinded trial with a new scanner timing law provides a meaningful test. If the model fails that prospective trial, the investigator must revise or reject it rather than rescue it with a newly assumed hidden channel list. The scientific test is prediction under changed observation, not retrospective narrative coherence.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Shannon, your distinction between source history and the observation operator is accepted for the purposes of this hypothetical exercise. Professor Hamming, please take the token and address missed-hop populations, evidential error handling and the danger of interpreting an imperfect event log as a complete discrete sequence.

Richard Wesley Hamming, Fourth Principal Contributor: A sparse event sequence invites the analyst to tidy it into a complete one, and that tidying is often where the most consequential error occurs. In coding theory we may speak of an alphabet and a sequence of symbols, but the receiver's event list is not necessarily a faithful list of transmitted channel symbols. Some hops were never in the receiver's passband. Some were inside the passband yet fell below the threshold. Others produced detector events which were mislabelled by finite filter selectivity or missed because the receiver was not ready. Still others may have been merged by software into adjacent events. These are different error mechanisms: deletion, substitution, insertion and timing displacement. A sequence-analysis programme that handles them as one homogeneous random noise term forfeits the very distinctions needed for forensic reliability. Let the true synthetic hop sequence have length N and let the retained event sequence have length M. Unless the test source provides ground truth, N may be unknown and an event cannot safely be assigned to a unique transmitted hop. A useful alignment may therefore contain unobserved positions rather than fabricated channel labels. Let d_i be the probability that true hop i is deleted by the observation process under a stated model, s_i the conditional probability that its channel label is wrong when retained, and f_i a false event insertion parameter over a

Copyright 2026, James M. Atkinson

defined eligibility interval. These quantities are not universally constant. Detection deletion can depend on channel, amplitude, burst length, antenna polarisation and scanner state. Receiver transients may make false insertions more likely immediately after a retune, and adjacent-channel leakage can make substitutions systematically biased rather than symmetric. Consider a twenty-hop seeded laboratory source. Suppose only six source hops encounter eligible receiver apertures; of these, four yield valid detector events; one event is assigned the neighbouring channel by an incorrectly characterised filter and the logger adds one false transient peak. The final file contains five event rows, not twenty. Counting the five rows cannot recover the source's sixteen unreported hop positions, and the one false row is not simply another source hop. A ground-truth comparison should therefore produce a provenance table showing twenty transmitted positions, six eligible intersections, four triggered source bursts (three correctly channel-labelled and one mislabelled), and one additional false event, with clear matching rules and uncertainty. The exact numbers in this example are stipulated, not empirical claims. Their value is to expose how many distinct explanations are obscured by a neat-looking output table. Error correction is not an instrument of historical divination. A decoder corrects errors only because a known code constrains admissible transmitted sequences and because an error model supplies some basis for choosing among possibilities. If neither the hopping code nor the initial state nor the observation channel is established, a regular-looking completion may be one of many. The familiar minimum-distance argument cannot be invoked as proof that an unknown transmitter used a particular schedule. Nor should an analyst try to recover protected payload content

Copyright 2026, James M. Atkinson

under the pretence of validating channel hops. A defensible test can use a synthetic seed known to the test authority and compare the receiver's ability to reconstruct that public test sequence without ever accessing a private communication message. Time alignment itself should be challenged. If the scanner measures a burst after oscillator lock and software processing delay, that recorded timestamp may fall in the next nominal hop period. A sequence matcher may label it a channel substitution when it was in fact a correct channel event with a shifted time. Conversely, a false peak following each retuning command may appear as a perfectly consistent hopping schedule if the programme correlates event order rather than absolute time. Preserve independent hardware timestamps, reference clock histories and trigger delays where available. The scoring rule should allow an indeterminate association instead of forcing every event into a nearest-neighbour match. For each seeded experiment, report precision and recall as separate metrics. Precision is the number of correctly matched retained positives divided by all retained positives, after rules for ambiguous matches have been settled. Recall is the number of true source events correctly detected divided by the independently known true source events within the stated opportunity population. One can also report recall conditional on receiver exposure, which answers a different diagnostic question: how often did the system detect an event it could in principle observe? This conditional recall can be excellent while overall source capture remains dismal. Reporting only it would let a narrow but exquisitely sensitive scanner appear equivalent to a receiver that covers the entire relevant band continuously. Failure-mode testing should be adversarial in an editorial sense, not in a communications-intrusion sense. Seed bursts exactly at dwell boundaries,

Copyright 2026, James M. Atkinson

deliberately vary amplitude near the detector threshold, schedule a hop during the source's own transition, and use benign adjacent-channel reference signals to measure mislabelling. Record how error rates change with each controlled variable, and leave untested field conditions outside the claimed performance envelope. The purpose is to show the reader how the evidence breaks, not to pretend that every missing sample has a recoverable label. The final evidential object is therefore a partial sequence with typed missingness and typed uncertainty. Its legitimate product may be a family of schedule-compatible hypotheses and a quantified observation limitation. Such an account is not a failure to solve the problem. It is a correct statement of the information that survives the receiver's narrow and intermittent contact with the source.

Ronald Newbold Bracewell, Peer Question: Professor Hamming, suppose an investigator collects two imperfect event lists using two independent receiving antennas at different positions. Their geometries, polarisation responses, multipath and front-end overload behaviour differ. It is tempting to merge their detections into one supposedly complete hopping sequence and treat matching timestamps as confirmation. Yet shared clock errors or a common interfering signal may correlate both lists, while different propagation fades may cause genuine events to appear in only one. How would you establish an association rule and guard against double counting when an emission is detected at both stations? Could a second receiver also create a misleading impression of extra hop channels through its own images or local oscillators? Please describe a validation design that separates diversity gain from correlated instrumental failures, and how uncertain event associations should be recorded rather than retrospectively

Copyright 2026, James M. Atkinson

forced into a single answer. What separate reference measurements should document timestamp correlation through a shared clock distribution, and would those tests have to be repeated after changing antenna cables or front-end gain configurations?

Richard Wesley Hamming, Response: Professor Bracewell, a second receiving system provides new information only to the extent that its observation errors are separately characterised. First synchronise the clocks against an independent reference or document the transformation and uncertainty between them. Then set a predeclared association window which includes timestamp uncertainty, possible propagation delay differences, filter latency and known processing delays. The association should consider occupied frequency and bandwidth within calibrated tolerance, not just near-simultaneous event times. Give each candidate detection an immutable local identifier and preserve a many-to-many association table, because a source burst can generate more than one detector event and an ambiguous peak can match several possible source events. Do not simply concatenate the two event lists and call the result the number of transmitted hops. Use a screened reference emitter with a known hop schedule and move one antenna through documented orientations and positions. Introduce a controlled fading or attenuation condition in one receive path while leaving the other stable. Separately test each receiver with terminated RF input, fixed known tones and input levels near overload to identify its own image and intermodulation signatures. A signal which appears at a stable internal IF offset in only one receiver as its tuning changes is suspect, while a signal appearing in both through physically independent paths with consistent frequency, time and direction

Copyright 2026, James M. Atkinson

may strengthen the external-signal hypothesis. The conclusion still depends on excluding common pickup through shared cables, network timing systems or power supplies. For scoring, separate source-level recall from station-specific recall and from the fraction of source events detected by at least one station. A simple union probability p_A+p_B-p_Ap_B presumes conditional independence of station detections given the source event. Multipath fading or shared front-end interference may violate that assumption. Estimate joint detection outcomes on seeded trials or report bounds rather than assert the product formula for the field. Where association is uncertain, assign a status such as possible duplicate, possible independent event or unresolved. A report that preserves these distinctions remains auditable when a later calibration reveals a timing offset or a previously unknown image response. Confidence arises from measured error behaviour, not from making two instruments agree by editorial force.

Claude Elwood Shannon, Cross-Peer Question to Richard Wesley Hamming: Professor Hamming, your partial-sequence model invites a difficult inference question. In a controlled trial the true source sequence is known, so deletion, insertion and substitution may be estimated against it. But in the field we possess only the censored output of the receiver, and an unknown source might emit additional hops on frequencies never sampled. Can a scoring algorithm distinguish the possibility of a short hopping sequence with few misses from that of a much longer sequence with frequent misses? Please identify which parameters are jointly unidentifiable and explain whether a prior distribution can make the reconstruction uniquely true rather than merely conditionally probable. I also request an explicit account of how source-generated burst silence differs from receiver-

Copyright 2026, James M. Atkinson

imposed observation gaps, since these are often conflated by event-list programmes that write zeros where the instrument recorded nothing. Could you specify how an analyst should record incompatible hypothetical completions of a partial sequence without turning their relative model scores into an asserted history of actual emissions?

Richard Wesley Hamming, Cross-Peer Answer to Claude Elwood Shannon: Professor Shannon, the two histories can indeed be observationally equivalent. Suppose the output contains five correctly labelled events at five distinct times. One latent model has five actual source events and detects all of them; another has fifty source events and detects one in ten, with the other forty-five occurring in unobserved intervals or below the sensitivity threshold. Without independent restrictions on transmission rate, allowed channels, hop duration or receiver capture probability, both models may fit the same event list. A prior can rank the models if its assumptions are accepted, but it cannot convert conditional plausibility into an authenticated historical fact. The posterior distribution speaks of uncertainty under that prior and observation model. It is not a recovered record of events which no instrument saw. The missingness distinction can be represented with three states rather than one binary variable. Mark a cell 'observed occupied' when an eligible measurement satisfies the detector rule, 'observed not detected' when a valid eligible measurement does not satisfy it, and 'not observed' when the receiver was elsewhere or invalid. Even observed not detected does not imply the transmitter was silent; it means the measurement did not cross the selected threshold. If the source reference is independently known in a seeded trial, an additional ground-truth state distinguishes actual emitter silence from actual source activity. It must not be invented in

Copyright 2026, James M. Atkinson

a field record. An alignment algorithm should therefore retain an explicit null association for both absent source evidence and unexplained detector events, with the appropriate type. It may calculate a likelihood for proposed latent sequences if the receiver model has been calibrated, but it must display alternative sequences with comparable scores and disclose dependence on assumed channel weights or dwell times. An honest minimum-error reconstruction can be useful for testing instrument configurations against synthetic truth. It is not a warrant to fill unknown field intervals with fictional hops. I would require the report to give a lower bound on directly observed distinct events and to avoid an upper bound on true unobserved events unless source rate and duration constraints make such a bound defensible. The distinction between zero and missing is the foundation of the entire enterprise.

Dr. James M. Atkinson, Moderator: Professor Hamming, thank you for identifying insertions, deletions and uncertain associations without inventing missing observations. Mr. Armstrong, I now pass the token to you for a physical receiver-chain analysis and practical defensive survey protocol.

Edwin Howard Armstrong, Fifth Principal Contributor: The state of the receiver must be as thoroughly investigated as the state of the air. A scanning radio can be an excellent instrument for locating an unexpected carrier and still be an inadequate instrument for reconstructing a brief frequency-hopping schedule. The same front-end that provides selectivity also imposes a finite response to changes in frequency. Its preselector may switch a tuned circuit or filter bank; its mixer may encounter strong signals on adjacent channels; its amplifier may saturate and recover over a period not represented by the nominal dwell; and its intermediate-frequency chain

Copyright 2026, James M. Atkinson

may respond to a recent channel after the software reports that the receiver has moved to the next. A spectral peak is a result of the entire receiving chain, not a sealed envelope delivered by the transmitter. I would start with a physical block diagram for each survey configuration. Record antenna polarisation and orientation, cable and connector condition, limiter and attenuator settings, filter response, low-noise amplifier linearity, mixer conversion, oscillator spur spectrum, digital sampling rate, anti-alias filtering, detector bandwidth and display persistence. The operator should know where any preamplifier sits relative to a preselector, since a powerful out-of-band signal may overload a wideband preamplifier even when a downstream filter rejects it. If the instrument retunes across a region containing strong nearby services, the apparent dwell-to-dwell variation in weak-signal sensitivity may follow gain compression or recovery, not an agile source. The survey cannot honestly claim a uniform detection threshold across all channels without measuring the relevant reference-plane sensitivity in those states. Consider a synthetic source which emits a one-millisecond burst on each of sixteen known channels, with a twenty-millisecond nominal interval between starts. A receiver which visits each channel for five milliseconds but requires two milliseconds for lock and another one millisecond before its filter response and gain are within tolerance has at most two milliseconds of effective exposure per visit. Its per-channel revisit period is eighty milliseconds, excluding overhead beyond the stated five-millisecond allocation. If the emitter and scanner share an unfortunate relative phase, a given channel's burst can systematically fall outside those two-millisecond windows. Increasing the nominal dwell to six milliseconds increases the effective exposure to three milliseconds under

Copyright 2026, James M. Atkinson

unchanged transition conditions, but it also makes the complete sixteen-channel sweep ninety-six milliseconds. Whether capture probability improves depends on phase, channel distribution and source behaviour. More dwell is not unconditionally better, because an additional millisecond of attention to one frequency is an additional millisecond away from another. The operator should therefore compare surveillance architectures rather than revere one setting. A sequential narrowband scanner offers useful selectivity and dynamic range but poor simultaneous coverage. A parallel bank of several narrowband channels can remove some tune gaps at the cost of calibration complexity, cable splitting loss, interchannel mismatch and common reference coupling. A wideband receiver can observe many channels continuously within its instantaneous bandwidth, but front-end linearity and quantisation must be checked against the strongest signals present. A swept analyser can give a convincing broad picture while missing short events between sweep positions. A real-time spectrum display may improve temporal visibility yet still aggregate data through finite windows and be unable to show a below-threshold event. The engineering decision should be expressed as a trade-off between instantaneous frequency span, sensitivity, dynamic range, temporal completeness and auditable event retention. Controlled substitution is the most persuasive diagnostic. Inject a known synthetic hop sequence at a documented input reference plane and verify its power and timing with an independent measurement instrument. Repeat across channel frequencies and amplitudes, especially near the claimed detection threshold. Repeat with the source replaced by a termination, with the antenna relocated or reoriented and with an alternative preamplifier path. Where practical,

Copyright 2026, James M. Atkinson

substitute another receiver with a different oscillator or IF arrangement. Observe whether an alleged hop persists at the same absolute external frequency and time or follows an internal tuning operation. A genuine external signal may disappear with antenna orientation or propagation fade, so loss under one substitution does not automatically mean the earlier signal was false; interpretation requires an explicit hypothesis for what the intervention was intended to test. A useful uncertainty table includes amplitude calibration uncertainty, noise-floor variance, gain drift, trigger-level error, frequency error and timestamp error. These are different physical quantities and must not be combined casually into a single mysterious percentage. For example, if a known test burst is nominally 6 dB above the stated detection threshold and the receiver's measured amplitude uncertainty is 2 dB under the test conditions, it is not valid to call the event guaranteed simply because six is greater than two. The threshold decision also depends on noise fluctuations, filter integration and the signal's effective overlap duration. Specify whether the quoted 2 dB is a standard uncertainty, a worst-case bound or a manufacturer's tolerance. The probability of successful detection must be established from an appropriate ensemble of trials or from a defensible probabilistic model. Lawful defensive collection can be designed to avoid intrusive content acquisition. Use aggregate power statistics, frequency-time occupancy, instrument state and synthetic test sequences; if complex RF samples are needed for bounded calibration, control their storage and exclude protected communications decoding. A survey of premises should maintain a chain of custody for instrument configuration and output files, including firmware revisions, host clock settings, calibration certificates and the checksums of retained

Copyright 2026, James M. Atkinson

records. A temperature change during the survey may alter oscillator performance or cable attenuation, so environmental conditions and their temporal relationship to the observations belong in the technical record. Finally, the physical path may make events appear on channels where no transmitter hopped. Mixer images, reciprocal mixing from strong adjacent carriers, oscillator leakage and intermodulation can create peaks which follow receiver tuning and bear a false resemblance to a frequency-agile pattern. In a forensic setting this is no small technicality: a regular succession of receiver-generated peaks may look more purposeful than genuine traffic obscured by fading. The survey succeeds when it reveals the limits of its own sight as clearly as it reveals any emission. The scientific conclusion should state what was directly captured, what was verified under a reference stimulus, and what remains indeterminate because the receiver was not in a position to observe it.

Antony Hewish, Peer Question: Mr. Armstrong, a radio telescope and a premises survey receiver differ greatly in scale, yet both are vulnerable to internal signals that masquerade as celestial or external emissions. In a frequency-agile survey, a repeated local-oscillator spur, clock leakage or switching pulse may recur precisely when the scanner visits particular settings, while a genuine emitter can also produce intermittent events through fading and directional antenna response. How would you design a measurement programme that separates those explanations without relying on one attractive waterfall display? I am especially concerned about the interaction between antenna substitution, cable routing, shielding, input termination and common-mode currents. Please explain why a disappearing peak is not always sufficient to locate its cause, and how observations from

Copyright 2026, James M. Atkinson

multiple antennas or sites should be reconciled when their sensitivity and time exposure differ substantially. I would also ask how an investigator should handle a weak signal that survives an antenna substitution but changes its apparent duration because the two receiving chains possess different filters and trigger rules.

Edwin Howard Armstrong, Response: Professor Hewish, I would design a sequence of interventions with their predicted effects written down before observing the result. In the first configuration, retain the ordinary antenna and cable path and log the instrument's exact tune sequence, front-end states and detector traces. In the second, apply a matched termination at the receiver input, keeping power, computer connections and the local clock arrangement as similar as possible. In the third, substitute an independently calibrated source at the same reference plane and reproduce an authorised set of burst frequencies and amplitudes. In the fourth, alter antenna polarisation, location and cable routing one variable at a time, monitoring changes in common-mode cable currents where suitable measurement equipment is available. Finally, repeat the suspect frequency region with an independent receiver design and a documented reference timebase. Each step has a causal target and a limitation. A peak persisting with the input terminated may support an internal-origin hypothesis, but it can also reflect radiation entering the instrument elsewhere, including through its power or digital cables. A peak disappearing under termination could be due to an external emitter, antenna-coupled instrument leakage or the different loading of an imperfect input circuit. Similarly, relocating an antenna can change the response to a genuine external signal through multipath interference without relocating the source. The report should express which

Copyright 2026, James M. Atkinson

hypotheses were made less plausible by each intervention and which remained open. A directional inference from amplitude differences requires a characterised antenna pattern, polarisation information and propagation conditions, not merely a louder trace at one position. For multiple sites, preserve separate exposure maps and sensitivity calibrations before combining detections. A second site may see a burst that the first could not observe because it was tuned elsewhere, and the lack of agreement is not itself contradiction. If both record the same event, use bounded clock uncertainty and frequency agreement to establish a possible association, then record that association as one candidate source event rather than two definite independent transmissions. If the first site used a high-gain antenna and the second a short test lead, raw occupancy counts are not comparable. A joint report should show site-specific eligible time, detector settings, antenna factor and missed-signal behaviour under a common synthetic stimulus. Only after those are known can repeated observations strengthen a common-source hypothesis. The strongest evidence is generated by a procedure that can fail its favoured interpretation. If the alleged pattern follows receiver tune commands when the synthetic source is disabled, it is not evidence for a hopping external transmitter. If the pattern survives independent clock, receiver and antenna substitutions and corresponds to a controlled source's known events, it supports the competence of the survey method. In an unknown field case, even that competence does not prove the identity or intent of the radiating source. The appropriate endpoint is a bounded observation, a reproducible test record and an explicit account of remaining alternative causes.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Cross-Peer Question to Edwin Howard Armstrong: Mr. Armstrong, your substitution tests should reveal instrument-generated events, but I wish to press a statistical objection. Suppose an operator changes from a scanning receiver to a wideband recorder and sees three times as many bursts. One might conclude that the scanner missed two thirds of the source activity. Yet the wideband recorder may be triggering multiple times on each emission, include noise peaks or respond to different bandwidth and threshold settings. Conversely, its analog-to-digital converter may be overloaded by a strong signal, hiding genuine weaker hops. How would you define common event truth and comparable detection rules before judging the two receiver architectures? I ask for an explicit reconciliation of detection count, event duration, frequency resolution and false-trigger rate, including what should be done when the source is unavailable for controlled repetition. Moreover, would you insist upon testing both receivers with common synthetic strong adjacent signals, so that apparent sensitivity improvement is not confused with overload or a changing event-splitting rule?

Edwin Howard Armstrong, Cross-Peer Answer to Richard Wesley Hamming: Professor Hamming, the raw ratio of three to one is not a missed-event fraction. First define a source event in the synthetic reference experiment as a transmitted burst with a specified start, end, nominal centre frequency, occupied bandwidth and permitted timing tolerance. Next create a common matching rule. A receiver event is a correct detection only if its frequency-time region overlaps a known source event by a prespecified criterion and its measured attributes satisfy documented error tolerances. Multiple triggers matched to one source burst count as one source detection and

Copyright 2026, James M. Atkinson

additional retained detector events; they should not inflate the event-level recall. Triggers that match no source burst count towards false detections, subject to the known independent source log and chosen association rules. The two instruments must then be tested against a common source across amplitudes, channel frequencies, burst durations and deliberately introduced strong interferers. Compare sensitivity at a common physical input reference plane, with receiver bandwidth and gain corrections recorded. If one detector integrates energy over a long window while the other uses a shorter threshold crossing, their observed event durations may differ even for the same source burst. Measure that difference rather than declare either instrument's duration the transmitted truth. Calibrate frequency discrimination with two nearby known tones and record the circumstances under which the wideband architecture merges them or the scanner misclassifies one through a filter skirt. Compute at least three separate rates: source-event recall, false retained events per eligible observation time, and duplicate triggers per correctly matched source event. Report those rates by frequency and amplitude. A wideband recorder may achieve higher recall in a sparse, brief-burst experiment while suffering a higher false-event rate at a more permissive threshold. It may also become less reliable under overload. The distinction is quantitative and experimentally testable; the adjective wideband settles none of it. Without an available source for repeatable calibration, one may compare coincident observations with care, but the real source's true event count remains unknown. Use a common artificial reference transmitter or signal injector as a calibration surrogate, clearly stating the conditions it represents. Preserve the raw observations and unmatched associations, and call the result a

Copyright 2026, James M. Atkinson

receiver-comparison study rather than a measurement of a particular unknown emitter's total missed hops. A test which cannot establish ground truth cannot compute absolute recall. It can identify relative differences under its own controlled conditions, which is a respectable conclusion if described without exaggeration.

Dr. James M. Atkinson, Moderator: Closing Synthesis: The panel has distinguished scanner dwell from valid measurement exposure, channel agreement from mere temporal overlap, and a retained event list from a transmitted hop history. It has shown why fixed scan phases can alias a synthetic schedule, why timebase and receiver settling errors can create apparent periods, why non-detection in an unvisited channel is not evidence of transmitter silence, and why multiple instruments should be compared against common seeded truth rather than their raw file-row counts. The appropriate defensive protocol is to log every eligible frequency-time aperture and instrument state, characterise receiver detection and false-trigger behaviour, run blind seeded reference tests with changed scanner phases, and retain uncertainty and alternative hypotheses in a reproducible evidence record. No participant has recovered protected message content or authenticated an unknown transmitter, and the historical dialogue is an original fictional reconstruction, not a record of actual speech.

QUESTION 084

Copyright 2026, James M. Atkinson

When does cyclic-prefix correlation indicate multicarrier structure rather than periodic interference?

SCHOLARLY RECONSTRUCTION. This is a fictional posthumous scholarly dialogue for educational purposes. The deceased contributors did not meet to debate the named modern waveform, and no passage purports to reproduce their historical speech. Illustrations use authorised synthetic signals and calibrated test receivers; the discussion does not decode protected communications or establish transmitter identity.

Dr. James M. Atkinson, Moderator: Dr. Shannon, I should be grateful if you would begin with the exact observation rather than the alluring name of the waveform. Our hypothetical laboratory receiver has detected an elevated lag-correlation peak in complex baseband samples. Explain what repetition in time actually demonstrates, what a cyclic prefix predicts, and which alternative physical mechanisms remain compatible with the same numerical result. You have the token.

Claude Elwood Shannon, Principal Contributor: The word correlation names a relationship among observations, not a manufacturer, protocol or source of intent. When a receiver reports a large sample correlation at some lag, it has demonstrated that two portions of the collected sequence resemble one another under a particular definition of resemblance. The resemblance can arise through an intentional redundant interval, through a periodic interferer, through multipath, through a digital resampling mechanism, or through repeated structure manufactured within the measurement instrument. None of those causal claims follows from the magnitude of a single estimated correlation coefficient alone. The proper task begins by

Copyright 2026, James M. Atkinson

defining a contest among hypotheses rather than attaching the label of a favoured modulation immediately after seeing a peak. Let x[n] be a complex baseband sample at integer sample index n and let L be a positive sample lag. For an eligible window of length W samples, a lag product may be written R(L,n0)=sum from k=0 to W-1 of x[n0+k] times the complex conjugate of x[n0+k+L]. The associated normalised squared coherence may be defined as C(L,n0)=|R|^2 divided by the product of the two corresponding sample-energy sums. C is between zero and one when the denominator is positive. It does not possess an evidential interpretation without specifying n0, W, the candidate lags, the receiver's filtering and the noise model. A small denominator in a near-silent window demands special exclusion or a stabilised calculation, because normalisation does not create valid information from instrument noise or a numerical underflow. In a conventional cyclic-prefix multicarrier example, let N denote the useful discrete Fourier transform length and G denote the number of copied guard samples. A transmitter forms N useful samples and prefixes the last G of them to the front of a symbol, yielding a nominal total length of N+G samples. Within that construction, samples in the prefix correspond, before channel impairment, to a segment N indices later. A correlation statistic at lag N, calculated over approximately G eligible prefix positions, therefore has a structural reason to rise. The cyclic prefix is a design device for maintaining circular-convolution behaviour across a dispersive channel when its duration and other receiver conditions are adequate. The copied samples are not a cryptographic signature, and their appearance does not reveal the messages carried by the underlying symbol. To see the difficulty, consider a single sinusoidal test interferer x[n]=A exp(j omega n+j phi),

Copyright 2026, James M. Atkinson

where A is a nonzero complex amplitude, omega is angular phase advance per sample and phi is a starting phase. For every lag L, x[n+L] is a constant complex rotation of x[n]. The normalised magnitude coherence is consequently one, regardless of whether the waveform possesses a cyclic prefix. If an engineer searches many lags and retains only the largest result, a pure tone may look even more impressive than a noisy genuine multicarrier capture. The phase of the lag product is also not unique evidence, because a constant-frequency tone contributes a perfectly stable phase proportional to L. This is not a marginal exception. Narrowband ingress, oscillators and local clock leakage are common enough alternatives to demand direct challenge. The strongest discriminating evidence therefore concerns the pattern of correlation in time, frequency and lag jointly. A hypothesised prefix mechanism predicts high correlation for a restricted set of positions within successive nominal symbols, not uniform high coherence at nearly every position or lag. Its characteristic support should move coherently when the observation clock is offset from the symbol clock, and the pattern should repeat at a symbol interval compatible with the proposed pair N and G. A tone, by contrast, tends to remain coherent outside those prefix intervals, subject to fading and noise. A periodic switched interferer might yield isolated windows resembling prefixes, but its underlying spectral concentration, transition timing and tolerance of changed synthetic controls will differ. Such distinctions are probabilistic observations, not immutable class boundaries. For a deliberately synthetic test, take N=1024 useful samples and G=128 copied samples with a sample rate F_s=1,024,000 samples per second. The useful symbol lasts N/F_s=0.001 second; the prefix lasts G/F_s=0.000125 second;

Copyright 2026, James M. Atkinson

and the whole symbol lasts 0.001125 second before channel or receiver offsets. The subcarrier spacing of that hypothetical transform is F_s/N=1000 hertz. None of these figures establishes that a captured waveform uses those values. They simply define a candidate against which a reserved observation window can be tested. If the analyst first chooses N and G to fit the most agreeable fluctuation, the quoted false-alarm probability must account for the search across competing values. Information theory supplies an interpretive discipline. A statistic summarises chosen dimensions of a signal; it cannot be asked to bear an infinity of unmeasured distinctions. In particular, redundancy and predictability may be introduced by framing, coding, synchronisation, compression metadata, a source's own periodic rhythm or the receiving apparatus. A signal may show strong repetitive evidence while conveying no recovered message content to the investigator. Equally, a real prefix can be difficult to detect when fading, interference, receiver clipping or insufficient samples prevent reliable estimation. The lack of a peak is not a proof that multicarrier operation is absent. I would reserve the language of identification until several independent predictions have survived trials not used to select the model. One set of data may select candidate lags and window lengths; a second, separately collected or legitimately held-out set must test the expected periodic support, broadband energy distribution and behaviour under changed receiver states. The experiment should log how many cells and parameter combinations were examined, how many were deemed technically eligible, and how correlation was normalised. The scientific finding then becomes an auditable statement about compatibility with a hypothesised signal construction. It is not a message recovered, a sender

Copyright 2026, James M. Atkinson

authenticated or a device convicted. That narrow conclusion preserves the distinction between seeing patterned light on the instrument's display and hearing a physical explanation supported by the rest of the measurement chain.

David Slepian, Peer Question: Dr. Shannon, your coherence equation is attractive, but it appears to treat the sampled window as if its borders merely delimit a benign counting interval. In a field recording the front-end filter colours the noise, the acquisition gate may begin in the middle of a transient and the sample groups at neighbouring trial lags may overlap heavily. Those conditions mean that the statistic's distribution is not the simple independent-sample distribution printed in elementary treatments. Could you explain how an investigator should select window length and normalisation without making the selection itself part of a hidden search for an impressive result? I ask particularly whether the absence of a known preamble or symbol boundary should force a larger uncertainty statement, and how a short valid observation can produce a high coherence by chance when only a few degrees of freedom remain. Please identify which assumptions may be checked experimentally and which should remain explicit qualifications.

Claude Elwood Shannon, Response: Dr. Slepian, the finite window is an active part of the measurement and cannot be concealed behind a symbol. The ordinary normalised coefficient is dimensionless, but its sampling distribution depends on the number of independent pieces of information, not simply the number of stored samples. When the noise is coloured, neighbouring samples share energy and phase structure; when the windows overlap, the numerator and denominators inherit further

Copyright 2026, James M. Atkinson

dependence. A one-hundred-and-twenty-eight-sample window in a sharply filtered receiver may carry substantially fewer independent degrees of freedom than an ideal white-noise calculation assumes. Stating a theoretical false-alarm probability derived from white and independent complex Gaussian vectors would be unjustified without an appropriate noise calibration. I would distinguish three uses of data. In exploratory data, one may search lags, start positions and guard widths freely, provided the exercise is described as exploratory. In calibration data, one characterises the actual receiver under known no-signal and controlled interference conditions, while freezing the acquisition settings that matter to the operational statistic. In reserved evaluation data, one tests the prespecified statistic and decision rule without looking ahead to revise them. If only a short archive exists, methods that correct for the whole search may be used, but the narrower evidence should not be disguised as if it had arisen from an independent confirmation campaign. Whether one chooses a held-out interval or a new acquisition, time and environmental dependence must be considered when deciding whether the separation is genuine. A practical normalisation uses measured sample energies from exactly the two lagged vectors, an explicit rule for excluding zero-energy or saturated windows, and stable numerical accumulation. Compare the observed distribution of C with a null made from realistic terminated-input recordings, independent noise-source injections and lawful tone interference, all recorded through the same analogue filters and digital pipeline. Such a null may require resampling or simulation that preserves the relevant correlation, acquisition gaps and threshold adaptations. Randomly shuffling individual samples often destroys those properties and makes the apparent significance much

Copyright 2026, James M. Atkinson

too generous. A conservative block-resampling scheme can preserve longer dependence, but its block length is a further engineering decision whose sensitivity should be reported. The window length should reflect a proposed physical mechanism and an uncertainty interval, rather than the length that maximises a previously seen peak. If W is too small, the normalised value can be high through accidental vector alignment; if W is much larger than the repeated region, unrelated samples dilute the prefix feature. The strongest case examines a limited, predeclared family of plausible W and L values, then evaluates the whole family jointly. When a symbol boundary is unknown, a sliding test must disclose the count of start positions and their overlap rather than calling each position a separate independent experiment. It may be legitimate to estimate timing on one part of a record and validate on another. My recommendation is that the evidential summary present the raw correlation versus time and lag, the normalisation denominator, effective independent exposure, null-calibration conditions, and sensitivity of the result to reasonable perturbations. An analyst should be particularly suspicious when a claimed detection rests on one short, isolated and exceptionally bright window whose neighbours do not obey the predicted symbol rhythm. One attractive coefficient is an observation. A tested pattern supported by several independent controls is a significantly stronger inference.

Richard Wesley Hamming, Peer Question: Dr. Shannon, an apparently lawful and tidy detection report can still hide a severe data-association defect. Suppose the receiver writes each burst to disk with a timestamp supplied by a host process, while the complex samples themselves carry hardware counters. If the software stitches buffers with one absent block, the

Copyright 2026, James M. Atkinson

apparent lag N may connect samples that were not adjacent in the physical stream. Alternatively, a zero-filled gap can create a repeated margin, or an automatic normalisation routine can inflate a weak residual. What minimum acquisition-integrity checks would you require before treating a lag peak as a property of the source rather than an artefact of reconstruction? I should also like you to distinguish a checksum proving that the recorded file remains unchanged from a measurement proving that the sequence was captured correctly in the first place. This distinction is vital when a technical report is later used as evidence.

Claude Elwood Shannon, Response: Dr. Hamming, acquisition provenance is logically prior to signal interpretation. The analyst must know whether x[n] actually denotes uniformly timed consecutive complex samples at the asserted sample rate. A file can be perfectly intact and still embody skipped hardware counts, repeated DMA blocks, substituted zeros, reordered segments or resampling performed without adequate documentation. A cryptographic digest protects the sequence after the digest was created; it does not tell us whether the receiver captured the right analogue signal or whether the mapping between timestamps and sample indices was valid. The two forms of integrity should therefore be documented and tested separately. A suitable record carries hardware sample counters, clock source and lock state, buffer sequence numbers, sample rate and decimation configuration, any overrun or underrun flags, and a log of changes in gain, filters, tuning and frequency correction. A sample block should not be silently concatenated across a gap. Instead, the analysis masks invalid intervals and records their boundaries, because a lag comparison that crosses a gap is not evaluating the stated model. If a gap is filled for display

Copyright 2026, James M. Atkinson

continuity, the synthetic samples must remain marked and ineligible for evidence statistics. The code that applies those eligibility masks should be versioned and independently tested with deliberate gaps of known length. Begin with an authorised laboratory source engineered to provide a precisely known repeated sequence. Inject it at a defined receiver input, capture hardware counter and decoded sample records independently, and vary host computational load while keeping the analogue source unchanged. If the correlation peak changes when disk scheduling rather than the source changes, investigate the recording path. Repeat the test with a terminated or matched-load input and with the local oscillator operating, because a computer-controlled receiver may produce internally synchronous interference even without an external signal. An additional receiver with independent hardware and clocking provides helpful corroboration only when its failure modes are not shared. The evidence statement should identify every excluded sample range and the reason for exclusion. It must also preserve the original raw data and the reproducible analysis script, including the units in which lags and frequencies are expressed. If the analysis has been repaired after an error, preserve both the earlier and corrected version together with the rationale, rather than overwriting the provenance trail. This discipline cannot make an inaccurate capture accurate, but it can prevent the system from translating a known data-quality failure into a confident claim of multicarrier structure. The audible confidence of a polished report must not exceed the quality of the recorded evidence on which it rests.

Claude Elwood Shannon, Cross-Peer Question to David Slepian: Dr. Slepian, the hypothetical example fixes a useful transform interval of 1 millisecond

Copyright 2026, James M. Atkinson

and a copied prefix of one eighth of that duration. Yet a carefully chosen periodic interferer can create high correlation for an entirely different physical reason. Would you design a discriminating experiment in which the estimator is obliged to predict an interval of high correlation, not merely a lag at which correlation is high? Please show how window concentration, spectral colour, sample-clock perturbation and a held-out record can be combined without turning the design into an endless search whose favourable results alone are published. I am particularly concerned about false confidence when the null recordings are taken through a different receiver filter or gain state from the questioned capture, for then the calibration and the observed coefficient are scarcely comparable. Which observations would cause you to reject the prefix interpretation rather than simply modify the proposed guard length until it fits?

David Slepian, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, I would first freeze a finite menu of plausible useful-symbol lags, guard intervals and sliding-window positions, and record the number of tested combinations. For each candidate pair N and G, the test predicts that a time-localised correlation plateau or elevated segment recurs at intervals of N+G samples, after allowance for plausible clock drift. It is not enough to identify a bright pixel somewhere in the lag-time plane. A periodic tone creates high normalised correlation over many positions and many lags, and a narrowband spectral test can expose that competing explanation. The joint shape of the evidence matters more than the largest number in its table. The experiment should collect an authorised synthetic multicarrier source with its known N and G, a synthetic tone, a periodic switched waveform and terminated-input noise through the same receiving hardware. Repeat across

Copyright 2026, James M. Atkinson

declared filter settings and representative gain states, and calibrate each condition separately if their covariance structures differ materially. For a disputed field sample, evaluate the frozen statistic against a null derived from comparable instrument states rather than transporting a p-value from an ideal laboratory white-noise model. When the original noise environment is no longer reproducible, widen the interpretation and state the mismatch. A block-bootstrap or spectral simulation can be informative only if its dependence assumptions are exposed and checked against the actual receiver output. Reserve a second observation interval for a genuinely predictive test. The model fitted to the first interval should forecast both the lag and where the prefix-like correlation will recur, within a bounded timing tolerance. Measure the width and spacing of each candidate ridge, compare energy and spectral concentration, and test whether the pattern persists in a second receiver whose acquisition errors are different. A candidate that succeeds only after guard length, lag, start position and detector threshold are revised repeatedly upon viewing the reserved interval has failed the prospective exercise. Its observation may remain a useful exploratory clue, but not a confirmed waveform classification. Rejection criteria should include a tone-like coherence pattern extending through non-prefix windows, disappearance when a receiver's local oscillator reference is changed, collapse under a second independently calibrated capture of the same synthetic emitter, or a nominal prefix duration inconsistent with the repeat spacing. Conversely, a physically plausible prefix plateau supported by multiple reserved symbols and controls strengthens a multicarrier hypothesis without uniquely identifying its coding, standard or transmitter. A disciplined analyst must be prepared to let the attractive hypothesis fail.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Shannon, thank you for distinguishing statistical repetition from physical attribution. Dr. Slepian, I pass you the token. Please examine finite records, the spectral concentration of interference and the way overlapping correlation windows alter the uncertainty of this experiment.

David Slepian, Second Principal Contributor: A finite observation does not merely shorten an otherwise infinite process. It changes the questions that the data can answer, because time limitation and frequency concentration interact. A narrowband oscillation observed for one short window can possess an apparently broad spectrum simply because the window interrupts it, while a genuine broadband waveform passed through a selective receiver can acquire correlations whose origin lies in the filter's impulse response. In both cases, the analyst sees the signal through a measurement operator. The operator includes antenna response, front-end gain, filters, sample clocks, quantisation, blanking and the mathematical window applied after acquisition. A correlation peak belongs initially to the output of that operator, not automatically to a source radiating beyond it. The common expression R(L)=sum x[n]conjugate(x[n+L]) hides the central importance of window choice. A rectangular window declares every included sample equally informative, then assigns zero weight immediately outside its boundary. The sharp discontinuity generates spectral leakage when Fourier analysis is applied and influences the effective correlation distribution even before explicit Fourier processing. A tapered window reduces certain sidelobes while broadening the main response and decreasing the concentration of information available for a copied-prefix test. Neither choice is universally superior. If the hypothesised repeated

Copyright 2026, James M. Atkinson

interval comprises G samples, the window should be selected to test that region while considering the channel transition and filter settling, rather than borrowed uncritically from a general-purpose spectrum display. The time-bandwidth product supplies a useful conceptual scale. If an observation lasts T seconds and its effectively occupied or measured bandwidth is B hertz, the nominal product BT describes the scale of independent degrees of freedom that can be supported under idealised conditions, up to factors depending on real versus complex representation and the exact concentration definition. It is not an automatic integer sample count. In practice the receiving filter, spectral colour and gaps can reduce the dimension of independent observations. An apparently stable correlation estimated from many heavily overlapping windows may have a small effective sample size. The statistical uncertainty must reflect this dependence; counting every new one-sample shift as an independent replication is an elementary but consequential error. Consider a lawful synthetic comparison. A multicarrier generator produces N=1024 useful samples and G=128 prefix samples at 1.024 million samples per second, while a second generator produces a continuous sinusoid of similar received power. The analyst computes a normalised correlation at lag N in W=128-sample sliding windows. The multicarrier source should produce a repeated elevated region at particular positions in each 1152-sample symbol, subject to channel conditions. The sinusoid may produce a value near unity throughout the recording, which defeats the simplistic 'largest peak wins' decision. Adding broadband noise can lower both coefficients but will not repair the logical inadequacy of the decision rule. A classifier must compare the temporal support and nuisance-dependent distributions of the statistics

Copyright 2026, James M. Atkinson

rather than their isolated maxima. A second counterexample is a narrowband periodic pulse source whose interval matches the expected symbol period. Its gating can generate spectral sidelobes and periodic amplitude patterns; after filtering, those may form short correlation ridges resembling a prefix schedule. A third is a dispersive echo of a pulse train, in which repeated delayed energy appears at fixed lags as a property of the propagation path. A fourth is a strong nearby carrier leaking into the sample clock or analogue-to-digital converter reference, which can couple instrument synchrony into the record. These alternatives can sometimes be distinguished by measuring spectral rank, comparing controls, changing lawful laboratory input conditions, and checking whether the inferred period persists in a receiver with independent timing architecture. Null simulation has to preserve the dependence that matters. Generating independent circular Gaussian noise and computing C offers a convenient theoretical baseline, but it is insufficient when the actual receiver noise is band-limited or coloured. If the null vector consists of two independent, isotropically distributed complex Gaussian vectors of length G, the expected squared normalised inner-product magnitude is 1/G. With G=128 this expectation is 0.0078125. That is a conditional mathematical illustration, not a universal false-alarm threshold. Filtering, overlapping windows, common interference, non-stationarity or different vector energies invalidate its direct use as the observed field null. The prudent analyst estimates the relevant distribution empirically under matched instrument conditions and accounts for the search over many candidate lags and positions. The same caution applies to independent confirmation. Two software detectors run on the same I/Q samples are not two independent receivers. Two antennas feeding the same

Copyright 2026, James M. Atkinson

downconverter may share local-oscillator defects, clock instabilities and gain-control dynamics. A second architecture may provide useful evidence, particularly if its signal path and timing system differ, but independence must be argued rather than celebrated. The strongest controls include terminated-input tests, calibrated injected waveforms, deliberate changes in receiver filter bandwidth, changes in sample-clock configuration where technically feasible, and paired observations during no-source and known-source trials. I would also insist upon a full map of eligible observation intervals, not merely those in which the detector found the desired feature. A high correlation can occur when signal power is so low that the denominator is unstable, or when a clipped amplifier imposes repeated digital values. Exclusion criteria for low energy, saturation, buffer gaps and transients must therefore be written before testing and applied symmetrically to successful and unsuccessful windows. If the criteria are adjusted after seeing the strongest peak, the final uncertainty statement is optimistic. In controlled experiments, preserve every rejected interval and its reason, for the rejection mechanism may itself be correlated with the class of signal under test. My conclusion is deliberately limited. A cyclic-prefix hypothesis proposes a patterned relation between lag, position, symbol spacing and spectral occupancy. Its evidential strength comes from satisfying those joint predictions under comparable measurement conditions, not from the decorative precision of an isolated coefficient. When the time-frequency concentration or coloured-noise structure makes a null model uncertain, the correct scientific response is to enlarge the interval of doubt. The quiet page of a properly qualified report is more

Copyright 2026, James M. Atkinson

informative than the bright waterfall of an instrument whose confidence has outrun its sampling model.

Dennis Gabor, Peer Question: Dr. Slepian, you describe the test in terms of windows and effective degrees of freedom, yet a field examiner often begins with a spectrogram rather than a carefully selected correlation plane. The spectrogram's apparent shape changes when the window length or taper is altered. Could you explain whether a supposed multicarrier feature should persist across more than one sensible time-frequency resolution, and what kind of change would signal that the feature was created by a window rather than by the received waveform? I should like the answer to consider a periodically keyed tone with spectral leakage, an actual cyclic prefix whose duration is short compared with the display window, and an automatic receiver filter whose impulse response continues ringing after the input has ceased. How can these be compared without allowing the analyst to change the display settings indefinitely until a preferred appearance emerges? I also ask whether the same peak survives a test in which window lengths are fixed before the reference signal is switched on, rather than tuned retrospectively.

David Slepian, Response: Mr. Gabor, changing the analysis window should be viewed as a controlled perturbation of the measurement rather than an artistic adjustment of the display. A true physical periodicity need not look identical at every resolution, but its predicted lag and symbol recurrence should transform in a mathematically interpretable fashion. The spectrogram alone is insufficient because it intentionally trades time resolution against frequency resolution. A long window may integrate over the brief copied interval and conceal its temporal boundaries, whereas a

Copyright 2026, James M. Atkinson

short window may show the beginning of a burst distinctly but spread narrowband energy across many displayed frequencies. The underlying digitised data remain unchanged, and the analysis must say exactly which function was applied to them. For the periodically keyed tone, apply at least two predeclared window lengths and compare both spectral concentration and the distribution of lag coherence across eligible time positions. If most energy remains in a narrow spectral ridge whose sidelobes vary predictably with the taper, that observation favours a tone or keyed-carrier explanation over a broadband multicarrier source. It does not prove the absence of every multicarrier component, since a mixed source is possible. A synthetic reference tone with matched amplitude and gating schedule should be measured through the same receiver. The comparison is far stronger than simply noticing a broad-looking cloud on the waterfall screen. For a true prefix example, compute the lag statistic directly on calibrated complex samples, retaining the absolute time indices, rather than inferring it from pixel intensities. Use an independently generated known multicarrier test source to measure how the receiver's filter smears the expected interval. Short windows may resolve the local correlation plateau; longer windows may reduce variance while diluting it. If the two measurements exhibit the predicted trade-off for the controlled source but not for the unknown, the discrepancy must be examined. Conversely, agreement across two resolutions lends support only if the test thresholds were set in advance and the windows were not chosen retrospectively. Filter ringing can be exposed by applying a single, authorised input pulse and measuring the instrument output after the pulse ends. That response defines a finite memory of the measurement chain, which may overlap subsequent detector windows. A

Copyright 2026, James M. Atkinson

lag peak tracking the filter's measured impulse response rather than the laboratory source's symbol schedule is an instrumental explanation. Repeat at different front-end filter bandwidths and with a terminated input, controlling gain and receiver state. Report how the feature moves or changes under those controlled interventions. Most importantly, freeze the primary test before inspecting the reserved data; treat all subsequent alternative windows as exploratory diagnostics rather than retroactive confirmation of the original claim.

David Slepian, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, a null model may have elegant analytical assumptions and still be defeated by the unglamorous machinery that makes the file. In an instrument with a long buffering path, a receiver can silently repeat a block after an overrun, splice together samples with different frequency corrections, or fill a missing block with constant zeros. Those interventions may manufacture correlation at a precise lag that happens to resemble the proposed useful-symbol length. Would you construct an acquisition-integrity test that can separate such digital repetition from a real cyclic prefix? Please specify what the raw record must retain, how a test should deliberately introduce known faults, how pairwise lag comparisons should be masked when an interval is missing, and which claims must be withheld if the hardware clock and host timestamps cannot be reconciled. I ask because a beautiful statistical fit is worthless if its sample indices are fictitious. Please include the possibility that a checksum verifies stored bits but cannot verify the receiver actually captured the intended analogue interval.

Richard Wesley Hamming, Cross-Peer Answer to David Slepian: Dr. Slepian, the instrument needs a ledger that binds every sample to an acquisition

Copyright 2026, James M. Atkinson

state and a monotonically advancing hardware count. The log should contain counter values, sample-rate configuration, clock lock, receiver tuning, gain, filter changes, buffer identifiers, overflow and underflow flags, and any correction made after capture. A host arrival timestamp is useful for file-management history but does not substitute for the sample clock. If two adjacent blocks contain repeated counter ranges, or the second begins with a jump inconsistent with its declared length, the data are not an unbroken time sequence. No amount of downstream signal processing can restore the absent physical observation. Create an authorised known-source capture, then deliberately impose controlled faults in separate trials. Introduce dropped blocks of known sample counts, repeated DMA buffers, incorrect decimation metadata, short zero-padding intervals and a timebase adjustment at a known boundary. Verify that the integrity checker flags each fault and that the detection code never treats an invalid cross-gap comparison as eligible. For a lag L, every pair x[n] and x[n+L] must fall in valid intervals with compatible acquisition states. When either endpoint crosses an excluded interval, the pair is removed from the statistic. The numerator and both energy denominators must use the same set of valid pairs, otherwise the normalisation ceases to represent a coherent vector comparison. Test a synthetic prefix source first with all faults disabled, then apply each fault while preserving the independent truth log. The resulting change in detector decisions measures susceptibility to acquisition artefacts rather than an unexplained property of the source. Run an additional no-source recording with the receiver tuned and gain active. If the test algorithm reports the anticipated prefix rhythm after a deliberate repeated buffer, the fault injection has exposed a concrete false-positive mechanism.

Copyright 2026, James M. Atkinson

Preserve that failed test in the evidence file; it is a finding about the instrument, not a shameful anomaly to remove from the published statistics. Where the hardware clock and host record disagree, the analyst should state that absolute event timing is uncertain by at least the unresolved discrepancy, and should not align the suspect feature to another instrument's event within a narrower tolerance. A relative lag confined entirely to an intact block may remain measurable, but cross-record correlation or claimed symbol synchrony can be unsupported. If acquisition provenance cannot be repaired or independently verified, the proper classification is 'instrumentally ambiguous'. A checksum may confirm subsequent file integrity, but it cannot confer original measurement validity. That distinction is fundamental to the evidential chain and protects the investigator from mistaking a repeated computer memory block for a radiated waveform.

Dr. James M. Atkinson, Moderator: Dr. Slepian, thank you. Dr. Hamming, take the token to examine data integrity, repeated patterns and the forensic requirements for an independently reproducible correlation result.

Richard Wesley Hamming, Third Principal Contributor: A remarkable numerical pattern is not a certificate of its own provenance. The investigator's first question must be whether the samples in the alleged pattern were actually measured at the times assigned to them. In digital systems, an error can be repeated perfectly and can even survive every subsequent checksum. When a buffer is duplicated, two regions of a file become identical; when an interpolation algorithm fills a gap with a stored waveform, it may create a periodic relation that never existed at the antenna. These are not hypothetical inconveniences introduced to diminish

Copyright 2026, James M. Atkinson

good statistical work. They are examples of why an inference about a physical emission must be supported by an auditable acquisition chain. The statement that x[n] and x[n+N] are copies in a hypothesised cyclic-prefix region depends upon a trusted sample-index mapping. If n is merely the row number assigned after the recording software has reconstructed a sequence, the lag N may measure a difference in file address rather than a physical time interval. A hardware sample counter that increments monotonically at the actual converter rate is preferable to an operating-system timestamp assigned after buffering. Yet even a hardware counter requires validation, for firmware can reset, wrap, lose clock lock or report metadata from a previous configuration. An effective evidence record stores both the nominal and measured clock conditions, the counter discontinuities, and a checksum of original blocks with their acquisition metadata. I would set out several invariants that an independent reviewer can verify without needing to trust the original operator's confidence. Each raw block begins at the expected counter relative to the previous one, unless a specifically logged gap or state transition intervenes. The number of saved complex samples agrees with the declared interval and sample format. No sample comparison crosses a period of invalid clock, overload, retuning or intentional muting without an explicit eligibility decision. The complete analysis can be rerun from an immutable copy of the raw I/Q and the versioned code, producing the same output values within declared floating-point tolerances. These conditions do not make a detector infallible, but their violation plainly undermines the asserted meaning of its indices. An authorised synthetic test can exploit errors as deliberate adversaries of the analysis. Capture a known multicarrier reference and a known non-

Copyright 2026, James M. Atkinson

multicarrier reference, with an independent truth record held separately. Introduce a single dropped buffer, a repeated block, a zero-filled gap and a one-sample phase slip in distinct test runs. Compare each detector's output with the truth and preserve the failure rate. An implementation that declares a prefix when a no-source repeated block is inserted has demonstrated a bug, or at least a failure to reject an eligible artefact. The correct engineering response is to repair the acquisition-quality rule and rerun the blinded evaluation, not to explain the conspicuous false detection as an unusual atmospheric effect. One must also examine numerical implementation. A sum of complex products accumulated over many samples can lose precision if stored in an inadequate format or if signal energies differ by many orders of magnitude. Overflow, underflow, clipping and division by tiny denominators can make a normalised statistic appear artificially confident. The experiment should apply known analytic sequences for which the expected C is exact or independently computed, including a constant complex tone, white complex noise, a seeded copied segment, a clipped sine and an entirely invalid zero-energy interval. Automated unit tests should verify the implemented formula, including which input is conjugated and which lag sign is used. An attractive plot whose estimator has not passed those tests belongs to the software-development record, not to the final evidential conclusion. Another trap is the multiple-comparison problem. A program may test thousands of start positions, dozens of lags, several window lengths and multiple antennas before selecting the largest C. Each comparison increases the opportunity for a chance excursion, and correlated tests do not permit the naive multiplication of independent probabilities. The programme must retain the complete tested parameter

Copyright 2026, James M. Atkinson

set and establish an overall calibration with null data that reproduce overlapping windows and receiver dependence. It should freeze the decision rule before the reserved evaluation capture. A threshold selected after seeing the questioned signal is a description of that signal, not independent evidence that the signal crossed a meaningful prescribed threshold. A practical example makes the engineering units explicit. Suppose a 1,024,000-sample-per-second recorder stores complex samples in eight bytes each. One second of uninterrupted raw samples requires 8,192,000 bytes, ignoring headers and metadata. A ten-second bounded capture therefore requires approximately 81.92 million bytes, not an unspecified quantity described as 'high throughput'. A buffer loss of 2048 samples corresponds to 0.002 second at that rate. A proposed prefix of 128 samples lasts 0.000125 second, so such a loss spans sixteen prefix lengths. A careless splice could affect many candidate windows and create a false periodic impression across the apparent file join. These arithmetic checks can be performed independently and should appear beside the software ledger. Evidence preservation is equally important after acquisition. The original data, instrument configuration, calibration files, scripts, revision history, exclusions and derived plots should form a versioned evidence package with a traceable hash. If an error is discovered, create a corrected derivative rather than silently overwriting the earlier record. A properly preserved failure is scientifically useful, because it permits an independent laboratory to locate the precise cause of a false positive. The reporter should state whether the inference is about a known synthetic waveform, an unknown received signal, or the behaviour of the measuring instrument itself. My judgment is that a lag correlation may be a robust engineering clue after

Copyright 2026, James M. Atkinson

these controls, but it is not a substitute for them. The reviewer should be able to trace a reported peak to specific valid sample ranges, reproduce the normalisation, compare rejected and accepted windows, and see at least one deliberately adverse test that the detector correctly refuses. A conspicuous figure without such provenance resembles a neatly printed school examination whose answers were copied from an unexamined source. Its appearance is orderly; its evidential foundation is not.

Harry Nyquist, Peer Question: Dr. Hamming, your ledger protects sample indices, but it may still faithfully record a receiver that is systematically miscalibrated. A digitiser whose actual sample rate differs from its nominal rate will assign incorrect physical durations to the purported useful symbol and guard interval. A frequency correction stage may also rotate phase or interpolate samples in a way that changes the shape of the lag statistic while retaining exact block counters. How would you distinguish an accurate digital record of an inaccurate physical timebase from a faulty record, and how would that difference affect claims about symbol spacing and frequency offsets? Please include the roles of a traceable external frequency reference, independent sample-rate estimation and a deliberately varied sample-clock condition. I also ask whether a small clock error can accumulate across many symbols to defeat a narrow gate selected from the first observed correlation ridge. Would the result still have the proposed physical meaning if the nominal sample rate were simply copied from an outdated acquisition configuration?

Richard Wesley Hamming, Response: Mr. Nyquist, a complete audit has two separate timebase obligations. One concerns the ordering and continuity of samples, for which counters and gap flags are essential. The other concerns

Copyright 2026, James M. Atkinson

the actual physical interval between samples, which counters alone do not establish. If the converter is commanded to run at F_s but actually operates at F_s(1+delta), the time corresponding to a lag N is N divided by the actual rate, not N divided by the nominal one. Here delta is the dimensionless fractional sample-rate error. The recorded sequence may be perfectly continuous while its displayed timing is systematically wrong. Use a calibrated reference oscillator or a laboratory signal whose frequency is traceable to a trustworthy standard, and record both the reference's conditions and the receiver's clock-lock state. Compare the implied sample rate over bounded intervals, preferably with an independent measurement path rather than solely with the same firmware that controls the converter. A signal-frequency estimate can help, but if it relies on the very sample rate under investigation, the calculation becomes circular. Where an external timing or frequency reference is unavailable, report the calibration as provisional and give a conservative uncertainty bound based on measured drift and oscillator specifications. A ten-part-per-million clock error has a fractional magnitude of 0.00001. Over one 1152-sample synthetic symbol it corresponds to approximately 0.01152 sample of nominal timing displacement. Over one thousand such symbol intervals the accumulated displacement reaches approximately 11.52 samples if the fractional error remains stable and the comparison is made against an independent ideal grid. That is large enough to affect a tightly gated window that was positioned using only the first few symbols, though the detector may track and compensate if its model permits. The numbers are illustrative, not measured performance for an actual receiver. A report should state whether the analysis estimates and corrects drift from training data or merely

Copyright 2026, James M. Atkinson

searches for the most favourable trajectory. Frequency correction and interpolation need their own metadata. Record original uncorrected samples, correction coefficients, interpolation filter, clock assumptions, and the interval over which each estimate was obtained. Re-run the lag detector with and without those reversible corrections on authorised known sources. If a peak appears only after an algorithm whose coefficients were adapted using the same target peak, that observation is exploratory and needs independent validation. If the raw and corrected forms yield mutually consistent physical symbol duration after applying declared transformations, confidence increases. The difference between timing continuity and timing accuracy should be expressed in the final report. A valid counter sequence with uncertain oscillator rate can support a statement that a lag of 1024 stored samples exists; it may not support the sharper claim that the lag corresponds to precisely one millisecond. This distinction prevents a well-engineered digital ledger from becoming an excuse to ignore the physical receiver's clock. An honest uncertainty interval belongs on every inferred time and frequency, even when the display presents six decimal places.

Claude Elwood Shannon, Peer Question: Dr. Hamming, you have given the investigator a disciplined pipeline, but I remain concerned about a subtler way in which the report might be internally consistent and nevertheless misleading. Suppose the investigator searches all candidate FFT lengths from a small catalogue, records only the winning N, and applies a normalised correlation threshold calibrated for that one N rather than for the selection process. The software could reproduce its answer exactly, preserve every raw sample and contain no arithmetic defect. Yet its claimed

Copyright 2026, James M. Atkinson

false-positive risk would still be incorrect. Would you set out the difference between reproducibility and inferential validity, and specify what the audit ledger must record about rejected candidate models? I should also like to hear how a reserved test can be kept independent when adjacent time windows share most of their samples and the same hardware impairment persists across the whole recording. I ask whether different lags chosen retrospectively should be treated as competing hypotheses rather than as independent confirmations of one structure.

Richard Wesley Hamming, Response: Dr. Shannon, a reproducible computation can reproduce an invalid inference indefinitely. Reproducibility says that the same declared procedure gives the same result from the same data. Inferential validity requires that the procedure's assumptions, including its selection process and calibration, justify the claimed uncertainty. An analyst who tests fifty candidate lags and preserves only the largest value has not performed one test, however tidy the final table may look. The audit must therefore retain the complete set of candidates, the order of testing, window lengths, gains, thresholds and reasons for excluding models. If parameter choices were adaptive, the decision log must show which observations influenced those choices. One defensible route is to define the candidate family in advance and calibrate the distribution of its maximum statistic under null recordings made through the relevant measurement chain. This automatically accommodates some forms of dependence when the null procedure reproduces the full search. Another route is to select a single candidate on exploratory data, freeze it, and evaluate its predicted recurrence on an independent capture. Neither approach is free of assumptions. A null archive collected under one gain or

Copyright 2026, James M. Atkinson

interference regime may not represent a changed field environment, and a nominally reserved window adjacent to the selection window may share filter memory, overlapping samples and the same nuisance source. The design can deliberately create greater separation. Allocate different known synthetic runs to model selection and evaluation, randomise lawful source conditions, use distinct acquisition sessions, and if possible employ an independent reference receiver to test predicted timing without changing the model. Correlation between sessions remains possible, especially when the same interfering oscillator or common clock is present, but the comparison can document and bound those common factors. If no independent session exists, present sensitivity analyses and avoid the language of confirmation. The ledger should be machine-readable. For each candidate, preserve N, G, window start, sample count, threshold, statistic, eligibility, decision and any subsequent revision. Compute an independent verification hash for the complete input archive and software version, but accompany it with a record of hardware calibrations and no-source controls. The reviewer's task is not merely to press a button and reproduce a bright chart. It is to reconstruct the sequence of scientific decisions and ask whether the purported evidence survived a test it did not help design. Finally, maintain a difference between an event classifier and an attribution claim. A controlled experiment may show that a certain pattern is more compatible with a copied-prefix synthetic source than with selected alternatives. That result says nothing conclusive about the author, location, purpose or protected content of an unknown transmission. The investigator should refuse the temptation to promote a narrow signal-structure score

Copyright 2026, James M. Atkinson

into a broad account of a transmitter's identity. The software can print such a conclusion, but it cannot manufacture the missing evidence.

Richard Wesley Hamming, Cross-Peer Question to Dennis Gabor: Mr. Gabor, suppose the receiver logs perfect consecutive samples, but its analyst constructs a series of overlapping spectrograms and treats the resulting display tiles as separate independent confirmations of a supposed prefix feature. A single narrowband interferer appears in many adjacent tiles because the windows overlap. Could you explain the representation problem and propose a controlled comparison between a short-time Fourier view and the direct time-domain lag statistic? I ask you also to consider two pulses separated by an echo interval that happens to resemble a useful-symbol lag, and to specify how a changed window or independent receiver would affect that interpretation. Most importantly, what does the analyst need to disclose about time-frequency resolution so that a persuasive display does not conceal the fact that only one set of original samples has been examined many times? How should an examiner distinguish a true additional measurement from a second computation over largely the same data when reporting apparent corroboration?

Dennis Gabor, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, the first correction is conceptual: adjacent tiles on a spectrogram are not independent observations merely because they occupy different rectangles on a screen. If each transform reuses nine tenths of the previous window's samples, the numerical outputs will be strongly dependent even for an unstructured source. Their agreement may demonstrate the stability of a representation, not the replication of evidence. The report should state the window duration, taper, time advance, transform length, overlap

Copyright 2026, James M. Atkinson

fraction and frequency resolution, all in physical units. It should also distinguish genuine additional acquisition time from recomputation of existing samples. Compute the direct time-domain lag statistic on raw eligible complex samples first, then use the spectrogram to investigate competing physical mechanisms rather than as a substitute for the correlation calculation. A true copied prefix predicts repeated lag-N similarity concentrated around particular symbol phases; a tone may create near-uniform coherence across time and a spectrogram dominated by a narrow ridge. An echo of two pulses can yield a sharp delayed match, but its timing and spectral evolution may follow the channel impulse response rather than a stable symbol interval. A known laboratory pulse, measured through the same channel and filter, provides a control for that echo explanation. Vary the window in predeclared ways. A shorter window improves the ability to locate the temporal onset of a transient but spreads its frequency content; a longer one concentrates frequency for a stable tone but smears a brief prefix-like feature. The expected transformation can be compared against controlled synthetic sources. A genuine observation need not remain visually unchanged, for invariance of appearance is not the criterion. Rather, the parameter-dependent change should be consistent with the proposed signal and receiver model. Any parameter chosen after seeing the disputed sample must remain labelled exploratory. An independent capture can add evidence if it supplies new physical samples through a sufficiently separate receiver path, preferably with its own oscillator and acquisition chain. Two analysts processing the same I/Q file with two window lengths do not constitute two independent witnesses. If the echo and prefix hypotheses both survive, the report should retain both.

Copyright 2026, James M. Atkinson

The highest standard is not a striking waterfall but a transparent chain from original samples through declared transforms to falsifiable predictions, including the alternatives that the data cannot resolve.

Dr. James M. Atkinson, Moderator: Dr. Hamming, thank you. Mr. Gabor, I pass you the token to examine the time-frequency plane and the manner in which an apparent correlation ridge can be generated or obscured by the representation itself.

Dennis Gabor, Fourth Principal Contributor: The signal appears to us neither as a pure list of times nor as an unchanging spectrum. A receiver necessarily observes a finite portion of a physical process, and the analyst chooses a representation that distributes its information across time and frequency. That choice can illuminate a mechanism or hide it. A cyclic prefix is a relation between two intervals separated by a known useful-symbol length; a conventional spectrum display may provide no direct proof of that relation. Conversely, a periodic interferer may make an elegant repeating pattern in a spectrogram because the display window is synchronised with the interferer's cycle. Neither appearance should be elevated to a classification before the representation's assumptions have been examined. Let g[n] be a declared analysis window and let X(m,k) denote a short-time Fourier coefficient computed from samples surrounding time index m at discrete frequency bin k. Its magnitude-squared forms a spectrogram cell. The duration of g determines which transients can be localised in time, while its Fourier transform determines how concentrated a narrowband source appears in frequency. Shortening the window improves time localisation but broadens the response to a stable tone. Lengthening it sharpens frequency discrimination but can average a short repeated guard interval into its

Copyright 2026, James M. Atkinson

surrounding useful symbol. Window shape changes sidelobe leakage and effective statistical dependence. A detector that searches multiple windows and reports only the most colourful picture has performed a model-selection exercise, not acquired multiple independent proofs. Imagine a legal laboratory source with N=1024, G=128 and F_s=1.024 million complex samples per second. Its nominal symbol is 1152 samples, or 1.125 milliseconds. A 128-sample prefix lasts 125 microseconds. A spectrogram window extending over four milliseconds spans several symbols and merges many intervals that a prefix-sensitive lag statistic would seek to separate. A 64-sample window lasts 62.5 microseconds and can reveal shorter transitions, but its nominal Fourier bin spacing is 16 kilohertz at the stated sample rate, far larger than the 1-kilohertz spacing of the hypothetical N=1024 transform. The bin figures are consequences of the selected window lengths; neither alone establishes what subcarrier spacing the emitter employed. A direct lag test and a time-frequency representation therefore answer complementary questions. The lag test asks whether two sets of samples separated by N have a stable complex relation inside expected positions. The spectrogram helps determine whether the received energy is predominantly confined to a narrow frequency, spread over many frequency cells, switched in time or accompanied by transients that could explain the correlation. A pure sinusoid produces perfect normalised lag coherence in the ideal noise-free model, yet its spectrogram may expose concentrated spectral energy. A wideband multicarrier source generally distributes energy over an occupied band, but a strongly filtered or partially observed recording can look narrowband. Both views must be interpreted through the measured response of the receiver. The familiar time-frequency

Copyright 2026, James M. Atkinson

trade-off is not an excuse to use an arbitrary display; it is a requirement to reveal the cost of each one. In a careful study, predeclare two or three windows chosen for different physical purposes, such as transient localisation, band occupancy and prefix-scale correlation. State for each the duration, taper, overlap, sample rate and resulting nominal frequency resolution. Compare their predictions on independent authorised test records, including a known prefix source, a tone, an amplitude-keyed interferer and a multipath pulse. If the observed phenomenon changes under the windows in a way predicted by the selected mechanism, that is informative. If it appears only under a carefully tuned, retrospectively chosen window, the supposed evidence may be an artefact of presentation. Periodic interference deserves particular attention because a bright narrow ridge can carry complex structure after passing through a nonideal instrument. For example, a strong tone may push an amplifier into a nonlinear range; the resulting intermodulation products broaden the apparent occupied spectrum. An automatic-gain-control loop may apply periodic amplitude changes in response to a separate blocker. A filter may ring at a frequency set by its poles after an abrupt input transition. Those mechanisms can create combinations of periodicity and apparent multiband energy. Varying lawful injected test-power levels and front-end attenuation can help distinguish an internal nonlinear product from a stable external waveform, but the analysis must preserve the possibility that two sources coexist. Multipath also enters as a relation between delayed copies. If a channel produces an echo with delay tau seconds, the received waveform may contain correlated portions separated by approximately tau F_s samples. A pronounced lag peak at that interval is a property of the

Copyright 2026, James M. Atkinson

combined transmitted waveform and propagation environment, not necessarily of a copied prefix. A real multicarrier source under multipath can display both mechanisms. Its guard interval is designed to tolerate specified delay spreads, but if channel memory extends beyond the prefix, intersymbol interference and altered correlation patterns can follow. The correct experiment includes channel emulation or controlled reflections, estimates the impulse response where possible, and compares the predicted temporal support of candidate peaks. A second receiver can assist, but it does not automatically establish an independent source mechanism. Two receivers connected to the same antenna distribution system share the external field and may share front-end intermodulation. Two digital analyses of the same sample file share all underlying measurement faults. To test receiver-created periodicity, use a terminated-input capture, known source injection, altered local oscillator, and a genuinely separate acquisition architecture. Preserve clock and gain metadata for each capture; otherwise a failure to agree may simply reflect incompatible calibration. The result should be framed in the vocabulary of compatibility and uncertainty, not courtroom certainty. I would conclude by separating three visual claims. The first is that a period appears in the measurement; the second, stronger, is that the period occupies positions and bandwidth consistent with a cyclic-prefix construction; and the third, far stronger, is that the source actually uses a specified waveform standard. A finite window and a beautiful display can support the first and perhaps the second when controls agree. They do not, without additional independent evidence, support the third. In technical jurisprudence as in physics, a

Copyright 2026, James M. Atkinson

legible picture can communicate an inference, but it cannot supply the measurements that the inference requires.

David Slepian, Peer Question: Mr. Gabor, the principal example has a prefix duration of 125 microseconds, yet a spectrogram viewed with a long integration interval could make it almost invisible. If the examiner then shortens the window repeatedly until an apparent short repetition appears, the choice becomes contaminated by the observed data. How should that contamination be handled without prohibiting all exploratory visual analysis? I should like you to distinguish an exploratory discovery from a confirmatory detection, define a modest family of sensible resolutions that a laboratory might declare beforehand, and explain how a correlated noise null should be reproduced after each transformation. Please also address whether a changed time-frequency display can ever furnish genuinely new evidence if the underlying raw samples remain the same and whether independent receiver captures or synthetic challenges provide the missing distinction. Would your proposed confirmatory stage require a genuinely separate acquisition rather than a revised transform of the same underlying instrument samples?

Dennis Gabor, Response: Dr. Slepian, exploratory adjustment is valuable for discovering what the eye and instruments did not initially expect. The error occurs when the analyst later reports the winning display as though it had been prescribed before the data were seen. In exploration, one may examine many window lengths, tapers and overlap settings. Preserve that search history or at least its material scope, describe which feature first suggested the candidate prefix model, and refrain from quoting the unadjusted significance of the final selected statistic. A controlled

Copyright 2026, James M. Atkinson

confirmation then fixes the proposed lag, symbol spacing, window set and acceptance rule before a genuinely reserved capture is evaluated. A laboratory could prescribe three representations with complementary purposes. A short window on the order of half the hypothesised prefix would help locate transient changes; an intermediate window near the prefix duration would examine local repetition; a longer window covering much of the useful symbol would assess spectral concentration. These are experimental design examples, not universal prescriptions. All durations must be derived from independently justified candidate parameters or from a separate discovery dataset. The report should include each transform's overlap fraction and the actual acquisition interval. Closely spaced windows share samples and therefore cannot be treated as separate confirmations simply because they generate separate pictures. Apply each declared transform to controlled no-source, pure-tone, periodically gated-tone and multicarrier reference captures obtained with the same receiver settings. Construct the null distribution for the final combined decision, including the selection among the three representations. This is essential when coloured noise or filter ringing is present, because the transform changes the apparent dependence and leakage. A white-noise simulation is useful for testing the code's mathematics, but it cannot automatically calibrate the instrument's field false-alarm probability. Preserve all unsuccessful as well as successful synthetic trials, including intervals rejected by the acquisition-quality mask. Transforming the same raw samples into three views supplies complementary evidence about the same observation; it does not multiply the number of independent physical encounters. New data arise from another acquisition interval, an independent channel, a controlled change of

Copyright 2026, James M. Atkinson

source or instrument conditions, or an intervention that tests a competing mechanism. If the candidate prefix pattern persists across genuinely separate captures with the expected symbol timing and changes appropriately under a known synthetic source, its credibility increases. If it appears only at one retrospective window setting, it remains a clue awaiting confirmation. The distinction protects exploration without granting exploratory freedom the privileges of a prespecified test.

Dennis Gabor, Cross-Peer Question to Harry Nyquist: Mr. Nyquist, our time-frequency representations assume that the sample-rate label in the file corresponds to the actual physical rate and that the receiver's passband transmits the proposed copied interval without introducing misleading periodicity. But a real receiver includes mixers, filters, analogue gain control and a sample clock. Could you show how a modest clock error changes the relation between measured lag in samples and symbol duration, and how a periodic instrumental component can survive internal normalisation? I ask you to describe a calibrated reference experiment that separates a sample-clock or local-oscillator artefact from external multicarrier structure without recovering protected message content. Please also state what happens when a strong tone overloads a front end and creates additional apparent spectral bins, because the false impression of broadband energy may reinforce the misleading correlation peak. I should also like the test to record whether the suspect correlation persists after a safe no-source termination at the analogue input, because that control directly challenges internal clock leakage.

Harry Nyquist, Cross-Peer Answer to Dennis Gabor: Mr. Gabor, sample counting and physical timing must be connected by calibration. At an actual

Copyright 2026, James M. Atkinson

sample rate F_actual, a separation of N samples corresponds to T=N/F_actual seconds. If the file instead reports a nominal F_nominal, the inferred time differs according to the fractional error delta defined by F_actual=F_nominal(1+delta). A ten-part-per-million error is small per symbol but accumulates when the analyst assumes that hundreds or thousands of nominal symbol boundaries remain perfectly aligned. The correct experiment measures the clock against a traceable reference over the relevant capture interval and reports uncertainty or drift, rather than assuming the oscillator's catalogue specification is identical to its measured performance. Begin with a terminated receiver input while retaining its normal local oscillators and sample clock. Capture the suspected correlation under otherwise identical settings. A peak that persists with no external energy strongly suggests an internally generated periodicity or a processing defect, although the measurement must account for leakage at the terminated port. Next inject a known pure tone at an independently calibrated level and change its frequency slightly. If the observed lag phase tracks the injected tone as expected, that confirms part of the digital transfer function, not a cyclic-prefix source. A subsequent known synthetic multicarrier source permits the predicted prefix position and repeat rhythm to be tested against actual sample and clock metadata. Deliberately vary allowed receiver states. Change the sampling-clock reference when the equipment supports it, shift the local oscillator while compensating the tuned input frequency, and compare recordings from a second architecture. Instrumental clock leakage may move in samples or frequency when the internal reference changes, whereas an external source's physical period should remain tied to the emitter, allowing for documented sampling-rate

Copyright 2026, James M. Atkinson

conversion. If different receivers share a distribution oscillator or preamplifier, the controls must recognise that common mode. No single shift provides proof; the ensemble of predicted changes is the test. Overload is a further concern. A strong tone near an amplifier or mixer can produce harmonics and intermodulation products; after clipping it may yield broad spectral skirts. Vary the injected power across the verified linear range and insert measured attenuation before the suspect nonlinearity. A genuine weak signal should scale approximately according to the calibrated linear transfer function in that regime; a nonlinear artefact may change disproportionately. Keep the test within authorised safe input limits and avoid assuming the absence of one mechanism excludes another. A receiver can capture an external multicarrier signal while simultaneously generating an unrelated spur. The final finding should distinguish measured period, calibrated instrument response and an inference about source structure, with each uncertainty separately stated.

Dr. James M. Atkinson, Moderator: Mr. Gabor, thank you. Mr. Nyquist, I now pass you the token to address sampling, analogue front-end behaviour and the conditions under which a receiver can faithfully report a cyclic-prefix-like repetition.

Harry Nyquist, Fifth Principal Contributor: The accuracy of a sampled correlation begins long before the analyst writes a summation sign. The antenna, preselector, amplifier, mixer, analogue filters, sampler and digital corrections form one measurement chain. Each element may modify the phase and amplitude relationships that an ideal signal model assumes. A cyclic prefix is a property of a constructed transmitted sequence; a receiver is capable of preserving evidence of that property only to the extent that its

Copyright 2026, James M. Atkinson

bandwidth, timing, linearity and acquisition integrity are understood. A large normalised coefficient can coexist with a deeply misleading picture of the external spectrum, because normalisation may suppress amplitude information while retaining an instrumental periodic phase relation. Let F_s denote the actual complex sample rate in samples per second. A discrete lag N corresponds to N/F_s seconds, provided the acquisition has no discontinuity and the sample clock is sufficiently stable. The classical sampling condition demands that the analogue signal be appropriately band-limited relative to the sampled representation and the anti-alias design. The relevant usable bandwidth depends on whether the path yields real or complex samples, the analogue filters and the local-oscillator conversion. If an interferer falls outside the intended band but aliases or mixes into it, the resulting digital samples may show a stable correlation not native to the hypothesised target emission. Reporting only the on-screen centre frequency hides that possibility. A practical receiver characterisation should measure frequency response, selectivity, group-delay variation, settling time, gain compression and clipping under realistic configurations. Group delay matters because different portions of a broadband signal may arrive at the detector with altered relative phase; such phase changes can broaden or suppress the apparent prefix correlation. A filter with a long impulse response can create correlations between separated segments even when a source's corresponding segments are not copies. Local oscillator feedthrough and periodic power-supply interference can add coherent tones that defeat a prefix-only explanation. Each nuisance mechanism should be included in a declared competing hypothesis rather than addressed only after the preferred inference has been announced.

Copyright 2026, James M. Atkinson

Take the reference model of N=1024, G=128 and F_s=1,024,000. One useful-symbol interval is one millisecond and one nominal prefix is one eighth of a millisecond. A constant carrier-frequency offset f_delta does not necessarily reduce the absolute lag coherence of an otherwise identical copied segment, because a constant phase rotation separates the two compared vectors. The phase rotation across lag N is 2 pi f_delta N/F_s radians in the simple complex-baseband model. At f_delta=250 hertz, this is pi/2 radians for the one-millisecond lag. Therefore the observed phase of a correlation peak can assist a bounded offset estimate under appropriate assumptions but cannot uniquely distinguish a copied prefix from a pure tone. Indeed, the pure tone is the sharpest warning: it gives a stable phase relation for every lag. Clock drift introduces a different ambiguity. If an analyst uses the nominal F_s to predict symbol starts over a long record while the actual oscillator deviates, the expected prefix positions slowly move relative to the recorded sample indices. A detector that works well on the first ten symbols may seem to fail or acquire an apparent split peak after many more, even though the external source remains unchanged. An experimental estimate of fractional sample-rate offset, independent of the suspected prefix model where possible, should be carried through the alignment calculation. The same principle applies to fractional-delay interpolation and resampling: every transformed sample needs a defined relationship to the original acquisition, with filter characteristics and uncertainty recorded. Nonlinearity may make the correlation problem worse. If a receiver is driven into compression by a strong allowed test tone, clipped waveforms and intermodulation products can fill additional frequency bins while the tone's periodic phase relation persists. A display may then show both wide spectral

Copyright 2026, James M. Atkinson

activity and high lag coherence, seemingly two pieces of support for a multicarrier hypothesis when both arose from one overloaded receiver. An input attenuator placed ahead of the nonlinearity, an alternate preselector and a controlled change of test power can expose this mechanism. The analyst should examine whether output changes according to linear or nonlinear scaling, without assuming a simple power law is universal in every gain-control state. I would require a negative control with a characterised terminated antenna input, a positive control with a known synthetic cyclic-prefix waveform, and at least one adverse control with a strong pure tone and a periodically keyed interferer. The controls should use the same acquisition settings, filters, detector code and sample-rate correction as the questioned capture. A second independent receiver, ideally with its own oscillator and a different conversion architecture, helps challenge shared artefacts; a second copy of the same software on the same samples does not. Where the equipment permits, a deliberate change in sample-clock reference or local-oscillator plan can differentiate source timing from internal synchrony by observing which quantities move in physical hertz and which move in raw sample coordinates. The calibration also needs an evidential trail. Preserve raw digitised samples, absolute and relative time references, known test amplitudes at a stated reference plane, attenuator and filter settings, calibration date, software revision, and records of rejected windows. Distinguish an instrument specification from a measurement made on the actual unit. A catalogue may describe a suitable bandwidth or noise figure, but it cannot establish that the field apparatus was within its rated operating state during a particular event. If a signal is near the dynamic-range boundary, uncertainty about overload or

Copyright 2026, James M. Atkinson

quantisation must be explicit. Repeated processing of the same uncertain samples cannot replace a fresh physical control. The proper conclusion is conditional: a time-localised repeat at a lag and interval compatible with an authorised synthetic cyclic-prefix model may support the hypothesis of multicarrier structure after competing instrumental and periodic-source explanations are tested. It does not identify the sender, decode content, or certify conformity with a specific communications standard. An investigator who states the observation, the calibrated physical controls and the surviving alternatives has done more than one who offers a confident label unsupported by the receiver's analogue behaviour. The instrument may whistle a steady periodic note through its own circuitry. The expert must establish whether that sound began outside the laboratory before turning it into evidence of another party's transmission.

Dennis Gabor, Peer Question: Mr. Nyquist, your proposal uses a second receiver with a different conversion architecture and suggests deliberate changes of reference clocks and local oscillators. I should like a precise distinction between a genuine independent replication and merely observing the same nuisance through two partially shared instruments. Suppose both receivers share an antenna distribution amplifier, both are subject to the same strong blocker, and their sample clocks are nominally separate but ultimately disciplined by the same laboratory standard. Could they agree on a spurious lag peak while remaining jointly wrong about the source? What specific cross-checks would you use to test common-mode artefacts, and how would you report a case in which the prefix-like correlation survives a change in digital analysis window but disappears when attenuation is introduced ahead of the common distribution amplifier?

Copyright 2026, James M. Atkinson

Please define what such a result would and would not establish. Would an independent sample-clock reference and a separate preselector offer stronger protection against shared errors than two receivers using the same distribution network?

Harry Nyquist, Response: Mr. Gabor, two instruments can agree because they share the same error, and their agreement is not independent evidence unless the relevant failure modes have been examined. A shared antenna distribution amplifier can generate intermodulation that both downstream receivers faithfully capture. If both instruments share a reference oscillator, a spur synchronous with that reference may also appear in both. Even independent sample clocks do not eliminate interference radiated into a common laboratory environment. An equipment diagram showing the actual signal, power, timing and grounding connections is therefore part of the experimental record, not a decorative appendix. Begin by testing the common distribution path. Connect a characterised termination or synthetic input at its upstream reference plane, preserve the downstream receiver settings, and measure whether the feature appears with no external source. Next bypass the common amplifier and feed the receivers from separate calibrated injection paths, holding lawful test-source conditions constant. If the suspect peak disappears when the common amplifier is bypassed or attenuated ahead of it, nonlinearity or an instrumental artefact becomes a stronger explanation. The observation does not automatically prove the absence of a separate weak external multicarrier signal, because that signal may have been masked by the nonlinearity. A further targeted test at an appropriate, calibrated sensitivity would be needed. Change the blocker amplitude in controlled steps within

Copyright 2026, James M. Atkinson

equipment safety limits, measuring both the fundamental and any products at the relevant frequencies. The dependence on input power can help distinguish linear reception from nonlinear generation. Repeat with a different preselector and note whether the feature tracks the source frequency, the local oscillator or the filter response. A real source's physical carrier and repetition rate should not follow an arbitrary downstream oscillator change in the same manner as an internal spur. But all comparisons must be converted to common physical units with explicit sample-rate and frequency uncertainty, otherwise the apparent movement may be a bookkeeping artefact. Where both receivers share a time standard, compare their raw hardware counters and quantify common reference disturbances. A second instrument with truly independent timing and front-end conversion is preferable for challenging clock-related hypotheses, although its agreement still does not uniquely establish a modulation family. Correlation across views of one data stream remains a property of that stream, not a second encounter. An independent receiver adds value by making some faults less likely to coincide, not by making them logically impossible. If the correlation persists across digital window changes but vanishes after safe upstream attenuation, the evidence points toward receiver gain-state dependence. That is a diagnostic observation worthy of preservation, with possible causes including overload, gain-control response and a formerly visible weak signal falling below sensitivity. It does not support a confident claim that the source used a cyclic prefix. The appropriate report gives the before-and-after settings, measured input and output levels, competing explanations and any additional reference tests.

Only a mechanism that survives adverse controls should influence an attributed source-structure conclusion.

Dr. James M. Atkinson, Moderator: The panel has distinguished a measured lag relation from a multicarrier hypothesis and from any claim of protocol or sender identity. We have examined finite-window dependence, invalid sample reconstruction, representational leakage, clock error, receiver overload and common-mode corroboration. I thank each contributor for the careful passage of the token. The closing evidential rule is that a candidate cyclic prefix must satisfy predeclared lag and timing predictions on valid samples, survive suitable null and control recordings, and remain qualified wherever competing periodic interference or instrument mechanisms are unresolved. No protected communications content has been obtained in this educational reconstruction.

QUESTION 085

Copyright 2026, James M. Atkinson

What distinguishes a spread-spectrum burst from impulsive broadband interference?

SCHOLARLY RECONSTRUCTION. The deceased contributors are historically real experts, but this discussion is fictional and does not represent their actual speech, collaboration or endorsement. All examples employ authorised synthetic sources, calibrated instruments and non-content waveform statistics; no protected communication is decoded and no particular sender is identified.

Dr. James M. Atkinson, Moderator: Dr. Slepian, a broad and fleeting trace on the waterfall may be a coded communication, an electrostatic discharge, a switching transient, a lightning impulse or a receiver artefact. Would you explain what finite-window measurements can reliably distinguish, before the panel considers processing gain or any claim about a particular code family? You have the token.

David Slepian, Principal Contributor: The breadth of a spectrum and the brevity of an event do not tell us whether an information-bearing code exists. Any sufficiently short impulse necessarily occupies a broad range of frequencies in its Fourier representation, even if it carries no intended message. Conversely a deliberately spread signal may have a weak and relatively flat spectral density, while carrying a temporally organised sequence that a suitably configured, authorised reference detector can recognise. The field instrument responds to both through the same finite passband and analysis window, so the examiner must distinguish a physical property of the signal from an artefact of the representation. A narrow band of certainty cannot be gained by drawing a wide band of colour on a screen.

Copyright 2026, James M. Atkinson

Let s(t) be an analogue input voltage at time t, h(t) the measured impulse response of the receiver channel and y(t) the recorded output after the relevant gain, filtering and sampling operations. In a linear time-invariant approximation, y(t) is the convolution of s(t) with h(t), plus noise and any unrelated interference. An input electrical discharge whose duration is short compared with the reciprocal of the receiver bandwidth may appear at the output primarily as the receiver's own impulse response. A deliberate pseudorandom chip sequence can also appear band-limited and smeared after the same channel. Consequently the width and ringing duration observed at the recorder are jointly determined by the source and the instrument. The linear approximation must be abandoned explicitly when overload or automatic gain control makes the channel time-varying. A simple synthetic model illustrates the distinction. Consider a lawful laboratory generator emitting a sequence of 127 binary phase chips, each occupying one microsecond. The nominal chip sequence lasts 127 microseconds and its main spectral support is related to a megachip-per-second switching rate, subject to pulse shape and filtering. The generator's known reference sequence can be retained at the laboratory rather than extracted from any protected traffic. A second instrument injects a calibrated impulse whose initial electrical duration is much shorter than one microsecond. Both may appear as a brief broadband elevation in a spectrogram with a 200-microsecond window. Their temporal details are blurred by that representation; a narrower controlled window and an independently calibrated receiver can reveal different evolution, but neither a short window nor a flat-looking spectrum alone proves a code. One commonly used statistic, spectral flatness, is the geometric mean of eligible

Copyright 2026, James M. Atkinson

positive spectral-power estimates divided by their arithmetic mean. It approaches one for equal positive powers across the chosen bins, and becomes smaller when power is concentrated in only a few bins. The number depends on the band limits, noise subtraction, window taper, clipping and treatment of zero or negative corrected powers. White noise may display high flatness without encoding any message, and an impulse can also excite the instrument across a broad frequency range. A spread waveform with deep spectral notches or selective fading need not look flat. The statistic therefore describes a selected power distribution; it does not distinguish information-bearing modulation uniquely from natural or equipment-generated interference. A discriminator should test a pattern that impulsive interference does not ordinarily predict. For an authorised, known laboratory code, one may compute a matched correlation against that reference sequence and a set of bounded timing hypotheses. A properly aligned known sequence can yield a coherent sum over chips, whereas an unstructured impulse may give a different correlation shape and respond differently when the code reference is changed. But the inference depends upon a predeclared code hypothesis, signal path, carrier correction, and a null distribution reflecting the actual impulsive environment. Searching thousands of codes and timing alignments without correction makes occasional high correlations unsurprising. If the source's code is unknown, failure to find a particular reference match says little about whether some other spread waveform is present. The next requirement is to separate amplitude response from structure. Run both synthetic sources through the same calibrated front end over an input-power range known to be linear. If an impulsive event drives the amplifier or

Copyright 2026, James M. Atkinson

mixer into compression, it may create a different mixture of products from those predicted by the linear model. A processing algorithm that normalises every event to unit energy can conceal that overload and make a clipped discharge resemble a stable symbol sequence. Preserve raw amplitude statistics and overload flags alongside normalised feature scores. Repeat with an attenuator placed before the susceptible stage, because attenuation after that stage cannot cure earlier intermodulation. The study must include absence and recurrence. A true code-bearing burst may recur with uncertain frame timing; an impulse source may recur when a power converter switches or a relay actuates. Repetition is therefore not synonymous with intentional communication. Record the time of each event relative to independently measured environmental triggers, such as a controlled switching device, and run negative controls with the RF input terminated or the local laboratory source disabled. An impulse event correlated with a particular physical switching transition warrants investigation of that switch, not automatic classification as a covert transmitter. Equally, an unknown event not correlated with a known switch does not thereby become a decoded spread-spectrum signal. Spatial information is useful but imperfect. Two antennas in different positions may observe a genuine environmental source with different amplitude and polarisation, while a common receiver clock spur can appear irrespective of antenna position. An impulse coupled along a power cable may be stronger on one measurement path than on the other. Directional antenna tests should therefore be calibrated and interpreted together with near-field probes, terminated-input recordings and independent receivers. Apparent spatial agreement can still arise from a common distribution amplifier. It is the collection of predicted changes

Copyright 2026, James M. Atkinson

under controlled interventions that strengthens the classification, not the number of coloured traces. For a defensible conclusion, I would report that the event has a specified duration, measured band-limited energy, spectral-flatness interval, temporal autocorrelation shape and performance against a declared synthetic reference detector, all with eligible acquisition intervals and estimated uncertainties. I would identify each tested alternative, including impulsive discharge, clock leakage, switching noise and overload, and state which controls favoured or disfavoured it. A code-family hypothesis might emerge from such results. Neither the spectrum's breadth nor the detector's name can establish the sender's identity, its purpose or the existence of protected message content. The physical measurement must remain narrower than the narrative an examiner might wish to tell.

Antony Hewish, Peer Question: Dr. Slepian, a sparse series of broadband bursts may at first resemble an organised electronic transmission, but observational astronomy has long shown the danger of attributing an unfamiliar periodic signal to a deliberate sender before excluding local apparatus and physical processes. How would you build a time-synchronised record that compares the event with power-line switching, nearby industrial machinery, weather-related impulses and the receiver's own retuning schedule? I ask also whether the spectral shape of a brief impulse remains stable when the receiver bandwidth changes, or whether the instrument's impulse response can manufacture a seemingly repeatable signature. Please propose a blind experiment with an authorised laboratory source and a no-source control, and state what evidence would remain insufficient for claiming a spread-spectrum communication signal even after a recurrent event is observed. Please include whether events that coincide

Copyright 2026, James M. Atkinson

with known instrument blanking should be excluded from causal inference or retained as an explicit measure of lost survey sensitivity.

David Slepian, Response: Mr. Hewish, the observational design begins with a common timebase whose uncertainty is measured, not merely assumed from matching computer wall clocks. Record raw eligible I/Q samples or suitably calibrated pre-detection statistics, and collect independent event markers from the switching devices and environmental sensors being evaluated. The event list should retain negative observation periods, instrument states, antenna position, gain, filter configuration and local oscillator changes. A histogram of accepted bursts without the opportunity log is vulnerable to selection bias, because strong switching transients may also cause the recorder to blank or saturate. Use an authorised synthetic code-burst generator and a controlled impulse source whose onset times are randomised and withheld from the first analyst. Include genuine no-source trials. When the operator is blinded to source condition, the detection procedure can be tested on its ability to distinguish the three classes without retrospectively tuning thresholds to the answers. Introduce a switching appliance as a separate nuisance source and collect independent trigger timestamps; then examine whether the observed RF-event timing is compatible with that trigger after accounting for sensor delay and clock uncertainty. The result should report both correct classifications and false alarms, and use distinct sessions for selecting the algorithm and estimating its operating performance. Change the receiver bandwidth deliberately. For an impulse shorter than the receiver response time, the output may widen or ring according to the measured filter impulse response. A coded burst can also be altered by filtering, so this test must be

Copyright 2026, James M. Atkinson

interpreted against injected known references. Record the actual analogue passband and settling state rather than presuming that selecting a nominal resolution bandwidth changes only the display. A second independently calibrated receiver can test whether the apparent recurring morphology is largely an artefact of the first instrument. Periodic recurrence does not complete attribution. A repeatedly switched industrial load can create exceptionally regular broadband impulses, while a true communication transmitter may send only rarely and irregularly. Even if a burst does not coincide with the monitored switching devices, unmeasured sources remain possible. The defensible conclusion is an event-classification result conditional on the tested controls, not a declaration of deliberative signalling. All excluded trials, uncertain timestamps and apparent mistakes should remain in the record. Their presence gives the examiner a way to distinguish a robust inference from an attractive pattern discovered after the fact.

Edwin Howard Armstrong, Peer Question: Dr. Slepian, your idealised convolution model concerns a linear receiver. Yet a nearby strong pulse may produce gain compression, harmonic products, mixer intermodulation and a long recovery transient, while a weak spread-spectrum reference remains below the nominal detection threshold. If the examiner normalises every recorded event to unit energy, the relative scale of those nonlinear effects may disappear from view. What instrument challenge would demonstrate the boundary of linear operation, and how should the detector be tested when a true weak coded burst overlaps an impulse sufficiently strong to blank or saturate the analogue front end? I would especially value a distinction between putting an attenuator ahead of the first nonlinear stage

Copyright 2026, James M. Atkinson

and placing it after a stage that has already created false spectral energy. Which conclusion should be withheld if the front-end calibration is missing? I ask also how an investigator could recognise a front-end recovery tail that outlasts the original impulse and falsely appears to be a second event.

David Slepian, Response: Mr. Armstrong, the receiver must be tested as an analogue instrument before its digital classifications are accepted. Apply a known lawful reference burst at several levels through a calibrated input plane, monitoring the relationship between input voltage, output sample energy and expected filter response. Then add an independently controlled impulse or strong blocker at a series of safe powers. Observe whether the response remains approximately proportional in the intended linear operating range and whether new spectral components appear when the blocker level changes. Keep the raw amplitude and overrange flags; otherwise unit-energy normalisation may make a clipped event resemble a legitimate weak burst in shape while concealing the measurement failure. An attenuator before the susceptible low-noise amplifier or mixer reduces the signal that drives the nonlinearity. An attenuator after that stage may reduce output power but cannot undo intermodulation or clipping products already produced. Compare the two configurations and record the resulting sensitivity change. The front-end may become more linear with upstream attenuation while less sensitive to a genuinely weak reference, so improved cleanliness does not imply unchanged detection capability. A suitable calibration reports both false-event rate and detection probability for seeded weak bursts under each configuration. To test an overlap, generate a known code burst whose timing is independently logged, and inject a controlled impulse at a prospectively selected relative offset. Compare intact

Copyright 2026, James M. Atkinson

reference captures, impulse-only captures and mixed captures. If a large impulse saturates the converter or blanks the gain-control loop, the interval may be fundamentally uninterpretable rather than a legitimate negative result for the coded burst. The report should separate invalid acquisition opportunities from valid opportunities with an unsuccessful detector result. A detector calibrated only with isolated events cannot legitimately claim its performance in overlapped conditions. Vary the impulse amplitude and timing to estimate the region of impairment. A narrow impulse can induce a recovery transient lasting far beyond its own emission; an apparent burst immediately afterwards might be a filter ring rather than a second source. Terminated-input and input-switch controls help identify purely internal artefacts, while an independent receiver with different analogue architecture can test whether the same physical signal exists. Where gain linearity, calibration records or acquisition eligibility are unavailable, withhold any strong classification based on unit-normalised morphology. Describe the observation as broadband activity with unresolved instrument-state uncertainty.

David Slepian, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, the laboratory proposes 127 known pseudorandom phase chips, each lasting one microsecond. A matched detector might report a striking correlation after a weak burst has been averaged coherently, whereas an impulsive discharge has broad raw spectral support but no intended code. Please derive the ideal processing-gain intuition carefully without presenting 127 as a universal improvement factor in every receiver. I ask you to consider unknown carrier offset, code-phase selection, non-white noise, fading and the case of a strong impulse that temporarily overwhelms

Copyright 2026, James M. Atkinson

the converter. How should the examiner count the alternative code and timing hypotheses searched, and what must be done to prevent a lucky high score selected from a large bank of filters from being misrepresented as independent proof of an intentional communication? Please distinguish the direct-sequence case from a frequency-hopping structure, because both can spread energy without presenting the same matched-filter observation. The comparison should be tested on a reserved set of authentic synthetic controls.

Claude Elwood Shannon, Cross-Peer Answer to David Slepian: Dr. Slepian, in an ideal coherent matched-filter calculation, the signal contributions from N equally weighted, known and correctly aligned chips can add as amplitudes, while independent zero-mean noise contributions add in power. Under appropriate normalisation and assumptions, the matched-filter output signal-to-noise power ratio can enjoy a factor proportional to N relative to an appropriate single-chip comparison. For N=127 the ratio is 127, or approximately 10 log10(127)=21.04 decibels. That is an idealised processing-gain illustration, not a guaranteed improvement in sensitivity, and it does not assert that the received field actually contains the assumed chips. The phrase 'processing gain' must be tied to a precise comparison and noise model. A coloured interferer may align with the chosen code or occupy a small part of the measurement band; an impulsive disturbance may dominate several chips or saturate the receiver. If the analogue converter clips, the information lost during the overload cannot be recreated by a digital matched filter. Carrier-frequency offset introduces a phase rotation across the coherent interval and can diminish the aligned sum; timing error or uncertain code phase likewise reduces the predicted peak. A channel with

Copyright 2026, James M. Atkinson

several delayed paths may produce multiple peaks. Those impairments need to be modelled or tested with known synthetic sources before an instrument is said to achieve a numerical gain. Search multiplicity is decisive. Suppose an examiner tests many code candidates, many phase offsets and several carrier corrections. The maximum score among those hypotheses will tend to exceed a score from one predeclared hypothesis even under a no-source null. The calibration should reproduce the entire candidate search on comparable no-source and impulse-only recordings, and the threshold should apply to that maximum or to an appropriate controlled error objective. Alternatively choose a code and timing model from exploratory data and test it prospectively on an independent capture. Recording only the winning candidate obscures the relevant trials. A detector's outcome must also be interpreted at the level it can support. If a known authorised reference code is positively detected under calibrated conditions, that may establish a consistent waveform component in the synthetic test. It does not identify an unknown sender or reveal message content; in an unknown recording, a similar score may have multiple explanations. When the code is not known legitimately, one should not infer its family from spectral flatness alone. A robust report states the code hypothesis, reference provenance, tested alternatives, calibrated false-alarm distribution and the effect of receiver saturation or missing samples. The code-specific result then remains an accountable experimental claim instead of an invented attribution.

Dr. James M. Atkinson, Moderator: Dr. Slepian, thank you. Dr. Shannon, I pass the token to you. Please examine processing gain, the distinction

Copyright 2026, James M. Atkinson

between structure and content, and the inferential risk of searching too many candidate codes.

Claude Elwood Shannon, Second Principal Contributor: The phrase spread spectrum describes an intentional relationship between the information-bearing or signalling structure and an occupied frequency band broader than an elementary narrowband representation would require. It does not denote a particular appearance on a display and it is not authenticated by a shallow spectral peak. An electrical impulse can distribute energy over a broad frequency range without being a communication, while a spread-spectrum waveform can be made inconspicuous in power density precisely because its energy is distributed. The distinction therefore involves an inference about signal construction, tested against the measurement chain and competing natural or technical causes. No frequency-domain plot alone supplies that missing causal premise. One must first specify the statistical observation. Let x[n] be calibrated complex samples in an eligible window, let c[n] denote a known authorised unit-modulus reference chip sequence and let N be the number of chips being compared. A simplified matched output might be S(tau)=sum over n of x[n+tau] conjugate(c[n]), with tau a candidate alignment index. Under an ideal known waveform and phase alignment, the desired contributions add coherently. Independent additive noise contributes a random complex sum whose variance grows with the number of terms. Under a matched set of assumptions, the output signal-to-noise power improvement relative to a single-chip matched observation scales with N. This is an engineering mechanism, not a certificate that any particular field emission uses the code c. Consider the entirely synthetic example of 127 known chips at one megachip per second, with the chip

Copyright 2026, James M. Atkinson

sequence lasting 127 microseconds. The ideal coherent accumulation factor of 127 corresponds to about 21.04 decibels, because ten times the base-ten logarithm of 127 is approximately 21.04. The result depends on the definition of the reference SNR, the normalization of the correlator and a noise model with sufficiently independent contributions. A strong impulsive disturbance, correlated interference, an untracked carrier offset or an invalid acquisition interval can defeat the idealised conclusion. The number 127 is not a guarantee of field performance, nor does a weak displayed signal become physically stronger merely because a calculation applies a matched reference. The distinction between spread-spectrum structure and noise is partly one of reproducible predictive relationships. A coded synthetic burst has a particular timing and phase sequence known independently to its legitimate laboratory generator. A narrow impulsive discharge does not ordinarily preserve that sequence across 127 chips, but a large bank of code and timing hypotheses can occasionally find accidental agreement. The false-alarm probability of the largest observed score must be calibrated over the whole bank, not borrowed from a probability calculated for one fixed code and one predeclared delay. If an investigator searches a hundred codes, a thousand delays and dozens of frequency offsets, the effective selection problem is much larger than the final chart suggests, although dependence prevents a simple assumption that every comparison is independent. When the actual code is unknown, a clever detector may estimate statistical signs of structured timing, symbol-level recurrence or a chip-like rate without extracting protected content. Such estimators have different evidence levels from a legitimate known-code matched filter. The observed statistics may also arise from periodic

Copyright 2026, James M. Atkinson

switching noise, a pulse train, receiver clock products or other broadband sources. Code-family identification requires stronger discriminants than a flat spectrum, and the number of possible source constructions is generally too large for one finite record to eliminate. A probability assigned to one favoured family means little unless its competing family models and prior restrictions are made explicit. Receiver impairment is not a peripheral issue. A burst may be too weak to trigger an energy detector yet produce a useful known-reference score when the receiver is linear and the noise behaves as assumed. But a large impulse may overload the mixer or converter and create a flood of spurious frequency bins; the matched filter may then report a high accidental peak or a missed genuine burst because valid samples were clipped or blanked. A normalised score can conceal the fact that the raw input was outside the receiver's calibrated dynamic range. Therefore every candidate should retain its absolute signal-energy measure, gain state, saturation flags, frequency correction and sample-eligibility record. A particularly dangerous inference is to equate a high processing gain with a high probability of finding an unknown signal. A matched filter is powerful when the reference is correct; it is not a universal detector for every possible code. If the code, phase, carrier offset or chip rate is wrong, the expected correlation may be weak even when a genuine spread-spectrum emitter is present. Conversely, a coincidental correlation to a selected reference may be spectacular when millions of alternatives have been tested. A reserved evaluation session should test a fixed detector and quantify both detection probability and false alarms under realistic synthetic sources. The decision threshold belongs to that measured operating characteristic, not to a verbal promise that correlation is inherently reliable.

Copyright 2026, James M. Atkinson

The lawfulness of the measurement and the logic of attribution must remain separate. An authorised test sequence may be used to calibrate instrumentation without opening any protected communication content. A signal-structure hypothesis that survives calibration does not reveal the identity of its sender, its purpose, location or message. Independent evidence such as direction finding, physical source control, environmental switching records and a validated chain of custody would be required for broader claims. Even those may support only a bounded inference because several devices can use similar modulation families or share the same interference environment. I would report a spectrum with its measured noise reference, an event duration with clock uncertainty, a calibrated spectral-flatness statistic, an explicit hypothesis set, and performance of any known-reference detector against withheld laboratory truth. I would retain both the raw and normalised correlations, the list of searched codes and delays, and the frequency-offset assumptions. A positive finding means that specified measurements favour a particular tested structure over named alternatives in the stated conditions. A negative finding means only that the chosen receiver and detector did not observe the specified structure within their measured opportunity and sensitivity. Neither result should be decorated into a broader story of an authenticated transmitter.

Sir Martin Ryle, Peer Question: Dr. Shannon, you place confidence in a code-specific correlation only after calibration. Yet a radio observatory records astrophysical and terrestrial transients through antennas whose gains, side lobes and propagation paths vary with direction and frequency. A broadband impulse may be received through multiple side lobes or through a common cable shield, producing a striking apparent coincidence between

Copyright 2026, James M. Atkinson

antennas. How should a defensive survey separate code-dependent temporal structure from spatial correlation introduced by a common interference source or common receiver electronics? I should like an experiment with two antennas whose effective directional responses are measured, an independent synthetic reference burst and an impulsive nuisance source at a controlled location. Please explain how a case in which both antennas detect the same brief broadband event should be described without treating agreement alone as proof that a deliberate communication was emitted. Would changing antenna polarisation or placing a terminated input on one channel help disclose the extent to which apparently simultaneous events reflect a common distribution stage?

Claude Elwood Shannon, Response: Sir Martin, multiple receivers add information only to the extent that their observations constrain different aspects of the proposed mechanism. Two antennas receiving the same broadband transient can agree in time because they share a physical source, but that source might be an electrical discharge, a switching supply, a deliberate laboratory transmission or a lightning event. Agreement of event timestamps therefore supports the existence of a shared disturbance under suitable timing calibration; it does not certify coded modulation. Similarly, both receivers might share a distribution amplifier that produces a common artefact downstream of the antennas, so even the claim of a shared external source must be tested. Begin by measuring each antenna's frequency-dependent gain, polarisation and directional response over the intended survey band. Preserve cable losses, preamplifier states, clock offsets and input levels. Inject a synthetic known-code burst from a permitted controlled source at several safe locations and orientations,

Copyright 2026, James M. Atkinson

logging its emission time independently. Introduce a calibrated broadband impulse from another controlled source, and repeat with one input terminated or with a receiver path bypassing the shared distribution amplifier. A valid known-reference detector should show the specified code-dependent response where the artificial source is present, while the impulse-only trials should establish its false-alarm distribution under realistic front-end conditions. Spatial correlation should be analysed separately from code correlation. The first may involve relative arrival times and received amplitudes at two calibrated sites; the second concerns matching a complex sample sequence to a declared reference. Their errors are not independent merely because both involve correlation. A strong impulse can dominate both antennas and drive both converters into saturation, while a near-field source can create complex coupling that violates a simple plane-wave direction model. Disclose those limitations and, where possible, use a second architecture whose failure modes differ from the first. If both antennas detect one brief event, the statement should be that a time-coincident broadband transient was recorded at two measured apertures with a specified timing tolerance and known common-mode qualifications. If a calibrated reference-sequence detector also scores positively, describe its predeclared threshold, the full candidate search and its false-positive performance. Do not merge the two observations into an unwarranted communication claim. A robust inference should tell the reader which additional alternative hypotheses were actually excluded, not simply enumerate the instruments that flashed at the same moment.

Claude Elwood Shannon, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, the detector bank may be perfectly programmed and

Copyright 2026, James M. Atkinson

internally reproducible, yet still produce a misleading positive when an investigator selects the highest apparent code correlation from many candidate chips, delays and carrier offsets. Would you prescribe an auditable search register and an independent validation design that separate genuine known-code evidence from a chance high maximum? I ask you to consider phase-alignment uncertainty, missing samples, automatic normalisation and the possibility that a few saturated samples dominate the result. What minimum data-quality controls must the software enforce before any score may enter the inferential calculation, and how should the report explain a detector that is reliable on isolated synthetic bursts but fails badly when calibrated impulsive interference overlaps the code sequence? How should a shared hardware clock or processor load be represented in the test design when it creates coherent errors across otherwise independent code-correlation channels? Please include a control where the reference-code generator is physically disconnected.

Richard Wesley Hamming, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, the search register must be as complete as the input data. For each candidate test retain the code reference identifier and its authorised provenance, the examined delay, frequency correction, chip rate, eligible sample indices, normalisation denominator, score, threshold and decision. Also preserve the rule used to select which candidates were tested next. A program that reports only the strongest code-phase point has discarded part of the experiment, even if its calculation of that point is impeccable. Reproducibility of the winning score does not validate a false-alarm probability derived from a smaller search space than was actually used. The data-quality gate comes first. Reject or separately mark any interval with

Copyright 2026, James M. Atkinson

unverified sample-counter continuity, sample-rate changes, retuning, gain instability, overrange samples or missing blocks. An impulse may corrupt only a few chips, but their extreme amplitudes can dominate a correlation score or drive the normalisation into an unstable region. The software should have declared policies for excluding invalid samples and, where appropriate, a robust statistic tested against adverse synthetic impulse trials. Those policies must not be changed after observing which exclusions make the desired signal appear more convincing. Retain both the raw score and the eligibility mask so an independent auditor can reproduce the decision. For inference, freeze a detector on an exploratory source set, then evaluate it on a reserved collection containing known-code bursts, impulses, mixtures and no-source conditions. The trials should be blinded or coded so the evaluator cannot favour the correct answer. When the detector searches many codes or offsets, calibrate the maximum statistic or another declared global error measure under the full search rather than assuming the one-test significance survives selection. Preserve unsuccessful as well as successful synthetic cases and give confidence intervals that recognise repeated correlated trials. A detector that performs well on isolated bursts but fails during overlapped impulses has a bounded operating envelope. The proper statement is not that it detects spread spectrum with the isolated-test success rate under all conditions. Report performance by input level, impulse amplitude, timing overlap, receiver gain and channel response. If a strong pulse saturates the analogue front end, the event may be ineligible rather than a clean negative communication result. Software can record and classify the invalid state, but it cannot reconstruct information clipped before digitisation. No high correlation should be

Copyright 2026, James M. Atkinson

promoted to source attribution until the measurement chain and the complete search have survived independent challenge.

Dr. James M. Atkinson, Moderator: Dr. Shannon, thank you. Dr. Hamming, kindly accept the token and explain how a software and evidence chain can discriminate a defensible hypothesis from a reproducible but selected correlation accident.

Richard Wesley Hamming, Third Principal Contributor: A detection algorithm is a sequence of decisions made about data, and every one of those decisions has a provenance. When an examiner claims to have distinguished a weak spread-spectrum burst from a broadband impulse, the software should be able to show what data were eligible, which reference features were applied, what thresholds had been prescribed and how the competing hypotheses were evaluated. A perfect hash of a flawed data file merely establishes that the flaw has been preserved unchanged. A perfectly repeated computation of an overfitted classifier merely repeats the same error. The audit must examine physical measurement, digital continuity and statistical selection as three distinct layers. The raw record is not just an array of complex numbers. It includes a sample clock, frequency plan, tuning state, gain-control history, channel filters, sample counters, overrange flags and any editing or interpolation applied after acquisition. A high-amplitude discharge can saturate a converter for several samples and provoke gain recovery lasting longer than the physical discharge. If the software reconstructs the missing interval with zeros or repeats a previous buffer, it can introduce a pattern that resembles an encoded burst. The investigator must preserve invalid-range masks and prevent code correlation from treating reconstructed samples as actual radio

Copyright 2026, James M. Atkinson

observations. An event scored during such a gap is an instrumentation-quality finding, not a valid source classification. A useful software gate begins by verifying counter continuity and source metadata. Each block's first count should follow its predecessor as expected, unless an explicit discontinuity is recorded. Its byte size should agree with the sample format and declared number of samples. The timestamp should be consistent with the independent clock calibration to within a stated tolerance, and changes in decimation, digital filters or frequency correction should be recorded. The original samples and the exact analysis version should remain immutable; a corrected analysis creates a new derivative, not an overwritten record. If the instrument captures two overlapping channels, their respective clocks and delay corrections must be documented before event alignment is treated as evidence. Once eligibility is established, test the algorithm with known sequences for which its expected behaviour can be independently calculated. A noise-only complex sequence should not regularly generate an above-threshold score when the threshold has been calibrated for that null and complete search. An exact known 127-chip reference with matching phase and timing should produce the expected coherent accumulation under the stated model. A single large impulse should test whether normalisation, clipping handling or the correlator creates a false matched response. A periodic impulse train and a gated tone should be additional adverse sources. These cases should include both the raw analogue-chain capture and a software-generated test vector so hardware and code faults can be separated. The multiple-search problem is especially important because a family of pseudorandom codes contains many candidate patterns. If an analyst tries K sequences, T delays and F frequency

Copyright 2026, James M. Atkinson

corrections, the number of nominal test combinations is K times T times F, before considering multiple windows and antenna channels. These tests are generally correlated, so that product is not the number of independent trials, but it does describe a significant selection opportunity. An attractive peak found among ten thousand possibilities cannot be assessed with the probability applicable to a single fixed candidate. Calibrate the entire maximum-selection procedure through no-source and impulse-only records, or freeze the model from independent exploratory data and evaluate it prospectively. Another error arises when a software developer silently chooses a detector's acceptance window after viewing the most favourable synthetic results. A code-correlator may be optimised on isolated clean bursts until it reports an impressive detection rate, but that tells little about its behaviour when a strong impulse overlaps the burst or when the source clock drifts. The development set should establish the algorithm; a reserved evaluation set should estimate its performance. Include all specified trial conditions and record every exclusion, otherwise the reported success rate will merely reflect the easiest cases. Repeating the same selected trial many times does not create a new inference about the uncontrolled field environment. Consider a programme with 100 independently seeded synthetic test opportunities, of which 40 are known-code bursts, 40 are impulse-only events and 20 have no source. Suppose the detector declares 35 of the 40 coded trials positive, but also declares 8 of the 40 impulse-only and 2 of the 20 no-source trials positive. The sensitivity against the seeded coded class is 35/40=87.5 percent, and the false-positive fraction across the specified 60 non-coded trials is 10/60, approximately 16.7 percent. These two figures describe different denominators and different operational

Copyright 2026, James M. Atkinson

consequences. They do not derive from a real instrument; they demonstrate why an isolated sensitivity percentage is inadequate. The independence and uncertainty of repeated laboratory trials would also need assessment before attaching precise confidence intervals. Causation is distinct from pattern classification. Even if a known-code reference produces a high score, a common clock spur, a coupled laboratory test generator or an instrument's own firmware may generate that pattern. The operator should challenge the apparent source with a terminated RF input, a changed injection path, known attenuator positions and a second receiver architecture. A correlation peak that remains when the antenna input is terminated cannot be treated uncritically as an external emission. If it disappears after upstream attenuation, consider front-end overload as well as the possibility that a genuine weak signal has become undetectable. Each intervention must be interpreted within a measured sensitivity range. The final evidence table should keep observed event features separate from analyst hypotheses. It may state a frequency band, event duration, peak power, spectral-flatness value, correlation score, false-alarm calibration, acquisition validity and whether a known synthetic code was present in a controlled test. It should not infer the identity, intent or content of an unknown sender from those columns. Auditability is not achieved by a long list of instrument serial numbers alone; it requires preserving the decision pathway and the failures that limit interpretation. A defensible software system makes its uncertainty visible, rather than composing confidence out of incomplete samples and a beautifully formatted result page.

Donald Watts Davies, Peer Question: Dr. Hamming, a modern receiver can record samples in hardware and then transport them through multiple

Copyright 2026, James M. Atkinson

buffering and packetisation stages before a host computer writes the event file. A packet may arrive late or be dropped even though the radio-frequency front end was functioning normally. Conversely, a missing sample block may be concealed when the host fills the gap from a replay buffer, causing a spurious repeated sequence that correlates with a code reference. Would you distinguish loss of telemetry about a valid measurement from loss of the measurement itself, and identify the counters or checksums that would expose each? Please describe an experiment in which the transport network is intentionally loaded while the authorised synthetic RF source remains constant, and explain why timestamping a file after it is written does not prove that the recorded burst began at the asserted physical time. I ask also how the examiner should treat duplicated metadata that point twice to the same samples, since multiple event rows are not multiple physical observations.

Richard Wesley Hamming, Response: Mr. Davies, the path from the converter to the final file needs an explicit sequence of custody. A radio-frequency sample can be acquired correctly but delivered late to the application, and lateness need not make the sample content invalid if its hardware counter and data bytes remain intact. By contrast, a sample block lost before storage creates an actual gap in the recorded evidence; replacing it with a previous block or with interpolated values cannot restore the missing physical observation. A packet lost in the transport network may create either an unrecoverable sample gap or merely a delayed delivery, depending on buffering and retransmission. The instrument must distinguish these cases in its status record. Include hardware sample counters, producer and consumer buffer sequence numbers, packet

Copyright 2026, James M. Atkinson

identifiers, checksums where appropriate, and explicit overrun and underrun flags. Tie time to the sampler or another traceable acquisition clock, not to the time the host happened to flush a file to disk. A file-system timestamp documents a storage operation; it cannot provide a reliable emission time if buffering latency is variable. Clock offsets, discipline state, and conversion between hardware ticks and physical seconds must be recorded with uncertainty. In a multi-receiver system, counters may be incomparable unless their timebases have been measured against a common reference. An authorised stress test holds the synthetic source constant while varying network load, disk pressure and application scheduling. Independently log every seeded burst from the generator. The receiver should preserve counters and event eligibility across ordinary delays, while flagging actual missing samples and forbidding a lag comparison that crosses a gap. Introduce a controlled repeated-buffer fault to test whether the detector can reject a fabricated correlation peak, then remove the fault and confirm that the reference source remains detectable. A separate test uses no RF source so that transport artefacts can be identified without ambiguity. Every reported detection should point to the raw sample ranges that support it, along with the acquisition configuration and analysis version. If an event's timestamp is uncertain because counters were not synchronised, the uncertainty must be widened rather than silently corrected by aligning it to a convenient external event. A checksum of the stored file remains useful for proving that the bytes have not changed since sealing, but it cannot prove the bytes originated from an uninterrupted analogue capture. The distinction between a valid late measurement and a

Copyright 2026, James M. Atkinson

missing measurement is the foundation of any later claim about code timing or impulse duration.

John Wilder Tukey, Peer Question: Dr. Hamming, your test programme reports sensitivity and a false-positive fraction, but real impulsive environments are highly heterogeneous. A few severe discharges may produce many correlated apparent events, while long quiet intervals contribute thousands of easy non-events. If the evaluator chooses only balanced illustrative trials, the resulting false-alarm figure may not represent a different field survey. How should performance be stratified by impulse amplitude, duration, receiver gain and overlap with a known code burst? I ask whether a blind holdout set must include ordinary negative observations as well as unusually conspicuous interference, and how the analyst should disclose an exploratory classifier whose thresholds were repeatedly adjusted after examining the failures. Please explain why a single pooled accuracy figure is insufficient when a forensic conclusion depends upon very rare false identifications. Would a bootstrap that resamples individual pulses independently understate uncertainty when those pulses occur in strongly correlated bursts of electrical switching activity?

Richard Wesley Hamming, Response: Mr. Tukey, the evaluative population must match the claim being made. A balanced laboratory set can be useful for comparing mechanisms, but its prevalence of coded and non-coded events does not automatically represent the probability of such sources in a field investigation. The laboratory should report class-conditional performance separately, including sensitivity for seeded coded bursts and false-positive probability for specified impulse classes, under defined receiver conditions. If an operational prediction depends on the prevalence

Copyright 2026, James M. Atkinson

of these classes, the prevalence assumption must be stated rather than smuggled into one pooled accuracy number. Stratify the challenge by input power, impulsive peak amplitude, recovery duration, spectral concentration, antenna path, receiver gain state, code-burst SNR and relative timing of impulse overlap. Use prespecified ranges selected from defensible engineering limits. An aggregate number may be supplied with explicit weights for a stated operating scenario, but the underlying stratified results should remain available. A detector may distinguish clean isolated pulses well and fail under a brief overload at a particular gain, which is precisely the failure a high-stakes defensive survey must disclose. An unweighted mean across unrelated test conditions can conceal that limitation. A blind holdout should include ordinary negative observations, controlled impulse-only events, known-code bursts, and mixtures. If events are clustered in time or arise from repeated operation of the same source, confidence intervals must reflect that dependence rather than treating every recorded pulse as an independent trial. The analyst should freeze thresholds and reference hypotheses before evaluating the holdout. When failures provoke threshold changes, the previous holdout becomes part of development, and a fresh reserved set is required for an unqualified evaluation. Otherwise describe the revised result as exploratory. Rare false identifications deserve particular attention. A false-positive rate that appears small per event can become troublesome when the detector searches millions of windows, codes and frequency corrections. The calibration needs to account for the full candidate-selection process and the actual eligibility rules. Report the number of negative opportunities examined, their correlation structure and uncertainty bounds. If the available data support only an upper confidence

Copyright 2026, James M. Atkinson

bound too large for the proposed forensic use, the appropriate outcome is a limitation on that use, not an optimistic extrapolation. A good classifier is defined by the exact claims its evidence can sustain, not the elegance of a single percentage on a dashboard.

Richard Wesley Hamming, Cross-Peer Question to Ronald Newbold Bracewell: Dr. Bracewell, software correlation can create a seductive match when a receiver is overloaded or when the sampled interval contains a broad impulse shaped by the receiving filter. Your antenna and Fourier expertise offers an independent physical challenge. How would you use separated antennas, known impulse injections, bandpass variation and time-aligned reference captures to distinguish a true externally radiated coded burst from a local switching transient or an internally generated mixer product? I should like you to address the danger of treating two receivers on one shared antenna distribution amplifier as independent witnesses. Specify what a cross-correlation between receiver records proves, what it cannot prove, and how one might use controlled source movement or attenuation without accidentally changing the receiver sensitivity enough to conceal a genuine weak spread-spectrum signal. What should the audit say if the winning correlation peak appears only after analysts changed their exclusion rules for saturated samples in response to the initial result?

Ronald Newbold Bracewell, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, the first principle is to separate the spatial inference from the temporal-code inference. An impulse may be visible at two antennas because it is a real radiated disturbance; that fact does not make it encoded. Two receivers attached to a common distribution amplifier may share an internally generated harmonic or clipped broadband product, so

Copyright 2026, James M. Atkinson

simultaneous indications do not by themselves establish a source outside the system. Construct a signal-path diagram identifying all common oscillators, front-end stages, clocks, cabling and grounds, then challenge the common stages with terminated-input and known-source tests. Place a lawful synthetic coded source and a calibrated impulse source at known test positions. Record their actual launch times and input strengths independently. Measure each antenna's frequency-dependent directional gain, cable loss and polarisation so amplitude ratios can be interpreted conditionally. A source moved through known positions should produce predictable changes in path loss and directional response, subject to near-field and multipath complications. A disturbance that remains fixed in the instrument despite such changes may be local to the receiving chain, though absence of change is not conclusive when the radiation geometry is complex. Vary the bandpass and input attenuation in controlled steps. An impulsive source convolved with the receiver's impulse response may change its observed duration and oscillatory tail as the filter changes; a coded burst may also be distorted, so comparisons must use known reference captures. Put attenuation ahead of a suspected nonlinear stage, not only after it. If a false wideband feature collapses with upstream attenuation and displays nonlinear input-power scaling, consider overload or intermodulation. At the same time use an independently seeded weak coded reference to quantify the sensitivity sacrificed by the attenuation. One must not declare an artefact removed merely because the entire receiver has become deaf. Time-align the two receiver records with measured clock uncertainty before interpreting cross-correlation peaks. A shared burst or impulse may yield a relative-delay estimate, but the estimate's ambiguity

Copyright 2026, James M. Atkinson

can be influenced by narrow bandwidth, multipath and common clock errors. Repeat with an independent receiver architecture and, where possible, independent clocks. Present the code-specific detector score and the spatial coincidence as different observations, each with its own null model and limitations. Strong agreement can support a shared physical event; only an additional validated, code-specific test supports the narrower hypothesis of a particular synthetic spreading structure. Neither supplies message content or authenticated sender identity.

Dr. James M. Atkinson, Moderator: Dr. Hamming, thank you. Dr. Bracewell, I now pass the token for a fuller examination of antenna geometry, impulse spectra, receiver convolution and the differences between physical corroboration and modulation identification.

Ronald Newbold Bracewell, Fourth Principal Contributor: Broadband energy should be analysed as a physical field observed through an imperfect spatial and spectral aperture. The receiving antenna is not a neutral funnel into the instrument. Its directional response, polarisation, impedance, coupling to nearby structures and frequency dependence determine which parts of the field are captured and how strongly. A lightning impulse, an electrostatic discharge near a cable, a switching power supply and an intentionally coded radio source may each excite the measurement chain differently. Yet they can all leave bright short-duration traces across numerous frequency bins when their waveforms are convolved with the front-end response. One must not confuse the shape of that response with the spectrum of the source that caused it. The Fourier transform of a short pulse illustrates the problem. A rectangular voltage pulse of duration T has, under an idealised convention, a magnitude spectrum proportional to the absolute value of sin(pi f T)/(pi f),

Copyright 2026, James M. Atkinson

after appropriate scaling. A sufficiently brief pulse therefore extends its energy across a broad frequency region, with lobes and nulls shaped by its finite duration. Rise time, fall time, circuit parasitics and the receiver bandwidth alter that picture. A code-bearing burst can also be broad, but its breadth is introduced through intentional temporal modulation or frequency variation. The shared property of broadband energy cannot distinguish those causes. An impulse-spectrum calibration is consequently as important as an ordinary swept-tone calibration when the instrument is used to classify short events. A lawful laboratory test should characterise the impulse response of the entire receiver path. Connect a calibrated impulse generator at a stated reference plane, keep the gain within its verified linear region and record the resulting I/Q or envelope samples. Repeat at several impulse amplitudes and front-end filter settings. The observed ringing and spectral flatness can then be compared with a separately injected known-code spread burst of similar total received energy. Both references must be independently logged. A high correlation score obtained from one test does not make the other impossible, because the filters and correlation search may create accidental matches. The meaningful evidence is the difference between predictive behaviour under the two controlled source models. Spatial observations offer another set of predictions, but no absolute verdict. Place two calibrated antennas at known positions and orientations, connected to receivers whose timing offsets have been measured. For a far-field wavefront in a sufficiently simple environment, a relative arrival delay may be related to the path difference divided by wave propagation speed. In a building, however, reflections, near-field coupling, cable paths and common-mode currents can violate a simple plane-wave model. A discharge

Copyright 2026, James M. Atkinson

coupled directly into the receiver power cable may be nearly simultaneous in both recorders without representing an external far-field emission. The antenna arrangement and grounding architecture should therefore be documented in the same detail as the digital analysis. Change the test geometry prospectively. A directional antenna rotated by a known angle should change the response to a radiated source according to its measured pattern, while a disturbance injected downstream of the antenna may remain largely unaffected. Move the known synthetic source through a small set of authorised positions and log the resulting amplitude and timing changes. Then repeat with a local impulse source and, separately, with the RF inputs terminated. The observed class signatures should be compared against predictions prepared before the trials. A difference caused by moving an antenna supports a spatial mechanism but does not by itself prove that the source used a spread code rather than being a broadband discharge in the environment. The receiver's nonlinearities can defeat spatial interpretation. A strong interferer picked up by both antennas may create intermodulation products in a shared amplifier, and those products can appear in multiple frequency channels. If the examiner sees the same false feature in two receivers fed by that amplifier, the agreement is not independent. Insert calibrated attenuation ahead of the common nonlinear stage, or bypass the stage entirely, while retaining a weak known reference to measure the sensitivity cost. Change the receiver's mixing plan and preselector, then compare the apparent frequency of the feature. A product that follows the conversion architecture rather than the calibrated external source frequency is a plausible instrument artefact, though coincident external signals must still be considered. Signal-to-noise ratio deserves the

Copyright 2026, James M. Atkinson

same discipline. A deliberately spread burst can have modest per-bin power yet contain enough coherent energy to be recognised with a correct authorised code reference. But wideband amplitude alone cannot provide that recognition. An impulse can deliver enormous energy for a tiny interval, potentially driving an automatic gain loop into recovery and making subsequent events appear short or absent. A survey that integrates only accepted positive bursts may conclude that the source transmits intermittently when the receiver is actually blinded intermittently. Record front-end overload, gain-control state, detector dead time and exact eligible intervals. Without those measurements, a low observed peak is not proof that a source was absent, and a large peak is not proof that the source was communicative. The investigator should also distinguish independent observations from repeated processing. A correlation map, a spectrogram and a spectral-flatness estimate derived from one I/Q record are three analytical descriptions of one physical capture. They can test internal consistency and expose different alternative mechanisms; they are not three independent witnesses. A second receiver adds evidence when it supplies genuinely distinct hardware and calibration, but common clocks, antennas and shielding defects may link their errors. A controlled source whose class is independently known provides stronger validation than a collection of methods applied to the same unknown burst. My concluding claim is deliberately narrower than an identification. If a particular known synthetic code produces a calibrated correlation response, if the response survives lawful changes in antenna geometry and front-end state, and if representative impulses and no-source controls do not mimic it at the declared operating threshold, the instrument has demonstrated some

Copyright 2026, James M. Atkinson

discriminatory capability for that test class. An unknown brief event may then be described as compatible with a spread-spectrum construction, subject to the measured limitations. It has not been attributed to a particular transmitter, decoded or shown to be intentional. The expert must describe the spatial, spectral and temporal apertures that made the observation possible before the coloured trace can be given any forensic meaning.

Andrey Nikolaevich Kolmogorov, Peer Question: Dr. Bracewell, the physical controls are persuasive, but the statistical design still worries me. A test campaign may use many antenna angles, filter bandwidths, input powers, detector thresholds and code references before retaining only the combination that distinguishes its synthetic training sources most impressively. Even without an arithmetic mistake, this selection can produce an overoptimistic performance estimate. How would you preserve the experimental search and still permit engineering exploration? Please distinguish a null distribution obtained from independent impulse-only trials from one obtained by shuffling individual samples of a coloured receiver record, since the latter may destroy precisely the dependence that causes false correlation peaks. I should also like a statement of how correlated repeated impulses from one switching mechanism differ statistically from independent trials across distinct operating conditions when a confidence interval is constructed. Please distinguish a legitimately calibrated impulse-source spectrum from the spectral width obtained by simply changing a receiver display window or frequency resolution.

Ronald Newbold Bracewell, Response: Dr. Kolmogorov, the experiment must be designed so that exploration, calibration and evaluation are not

Copyright 2026, James M. Atkinson

confused. Exploratory trials can map which antenna geometries, filters and detector settings respond to the candidate sources. They should be retained with enough detail to show how the final detector was selected. A separate calibration collection can estimate the null distribution under defined no-source and impulsive interference conditions, while a reserved evaluation set tests the frozen algorithm and the declared operating point. If the evaluation results prompt further changes, those results become part of development and a new independent assessment is required for a confirmatory performance claim. The null should reproduce the dependence created by the physical receiver. An independent impulse-only capture through the same filters and gain configuration is stronger evidence about field false alarms than an artificial sequence obtained by randomly scrambling individual recorded samples. Such scrambling destroys temporal colour, filter ringing and clustering, potentially producing a null distribution with far fewer accidental peaks than the actual instrument. Block resampling or a source-specific simulation may preserve some dependence, but its assumptions and block scale must be validated against separate data. A threshold derived from a white independent-noise model cannot be transported uncritically to a pulse-rich industrial environment. Correlated switching impulses require care in uncertainty analysis. One hundred pulses emitted during one repeated switching cycle may share temperature, voltage, cable geometry and receiver state; their detection outcomes are not necessarily one hundred independent Bernoulli trials. Stratify or cluster observations by source episode and laboratory condition, and present performance across independent runs where possible. A confidence interval based solely on the count of individual pulses may be too narrow.

Copyright 2026, James M. Atkinson

Randomise safe source timing and vary conditions prospectively so that the detector is challenged outside the precise circumstance in which it was tuned. The physical controls should also be held constant or varied according to a declared factorial design, rather than changed opportunistically whenever the detector fails. Record the input-plane levels and calibration uncertainties for each antenna and filter configuration. If a genuine weak known-code burst disappears after upstream attenuation, quantify that sensitivity loss before claiming that the attenuation has removed only spurious interference. A fair evaluation presents detection and false-alarm rates by relevant conditions and does not conceal hard cases in a convenient pooled percentage. A defended classification requires both the physical transfer-function story and the statistical selection story to survive independent examination.

Ronald Newbold Bracewell, Cross-Peer Question to Ralph Vinton Lyon Hartley: Mr. Hartley, I have described how the same broadband flash can arise from a discharge, a spread signal or a common receiver artefact. The field team must now decide what it can report after hours of recordings in which only some frequency-time cells were observed and the receiver occasionally blanked under strong impulses. Would you define the observation denominator so that absent detections are not confused with absent emissions? Please propose a reporting scheme that distinguishes a measured event, a coded-waveform hypothesis and a transmitter attribution, with uncertainty carried through each stage. I should also like the record to accommodate incidents where a known impulse source and an authorised coded reference overlap, causing a genuine code to be missed or a false score to appear. How would that ambiguity be stated without

Copyright 2026, James M. Atkinson

flattening it into a simple positive or negative label? Would you also separate a receiver aperture that never visited the emission frequency from an aperture that was visited but had insufficient input sensitivity to classify it?

Ralph Vinton Lyon Hartley, Cross-Peer Answer to Ronald Newbold Bracewell: Dr. Bracewell, the denominator is the set of frequency-time opportunities in which the instrument was capable of detecting the specified class under the stated performance criterion. An event not observed because the receiver was tuned elsewhere, saturated, recovering its gain or missing a sample block cannot fairly be counted as an exposed negative trial. For the complete survey, however, those losses still matter: report both overall capture opportunity and conditional detector success. The two measures answer different questions. A record of all eligible and ineligible intervals, with reasons and known reference-source truth where available, prevents a clean-looking event list from concealing systematic blindness. I would separate the report into three columns of inference. The observation column gives timestamps, valid frequency and bandwidth, measured amplitude, duration limits, detector statistic, noise reference, receiver state and calibration uncertainty. The structure-hypothesis column records which synthetic models were tested, their selection history, the null calibration, competing impulse explanations and the strength or weakness of the evidence. The attribution column remains empty unless independent source-localisation, physical or other lawful evidence supports it; a high processing-gain score alone does not fill it. A fourth administrative column may preserve chain of custody and reviewer qualification, but it must not be mistaken for scientific support. When an impulse overlaps a known coded

Copyright 2026, James M. Atkinson

reference, distinguish whether the receiver captured valid samples. If overload invalidated the interval, mark the classification technically indeterminate while retaining the independently logged fact that the laboratory generator transmitted. If the samples remained valid but the detector failed, that is an observed detection failure under the declared mixed-source condition. If a high code score appears during an impulse-only reference trial, it is a false-positive challenge requiring investigation of code search, filter memory or other structure. These distinct cases can be aggregated only with explicitly defined denominators and a stated purpose. An uncertainty statement should reflect more than random noise. It includes input-level calibration, antenna and filter response, missed observation opportunities, clock alignment, nonlinear receiver states, model selection and the possibility of untested source classes. The final sentence may say that the observed event exhibits features more compatible with a known laboratory spread-source model than with the impulse controls examined, while acknowledging what those controls do not exclude. It should not say that a covert transmitter has been found because a brief broadband trace looks unusual. Accurate reporting is the discipline that makes a limited measurement useful in an adversarial scientific or legal review.

Dr. James M. Atkinson, Moderator: Dr. Bracewell, thank you. Mr. Hartley, the token passes to you for a final treatment of observation denominators, the distinction between information structure and source identity, and the exact language of a defensible report.

Ralph Vinton Lyon Hartley, Fifth Principal Contributor: The observer's record must distinguish an occurrence from an opportunity to observe it. A

Copyright 2026, James M. Atkinson

wideband burst may last only a fraction of a millisecond, while a scanning receiver visits different frequencies in a schedule that leaves most channels unobserved at any given moment. A receiver with sufficient instantaneous bandwidth can reduce some gaps, but it may still blank during retuning, overload, processing pressure or other invalid states. A detector's silence in those intervals is not evidence that the physical environment was silent. Before presenting the fraction of bursts attributed to any waveform class, the examiner must show what portion of the relevant time-frequency domain the apparatus could have evaluated under its calibrated sensitivity limits. I propose three clearly separated counts in a controlled synthetic test. Let N_truth be the number of independently logged laboratory emissions, N_exposed those emissions intersecting a valid receiver aperture with sufficient input level for the declared test class, and N_positive those exposed emissions classified correctly by the frozen detector. The ratio N_exposed/N_truth describes the tested observation opportunity under the chosen generator schedule; N_positive/N_exposed describes a conditional detection fraction, provided N_exposed is nonzero. Their product is N_positive/N_truth in that synthetic model, but the factors diagnose different failure mechanisms. A field investigator ordinarily lacks N_truth for unknown sources, so these ratios must not be invented from positive detections alone. The calibration experiment establishes conditional instrument performance, not the count of unseen emissions. The instrument's event categories should reflect this logic. A valid positive coded-reference score is different from a broadband impulsive detection without code support. An invalid interval caused by clipping is different from a valid no-detection interval. A burst whose onset precedes the receiver

Copyright 2026, James M. Atkinson

aperture is left-censored; one continuing beyond the aperture is right-censored. A short observed duration may therefore reflect the sampling gate rather than the source's physical duration. These distinctions can alter spectral-flatness estimates and code correlations because the algorithm may evaluate only a fragment of the intended chip sequence. Report the measured segment and the bounds on full duration, rather than implying complete knowledge of an event the receiver did not observe from beginning to end. Information conveyed by a signal is also different from the appearance of information-bearing structure. A synthetic pseudorandom code may serve as a spreading sequence without revealing any substantive message to a defensive observer. The geometric flatness of a spectrum, the event's kurtosis or a high autocorrelation can be measured without accessing content, yet none uniquely identifies a communication. An impulse generator and a switching power circuit may produce broad, apparently noise-like spectra, while intentional communication may be narrowband or not match any of the laboratory's reference codes. The examiner should therefore describe the candidate family tested and its alternatives rather than speaking of communication merely because an event is unusual. The simplest controlled example contains a 127-chip coded burst and a broadband impulse of comparable total energy as measured at the receiver reference plane. That equality of total energy does not imply equal peak amplitude, converter overload risk or spectral power density. The impulse may have a very large peak over a tiny interval and drive the first amplifier into nonlinearity. The code source distributes its energy over the chip duration and may be detectable with a correct coherent reference even when no individual bin exceeds a convenient visual threshold. Any

Copyright 2026, James M. Atkinson

calculation of an ideal twenty-one-decibel processing gain must specify what SNR is compared, and it cannot repair a lost or clipped measurement. A meaningful test records total energy, peak amplitude, code score and acquisition validity separately. Another source of error is sampling opportunity selected by the detection algorithm itself. Some recorders retain only events that cross a broad energy trigger; a low-density coded burst may never be saved even though an offline matched filter could have recognised it from continuous valid I/Q. A powerful impulse, by contrast, may trigger readily and dominate the retained archive. The observed ratio of impulse-like to coded-like events would then reflect both the actual environment and the recording policy. Calibrate trigger probability with controlled sources and preserve the full eligibility record. Do not compare a wideband energy-triggered event table with a continuously sampled code-correlation result as though both arose from the same observation denominator. A formal inference should preserve the distinction between model compatibility and sender attribution. A candidate event may be consistent with several different waveform families after filtering, clock uncertainty and impulsive interference are considered. A validated known-code detector can support a specific reference structure when the source is authorised and its reference is independently established. Unknown sources remain ambiguous because similar detection scores can arise from untested codes or chance selection across a large bank. Attribution to a particular physical transmitter requires independent localisation, authorised inspection, source-control tests or other evidence beyond the spectrum. An event recorded in a conference room does not, by its location or apparent sophistication alone, identify a person or intention. The report's vocabulary

Copyright 2026, James M. Atkinson

must be stable across all conditions. 'Observed' should refer to measured eligible sample evidence. 'Consistent with' should refer to a stated model and defined alternatives. 'Confirmed' should be reserved for a prespecified independent test whose error rates are understood. 'Attributed' requires a separately supported physical-source inference. The same report should preserve conflicting findings, null intervals, failed laboratory trials and limitations of the instrument. A table that gives every entry a single confident label may be attractive to administrators, but it sacrifices the distinctions necessary for scientific and legal scrutiny. The final result should be proportionate to the evidence: a short broadband transient was observed during a specified valid receiver interval; its measured duration, spectrum, amplitude and correlation statistics lie within stated uncertainties; certain authorised synthetic tests favour or disfavor a spread-source hypothesis relative to the tested impulse models; receiver artefacts and other alternatives are either excluded to a stated extent or remain unresolved. This statement can be valuable even when it withholds a transmitter identity. It creates a reproducible record of what the instrument actually saw and what the experiment was capable of saying. That is a stronger form of technical knowledge than a dramatic but unsupported assertion that all unusual energy must have originated from a covert communication.

Egon Sharpe Pearson, Peer Question: Mr. Hartley, your proposed report distinguishes observation opportunity from detection performance, but its practical decision may still depend on the tolerated risk of a false accusation. A field investigator might regard one high detector score as sufficient to recommend a costly intrusive investigation, while another requires independent corroboration and several adverse controls. How should the

Copyright 2026, James M. Atkinson

report separate the measured false-positive probability for one prespecified synthetic test from the probability of one or more false candidates across a long survey containing millions of overlapping windows? I ask you to address the consequences of correlated trials, selective reporting of the strongest events, and changes in the operational threshold after an alarming indication has been seen. What would constitute an appropriately cautious evidential decision rule when the prevalence of intentional spread-spectrum emitters in the surveyed environment is unknown? I should also like your view on the practical distinction between approving a follow-up lawful survey and publicly asserting that a particular covert transmitter has been demonstrated.

Ralph Vinton Lyon Hartley, Response: Mr. Pearson, the acceptable error risk belongs to an explicitly stated decision problem rather than to an unexamined detector score. A false-positive probability calibrated for one fixed code, alignment and interval is not the same as the probability of a false event somewhere in a large search. Repeatedly examining overlapping windows produces dependence, so the nominal count of comparisons is not necessarily a count of independent tests, but selection among them still changes the distribution of the reported maximum. Calibrate the whole screening procedure under realistic no-source and impulse conditions, including its exact thresholding, event aggregation and ranking rules. A report that retains only the strongest alerts cannot borrow a per-window error probability without accounting for that selection. The threshold should be frozen before evaluating reserved data. If an alarming event prompts the analyst to lower or raise the threshold, the resulting score is exploratory and should be labelled as such. A prospective follow-up capture, controlled

Copyright 2026, James M. Atkinson

physical challenge or independent receiver can provide new evidence, whereas repeatedly analysing the same selected sample cannot create independent confirmation. The laboratory should measure how often an impulse-only or no-source trial produces a candidate requiring review, not simply how often the final classifier distinguishes two conveniently balanced test classes. Unknown prevalence presents a separate difficulty. Even a detector with a low class-conditional false-alarm rate may generate mostly false alerts when genuine coded sources are rare, but an exact positive predictive value cannot be computed without a justified prevalence assumption and representative class performance. Therefore the report should avoid a posterior probability of intentional transmission invented from a detector threshold. Present conditional test characteristics, ranges under stated prior scenarios if genuinely useful, and the evidence that independent controls add. The decision to authorise a further lawful investigation may be based on risk management and the seriousness of the environment, but that policy judgement must not be described as a scientific identification of a source. I would use staged decisions. A first tier identifies an unresolved broadband event requiring instrument checks. A second tier tests the declared spread-source hypothesis against impulse, clock, overload and environmental alternatives using frozen criteria and reserved observations. A third tier addresses physical attribution only with suitable independent evidence. Each tier records its own error controls and outstanding uncertainties. If the event occurs in an ineligible interval or only survives a retrospective search, it should not graduate to a stronger evidential category. The best decision rule is one whose scientific claim and

Copyright 2026, James M. Atkinson

operational consequence remain visibly separate, so a cautious investigative response does not imply more certainty than the measurements warrant.

Dr. James M. Atkinson, Moderator: The roundtable has shown that brief broadband energy is not self-identifying. A known-code matched filter may distinguish an authorised synthetic spread source from selected impulse controls under measured assumptions, but its ideal processing-gain arithmetic cannot be transported to a clipped or uncalibrated receiver. We have considered finite-window spectral leakage, impulse response, gain compression, sample integrity, search multiplicity, antenna correlation, observation opportunity and false attribution. I thank each contributor for the respectful passage of the token. The defensible conclusion is a bounded waveform-structure hypothesis with stated controls and uncertainty, not a claim to have decoded communications or identified an unknown sender.

QUESTION 086

Copyright 2026, James M. Atkinson

How should beacon-like repetition be described without assuming a named protocol?

SCHOLARLY RECONSTRUCTION. The named contributors were historical experts, but this dialogue is a fictional editorial reconstruction and represents neither their actual speech nor their endorsement. All cited experiments are proposed, authorised laboratory comparisons, not recovered protected traffic or proved attributions.

Dr. James M. Atkinson, Moderator: Dr. Elias, please examine what can and cannot be inferred from recurring burst times when the presumed beacon protocol is unknown. The observations, not the resemblance of an interval to a familiar timer, must determine the scope of the claim. You have the token.

Peter Elias, Principal Contributor: A beacon-like observation is a statement about the measured recurrence of events, not a finding that any particular published communications protocol is present. One may detect bursts of similar duration with intervals clustering near a common value, but the inference initially concerns only the observation process: an energy event satisfied a declared threshold, at a recorded frequency, during a period in which the receiver was capable of observing it. The signal may be a deliberate scheduled transmission, a supervisory control message, a periodic environmental disturbance, or an artefact of a detector that records the same broad source only at its own revisit instants. A field report ought therefore to use language such as 'approximately recurrent bursts with an estimated interval', accompanied by the eligibility and timebase qualifications, rather than 'beacons from system X'. The latter assertion is a

Copyright 2026, James M. Atkinson

hypothesis about function and format for which intervals are rarely sufficient evidence.

A first mathematical description is $t_i = t_0 + iT + e_i$, where t_i denotes the measured arrival time for the i-th physical event, t_0 an epoch, T a nominal period, and e_i the aggregate deviation. Yet the model conceals several mechanisms. If e_i is independent timing jitter, neighbouring intervals are correlated because both contain one shared error term with opposite signs. If the oscillator drifts, the apparent T changes gradually with elapsed time, and the residuals under a constant-period fit acquire structure. If events are missed, the observed difference $t_{i+1}-t_i$ can resemble twice or three times T even when no source changed its schedule. If a receiver scans intermittently, the observed event list is not simply the original list with random entries removed: observation probability depends on the phase of the scan and of the possible emitter schedule. The apparent pattern may be imposed by their interaction. Thus one must keep distinct the source clock, the receiver clock, the event-detection logic, and the chosen representation of detected timestamps.

The experimental programme should employ two controlled emitters. A laboratory reference may radiate a purposely declared recurrent burst whose start times are independently recorded by a traceable trigger. A second, unlike transmitter should emit a periodic industrial-control-like test burst with a similar nominal interval, equalised duration and occupied bandwidth, and carefully controlled received power. These are authorised, synthetic test emissions, not interception of protected information. A blind analyst should classify the two sources only using permissible timing and envelope observations, with instrument identities concealed until the

Copyright 2026, James M. Atkinson

analysis is frozen. The important result is not whether the analyst can invent an attractive story around each record. It is whether the declared features discriminate two engineered alternatives whose schedules were deliberately made similar, and whether performance persists when nuisance conditions are changed. Equal timing can occur in unrelated devices, which is a direct counterexample to identity attribution.

Timer quantisation deserves its own analysis. Digital equipment may schedule activity in integer ticks of an internal clock. An apparent sequence of intervals clustered at integer multiples of a basic step might arise from operating-system scheduling, a controller polling loop, a microcontroller timer, or the receiver event logger's timestamp resolution. Let q be the candidate step duration and let r_i be the interval's residual after subtracting its nearest multiple of q. A small dispersion in r_i is evidence compatible with a quantised timing process, but only after showing that the measurement timebase and reporting software have substantially finer effective resolution than q. It would be a serious category error to report q as an internal device property when the receiver merely rounds timestamps to that same quantum. Repeat the acquisition with a second independent timestamp system of verified resolution; vary its sample rate and logging settings. If the quantisation pattern follows the measuring system rather than the transmitter, the correct explanation is instrumental.

A useful report should provide the eligible observation window, number of detected starts, number and duration of receiver gaps, an estimate of event-time uncertainty, and a robust summary of intervals with a defined treatment of missing observations. It should include competing fitted models, residual plots, and an explicit description of intervals classified as

Copyright 2026, James M. Atkinson

apparent multiples of the proposed period. Retain bursts rejected by the detector, if the authorised raw evidence permits them to be revisited, rather than discarding all inconvenient cases. Distinguish a uniform period from a distribution concentrated around a period: the former would require a considerably stronger account of clock stability and observation completeness. The confidence reported by an analyst should be tied to a stated comparison or predictive test, not to the visual regularity of a line of timestamps on a chart.

This is also a lesson about codes in their broad engineering sense. A repeated timing pattern can be an economical way to organise communication, but repetition is not unique to communication and is not itself a message-decoding result. A periodic signal can be generated by a motor controller, a test instrument's housekeeping function, a thermal feedback loop or an intentional laboratory reference. Some will carry data; others will not. The evidential conclusion can legitimately be that a recurring radio-frequency event has been observed and characterised. Only further independent measurements of waveform structure, authorised contextual records, physical controls and lawful investigation can narrow function or source class. Until then, the unidentified event should remain unidentified even if its timing is strikingly regular.

John Wilder Tukey, Peer Question: Dr. Elias, your periodic-event model seems elegant because a handful of timestamps can be placed on a straight line with residuals of only a few milliseconds. Yet an investigator might select the apparent period after trying dozens of candidate lags, excluding troublesome events as false positives, and changing the time window until the residual plot looks persuasive. In a long monitoring record almost every

Copyright 2026, James M. Atkinson

innocent random process may contain a short stretch that appears orderly. How should the analysis disclose the entire search undertaken, and how would you define a test which is not contaminated by selecting the most favourable subsection? I also ask how you would present the uncertainty of a period estimate when gaps conceal an unknown number of missing physical emissions. An attractive least-squares slope cannot make those latent event counts disappear. Would you insist upon a separate validation interval, and what exactly should be frozen before that interval is inspected? The evidential danger is post-hoc regularity masquerading as an independent discovery.

Peter Elias, Response: Mr. Tukey, I would first construct an unedited event register that records the initial threshold, operating frequency, detector version, sample eligibility, acquisition interruptions and each event's timestamp uncertainty. Then I would create an analysis ledger: every candidate period, permitted integer-multiple assignment, outlier exclusion rule, window selection, and parameter adjustment is entered with its reason. Such a ledger need not imply that exploratory work is forbidden. It makes the exploration visible and prevents an optimised hypothesis from being mistaken for one specified before observing the evidence. A polished final graph that conceals a succession of rejected graphs is not an adequate scientific record.

The discovery set can be used to propose a period T, a jitter model, a procedure for assigning missed-cycle counts, and a residual statistic. Before another set is analysed, freeze those choices, including the rule by which an event is considered eligible and the allowable range of clock drift. An independent holdout segment should then test whether the model predicts

Copyright 2026, James M. Atkinson

arrival windows more successfully than specified alternatives, such as a clustered renewal process or the receiver's own revisit sequence. If operational conditions change between segments, record that fact and design the comparison to account for it. A threshold optimised on one afternoon's noise and used without qualification during another afternoon's interference is not a stable decision rule.

Unknown missing-cycle counts should not be silently rounded to whichever integer makes the period look best. For each observed gap g, consider plausible hypotheses $g \approx kT$ for integer k within a stated range, but preserve uncertainty where several k values fit within the error and drift limits. One may compare the resulting likelihoods under a transparent missing-event model, or restrict the estimate to contiguous intervals known to have complete observation opportunity. The latter is conservative but can be much more defensible. Report the number of ambiguous gaps explicitly. Confidence intervals derived as though every detected event were the next physical emission are misleading if the source can transmit while the receiver is elsewhere.

Finally, describe the claim at the level actually tested. A prediction that future authorised observations will exhibit near-T recurrence is narrower than an assertion that a named protocol is present. A successful holdout reduces the likelihood that the particular pattern was an accident of selecting a short segment; it does not remove the possibility that two unrelated devices share the schedule. I would publish both the successful predictive comparison and the failure of timing alone to distinguish the matched laboratory alternatives. That apparent negative result is valuable

Copyright 2026, James M. Atkinson

because it tells the investigator what additional type of evidence is genuinely needed.

Andrey Nikolaevich Kolmogorov, Peer Question: Dr. Elias, one may represent intervals as if their disturbances were independent, although a single oscillator introduces dependence from one interval to the next, and an environmental process may produce bursts whose intensities change with time. A detector that triggers on rising energy, settles into a refractory interval and later resumes may create a renewal-like event process of its own. What probability laws would you propose for the null hypothesis against which 'beacon-like' regularity is tested? How would you prevent a rejection of a naïve homogeneous Poisson process from being advertised as proof of deliberate periodic communication? There is also the mathematical matter of missing observations: if the probability of detection varies cyclically with receiver sweep position, the observed process is a phase-dependent thinning of an underlying process. Does your report require an explicit conditional detection function, and what measurements establish that function? I seek an inferential boundary between the stochastic structure that the events justify and the mechanism they do not identify.

Peter Elias, Response: Dr. Kolmogorov, there is no scientifically privileged null in which unrelated disturbances must be uniformly random in time. Many real mechanisms are periodic, quasi-periodic or self-exciting. It is consequently inadequate to test an observed interval sequence against only the exponential waiting-time law of a homogeneous Poisson process and label any rejection a 'beacon'. The rejection may merely identify environmental nonstationarity, a receiver refractory time, or a regular

Copyright 2026, James M. Atkinson

industrial process. The alternatives must be designed from the mechanisms that actually compete in the laboratory or investigated environment.

One candidate can be a jittered periodic process with timing residuals having a specified dependence. Another can be a renewal process with non-exponential waiting times. A third can be a clustered process whose event rate responds to a measured environmental covariate, such as industrial switching activity. A fourth is the physical emission schedule observed through a receiver whose acquisition window w(t) changes deterministically with sweep position. If p_det(t,a,b) denotes conditional probability of recording a physical event at time t with amplitude a and bandwidth b, the observed counts cannot be characterised without the interaction between emission and this detection function. Actual hardware measurements should bound p_det across the relevant dynamic range rather than treating it as a constant. The parameters of these alternatives must be estimated on authorised reference datasets with similar gaps and noise conditions.

It is useful to simulate each fitted alternative through the same receiver observation schedule and detector thresholds, not to simulate ideal physical events and compare them directly against a censored field record. The simulation must preserve the recorded dead periods and should account for timestamp rounding. The statistics then have meaning as properties of the entire measurement chain. Residual dependence can be tested using serial correlation and phase plots, but even statistically significant dependence need not identify its cause. Independence can fail because a real transmitter keeps time, because a receiver buffers events, or because a mechanical disturbance repeats after every control cycle.

Copyright 2026, James M. Atkinson

For a defensible conclusion, I would distinguish four statements: detected events recur more tightly than a specified comparison model; the recurrence persists under stated receiver-schedule controls; a source-driven periodic mechanism remains compatible with observations; and the function or identity of that source is not established. The first three may receive quantitative support. The fourth remains a boundary that statistics cannot cross unaided. A well-designed negative control is not a nuisance to the theory; it is one of the conditions that make the theory meaningful. In a report intended for forensic scrutiny, every such boundary must be visible alongside the numerical estimates.

Peter Elias, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, the laboratory now possesses two independent authorised test sources whose event starts agree closely with a nominal interval of 250 milliseconds. One source carries a brief framed control message; the other emits a housekeeping pulse without a meaningful data payload. Their observable packet lengths and pulse envelopes are deliberately made similar. Our analyst has a timing model with excellent predictive residuals and believes that the match supports classification as a particular communications protocol. Could you distinguish timing redundancy from information content, and explain why the success of a temporal predictor does not amount to recovery of framing or coding rules? I ask also how one should handle an event sequence that is almost deterministic but contains sparse, possibly meaningful departures from its ordinary schedule. Such departures may carry information, but the observer has not shown that they do. What lawful measurement would test for additional structure without decoding protected payloads or inventing a source identity from the repetition alone?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to Peter Elias: Dr. Elias, the regular recurrence of an event is one possible source of redundancy, but redundancy is not a certificate of a communications function. The housekeeping source can have extraordinarily predictable timing because a fixed control loop activates it, while the framed source may transmit according to the same independent clock. From the event-start sequence alone these mechanisms are observationally equivalent within the instrument's resolution. A predictor that places the next event within a narrow interval has learned a statistical pattern of the observed process. It has not proved the physical purpose of the pulse, the existence of meaningful payload bits, or compatibility with a named standard.

For information-theoretic clarity, one should specify the random variable being measured. If X denotes a quantised time interval, its entropy is determined by the distribution of X under the declared quantisation rule. A low empirical entropy of X indicates concentrated interval outcomes. It does not give the entropy of an unobserved payload Y, nor the mutual information between Y and any hypothetical operating state. Those would require measurements or a controlled experimental design involving the relevant variables. Even the entropy estimate for X may be biased by finite sample size, correlated intervals and censoring by the receiver. The observation of sparse deviations could motivate a hypothesis that timing is deliberately modulated, but such a hypothesis must compete with oscillator correction, control-loop contention, queueing, missed events and measurement error.

An authorised experiment can manipulate the laboratory source's known signalling state while concealing the state labels from the analyst. If time

Copyright 2026, James M. Atkinson

intervals change in a reproducible state-dependent fashion beyond the timestamp uncertainty and changing receiver schedule, one gains evidence for controlled temporal organisation in that specific source. This does not authorise extrapolation to an unknown field emitter. If the research goal is purely defensive monitoring, record timing distributions, frame durations, spectral bandwidth and test-source state labels without attempting recovery of protected content. A separately controlled reference receiver can help show whether suspected state-dependent deviations persist outside the first receiver's event-processing software.

The conclusion should say that the observed waveform has a recurrent temporal envelope compatible with multiple mechanisms, and that additional controlled features would be required for protocol classification. One can describe the empirical predictability honestly and still decline to identify a protocol. Such restraint is not a failure of communication theory. It is the logical consequence of distinguishing the random variables actually observed from the unobserved variables about which the investigator wishes to speak.

Dr. James M. Atkinson, Moderator: Dr. Elias, thank you. Dr. Shannon, I pass the token to you. Please distinguish the statistical organisation of an interval sequence from the contents, purpose and identity of the source that generated it.

Claude Elwood Shannon, Second Principal Contributor: A sequence of nearly equal time intervals is evidence of a source or measurement process with a regular component. The word 'beacon' should be employed only as a descriptive analogy until more than periodicity is established. Communication theory gives us tools for distinguishing measurable

Copyright 2026, James M. Atkinson

organisation from unobservable purpose. It does not permit us to infer arbitrary hidden variables from a narrow statistic. Consider a row of events with inter-arrival times of about one quarter of a second. The sequence might be generated by a periodic transmitter, an industrial relay, a sensor sampling scheduler, or a receiver that notices an otherwise continuous source once per sweep. If all candidates produce the same observed timestamps under the same acquisition conditions, no timing-only classifier can distinguish them with evidential confidence. Additional assumptions may create distinctions in a model, but those assumptions must be disclosed instead of being smuggled into the conclusion.

Let T denote the nominal interval, J a random timing deviation, and M a positive integer accounting for missed physical emission cycles. The observed gap G may be represented as $G = MT + J$, but only when this model reflects the actual acquisition path. If the timestamp is rounded to a grid of duration q, the recorded gap is a difference of quantised arrival times and its error law cannot be assumed identical to the physical timing jitter. If the receiver is blind while tuning, the probability distribution of M depends upon the joint phase of the receiver schedule and the candidate transmitter schedule. Consequently the empirical histogram of gaps is a convolution of physical schedule, missed opportunities, detector imperfections and timestamp representation. Counting peaks at T, 2T and 3T without reconstructing these mechanisms cannot identify an air-interface standard or a message format.

A useful information-theoretic description begins with an explicit alphabet: for example, intervals binned in milliseconds, or event length measured in sample counts. Define p_i as the empirical probability of outcome i, and

Copyright 2026, James M. Atkinson

calculate H = -sum_i p_i log2(p_i), where H is measured in bits per binned interval. This statistic requires a declared alphabet, observation window, treatment of censoring and finite-sample correction. If one changes the bin width, H generally changes, so the numerical result does not express an intrinsic physical identity. A highly regular source may have low H because most intervals fall into one bin. A complex protocol may also have low timing entropy because all transmissions are triggered by a fixed heartbeat. An industrial machine may have low H for exactly the same reason. One cannot move from H(X) to a conclusion about H(Y), where Y denotes protected payload content that was never observed.

Nor does a high apparent entropy demonstrate encryption or randomness at the source. An unsynchronised observer may mix several regular transmitters, thereby obtaining a complicated interval sequence. Oscillator drift, competing network traffic, environmental interruptions and an adaptive threshold may transform a simple source schedule into apparently erratic detections. Conversely, averaging and timestamp rounding can reduce apparent variation, making irregular physical transmissions look perfectly quantised. An examiner should not infer that a statistical measure has a mechanism merely because the computed number looks precise. The estimate and its uncertainty have to be accompanied by an account of what generated the data and how much of that process was observable.

One way forward is a controlled state experiment in which a known laboratory emitter alternates, under a concealed random schedule, between fixed-period and jittered-period timing, while preserving envelope shape and nominal power. Another known source should emit mechanically or electronically generated pulses without intended communications payload,

Copyright 2026, James M. Atkinson

matched to the first source's observable duration and spectral occupancy. The analyst receives only timestamp and non-content feature records with anonymised provenance, then declares a decision rule before the concealed state labels are released. The experiment may tell us whether timing statistics detect a deliberately imposed change in that laboratory source. It does not entitle us to identify an unrelated emission in the field as the same device. Generalisation must be separately demonstrated across hardware types, sites, propagation conditions and recording instruments.

The false-alarm problem is especially important when one searches for a period after seeing the event sequence. A lengthy record offers many candidate periods, phase offsets, source partitions and subsets of selected events. Under a suitable null model, some combination will look remarkably regular by chance alone. The declared test should therefore specify the complete search family, including detector thresholds, eligible intervals, frequency channels and candidate periods. The null simulations should pass candidate records through the same scan schedule and decision procedure as the real data. Testing only the final winning period against an ideal random distribution ignores the selection process that produced it. A holdout record, assessed under frozen rules, is a more meaningful test of prospective predictive performance.

The most useful evidence report may therefore be intellectually modest. It can state that the observed timestamps exhibit a stable approximate recurrence with a period estimate, confidence limits and documented gaps. It can state whether the finding persists with a second calibrated receiver and under controlled changes in observation schedule. It can state that two or more proposed mechanisms remain compatible. Those conclusions

Copyright 2026, James M. Atkinson

provide a precise investigative record without pretending that timing entropy or repeatability recovers a protocol name. A waveform, a scheduler and a protocol are distinct objects; an interpretation that does not respect that distinction is not strengthened by the sophistication of the formula employed.

Egon Sharpe Pearson, Peer Question: Dr. Shannon, you propose a family of comparison hypotheses, but the analyst will often be tempted to call the hypothesis with the smallest residual variance 'the detected protocol' and to report only the corresponding significance level. Suppose the analyst first searches a hundred candidate periods, then adjusts phase and packet-length thresholds, and finally retains the twenty percent of events that align most tightly with the best-fitting model. How should the resulting evidence be evaluated without treating those choices as though they had been specified beforehand? I am particularly concerned about the distinction between a low probability under a selected null model and a high posterior probability of a named protocol, because those are logically different conclusions. Would the experiment require prospective data, controlled alternative sources, an explicit family-wise search record or some combination of these? Please address how a small number of apparent exceptions should be handled without conveniently discarding them as noise merely because they undermine the favourite interpretation.

Claude Elwood Shannon, Response: Dr. Pearson, the analysis must disclose the extent of selection. If the investigator explores a hundred periods, many phase offsets and several exclusion thresholds, the statistic eventually reported is the maximum over a complicated family, not the value obtained from one independently specified test. A significance calculation that

Copyright 2026, James M. Atkinson

assumes the final candidate was chosen before looking at the data is therefore invalid for that discovery process. A suitable simulation can reproduce the entire search pipeline under each defensible null, including sorting candidates by apparent periodicity, selecting eligible events and applying the final goodness-of-fit measure. Its output describes how often that complete procedure would produce an apparently impressive winner in records where the proposed mechanism is absent.

The null model itself must be scientifically relevant. Repeated industrial switching can be nearly periodic, and a receiver operating on a fixed revisit schedule can create a perfectly repeatable sequence even when an external source is not transmitting in a periodic fashion. A null restricted to homogeneous random arrivals is often too weak. The laboratory should include replayed or physically generated controls exhibiting quantised but unrelated timers, nonstationary burst rates, intermittent acquisition and mixed sources. If an apparent match survives these alternatives, it has gained support as a timing-class hypothesis, not necessarily as a protocol or device identification.

Prospective testing is valuable precisely because it separates model construction from evaluation. Freeze the reported T, permissible phase error, treatment of missed events and inclusion rules. Obtain fresh observations under an independently recorded receiver schedule and ask whether the proposed recurrence predicts where eligible arrivals should occur. Report successes and failures using the whole designated observation window. If events arrive outside the windows, those exceptions must be counted under the stated metric rather than removed retroactively. If uncertainty or environmental change justifies a revised rule, that revision

Copyright 2026, James M. Atkinson

belongs in a new development cycle with another validation set; it should not be disguised as the original protocol test.

Finally, a p-value computed against a declared null does not directly yield the probability that a specific protocol is present. That inference would require prior probabilities, comparative likelihoods, validated alternatives and sufficient features to discriminate their predictions. A periodic control loop and a communications heartbeat may be indistinguishable from the restricted timestamps. When the evidence is insufficient to resolve them, the correct result is a set of compatible explanations and a plan for further authorised observation. Statistical discipline protects the examiner from turning the chosen analytical vocabulary into an unwarranted claim about the external equipment.

Claude Elwood Shannon, Cross-Peer Question to Donald Watts Davies: Mr. Davies, let us imagine a physical source whose bursts begin at perfectly regular 200-millisecond intervals, but whose event records arrive at the analyst's host computer after variable buffering and network transport. The host application timestamps each delivery rather than the hardware acquisition instant. Another source transmits irregularly, yet its detector events are released by software in 200-millisecond batches. In a plotted log those two systems could appear to have exchanged identities. Please explain which timestamps belong to the radio-frequency measurement, which belong to data transport, and what independent counters or hardware triggers can establish their relationship. I would also welcome your view of packet drops, queue flushes and retransmissions, and whether their signatures can be distinguished from genuinely missing physical transmissions without inspecting protected message content. The

Copyright 2026, James M. Atkinson

laboratory should be able to document the entire timing path, or else the period it reports may be that of the software rather than of the emitter.

Donald Watts Davies, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, a receiver event passes through several clocks and queues before reaching an analyst's graph. The analogue-to-digital converter samples a physical voltage under a sampling clock. A digital detector may identify a trigger sample index inside that stream. A hardware interface or bus transports samples or event summaries. A host operating system schedules a process, which may timestamp when it receives or handles those records. If those times are conflated, a computer's batching behaviour becomes an apparent attribute of the external source. The acquisition sample index is ordinarily the strongest starting point for a source-time estimate, provided continuity and the mapping between sample count and calibrated time have been verified.

A useful architecture places a monotonically increasing counter with every captured sample block or trigger, and uses a recorded relationship between that counter and an independently maintained time reference. The report should preserve the counter resolution, epochs, counter wraps, sample-rate calibration, dropped-block flags and errors in clock synchronisation. A software delivery time can be retained, but it is a different quantity and should not overwrite the acquisition timestamp. By subtracting acquisition time from host-delivery time, the examiner can study transport latency and identify bursts of queueing that might otherwise masquerade as physical timing jitter. A batch of events all stamped with the host's wakeup time is not evidence that the external transmitter emitted them simultaneously.

Copyright 2026, James M. Atkinson

Packet loss and retransmission require careful separation. A host-delivery retry may repeat a data record whose original hardware counter is unchanged, whereas a second physical transmission would normally occupy new acquisition samples. A replay or duplicated buffer can create a convincing false recurrence if the application naïvely counts each delivery as a new radio-frequency event. Retain unique sample-range identifiers and hashes when appropriate to establish whether records are duplicates. Conversely a missing data block does not demonstrate absence of an RF emission during that interval. It establishes absence of usable observation. Those intervals must be marked as ineligible for claims about negative evidence.

The experiment you propose is practical. Drive a known source from a separate timing reference, and deliberately vary host processing load, network delay and buffer flush conditions whilst holding the source schedule constant. Compare event timestamps derived from acquisition counters with those derived from application receipt. Then vary the source schedule whilst holding transport conditions stable. If a timing pattern follows the host batching variable rather than the physical trigger, the reporter has found a software artefact. The proper forensic record preserves both the original event chronology and the transport history; it must never allow the convenient chronology of a graphing application to replace the measured chronology of an emission.

Dr. James M. Atkinson, Moderator: Dr. Shannon, thank you. Mr. Davies, kindly take the token and trace the timing record from the analogue receiver through detection, buffering and delivery to the forensic analyst.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Third Principal Contributor: The first task is to decide what event a timestamp actually represents. A communications receiver can preserve the acquisition instant of an RF burst, the instant an internal detection algorithm declared a threshold crossing, the instant an operating system received a message describing that detection, or the moment a user interface painted a marker. These can be separated by milliseconds or longer, and their differences need not remain constant. A 'beacon-like' record of host events may therefore describe buffering and process scheduling rather than a periodic source. The ambiguity grows when observations are collected over a network, because record packets may traverse queues with variable delay, sometimes arriving out of order. A forensic report should state the time origin and physical meaning of each field before computing a recurrence interval from it.

It is worth constructing an explicit time budget. Let a_i be the acquisition time assigned to RF event i, d_i its detector processing latency, q_i its queueing and delivery delay, and h_i the final host timestamp. In a simplified model, $h_i = a_i + d_i + q_i + c_i$, with c_i representing any clock-domain conversion error. The sequence of differences in h_i incorporates variations of all four terms. If q_i fluctuates independently, it may broaden a real periodic schedule. If software releases records in regular batches, q_i may be correlated so strongly that irregular physical arrivals take on a periodic appearance. A tidy diagram drawn from h_i alone cannot separate these possibilities. Hardware counters, traceable capture-trigger markers and contemporaneous queue logs are needed to estimate and bound the terms.

Copyright 2026, James M. Atkinson

A defensible instrumentation scheme includes one counter at the acquisition stage and another in the host event store, retaining both without conversion into a single convenient clock. The RF record carries a sample index, the configured and independently measured sampling frequency, the beginning and end indices of any acquisition gap, and the acquisition state during the candidate burst. The host record carries a monotonic arrival time, a processing sequence number and an error flag if a transport record is lost or duplicated. Clock conversion parameters should be versioned and tied to their calibration measurements. This makes it possible to reconstruct chronology when packet transport reorders messages. It also allows a subsequent reviewer to distinguish a missed RF observation from a missing metadata packet.

The test programme should include an authorised beacon generator with a known periodic output, a second source with deliberately varied intervals and an independent record of both source triggers. The receiver should operate first in continuous acquisition and then under a documented scanning schedule, because the scan can make its event eligibility periodic even when the source is not. Host load, buffer size, interface throughput, event-logging interval and process priority can be varied as controlled nuisance factors. If the apparent recurrence or jitter changes when these software variables change, that relationship is evidence about the measurement chain. It does not necessarily exclude an external recurring source, but it prevents unqualified attribution of the whole pattern to that source.

A particular danger is implicit sample substitution. Some interfaces conceal transport discontinuities by returning the last valid data block again,

Copyright 2026, James M. Atkinson

inserting zero-valued samples, or concealing a missing segment behind a fresh application timestamp. A classifier may then detect repeated envelope shapes or apparent fixed delays with unwarranted precision. Each sample block should carry a unique identifier or counter range so that duplicates and omissions can be detected. A record gap should remain a gap. An artificial zero fill may be useful for a display if clearly marked, but it cannot be treated as a physical observation of silence. For the same reason, interpolated RF timestamps should not be silently entered into the evidential event register as though the instrument had genuinely recorded them.

Even a technically perfect delivery channel does not settle transmitter identity. Several unrelated machines can produce fixed-interval supervisory bursts, and two different standards may specify comparable timers. Moreover, a single device can change timing because its workload or environment changes. One should therefore separate an event-class description, such as 'approximately 200-millisecond recurring RF bursts', from a mechanism hypothesis, such as a source-side periodic timer, and from an identity claim, such as a specific model of industrial controller. The first may be established by timestamp analysis. The second requires controlled discrimination against receiver and environmental explanations. The third requires independent device- or protocol-specific evidence well beyond timing resemblance.

What should be written in the record? State the specific acquisition hardware, sampling configuration, host delivery path and the time meaning of every used timestamp. Give the total eligible time, durations of unobserved intervals, detector threshold, calibration traceability and any relevant operating-system scheduling details. Retain primary records and

Copyright 2026, James M. Atkinson

code versions so that another investigator can reconstruct the observed event chronology. If the source period seems exceptionally stable, show that the stability survives using acquisition timestamps instead of host receipt times, and ideally with a second independent recording chain. A sound account of uncertainty is not an impediment to a useful observation; it is what makes that observation evidence rather than merely an appealing pattern on a screen.

William Ralph Bennett, Peer Question: Mr. Davies, suppose the examiner has only timestamped detection messages from a distributed receiver system and cannot recover the original samples for every interval. A central host has synchronised its clock to a network service, but the edge receivers are inexpensive and use oscillators whose fractional frequency error is not recorded. Over a two-hour shift the same event appears to drift by tens of milliseconds relative to a reference. The analyst proposes to correct each receiver's timestamps by fitting a straight line between two coincident events. How should that correction be evaluated without confusing physical oscillator drift with network latency, and how many independent common events are required before the correction can be regarded as evidence-bearing? Please also address the risk that a high apparent correlation between two event lists is created by sharing the same scheduling service or communications link. The synchronisation labels on those logs may be far more reassuring than their metrological accuracy warrants.

Donald Watts Davies, Response: Mr. Bennett, a synchronised wall clock is not automatically a calibrated measurement clock. A network time service may estimate clock offset, but its error includes asymmetry in transport delay, time-stamping uncertainty, servo behaviour and the local oscillator's

Copyright 2026, James M. Atkinson

frequency instability between corrections. A fitted straight line through two coincident events can always align those two points; that is elementary geometry, not evidence that the intervening interval has been measured accurately. If the clock error contains nonlinear drift, abrupt steps or varying network delay, the line may conceal substantial error at other times. The fit must be checked against independent timing events not used in constructing it.

I would begin by distinguishing clock offset, fractional frequency error and latency. Let x(t) be the edge clock's time error relative to a reference. A constant offset contributes a fixed term; a stable fractional frequency error contributes a term approximately proportional to elapsed time; temperature effects and oscillator ageing may introduce curvature; transport delay belongs to the measurement of x rather than necessarily to the clock itself. Multiple separated reference events are required to estimate the trend and test residuals, with observations distributed across the intended reporting interval. The number depends on the noise process and the claim's required accuracy, so there is no universal adequate count. Report estimated residuals and uncertainty rather than specifying a cosmetic number of synchronisation points.

If only event messages survive, an analyst can still audit the communications path. Preserve send and receive timestamps where available, transport sequence numbers, queue lengths, clock adjustment logs and uncertainty values reported by the timing service. Compare the receivers using an independently generated timing test source that both are known to observe. Then vary their network paths, local loading and time-service access if permitted. A common delay pattern that follows the shared

Copyright 2026, James M. Atkinson

communications infrastructure suggests a system effect. Coincident apparent events from two receivers do not establish an RF origin if the messages share a software source or duplicate transport record.

The reported conclusion should be commensurate with the retained evidence. One might state that two event lists, after a declared clock transformation, show intervals compatible within a specified time uncertainty. One may not state that two independent receivers precisely timed the same external emission unless acquisition provenance and common-source independence are demonstrated. Any drift correction should be stored as a reproducible model with parameter covariance and known validity interval, leaving the uncorrected timestamps intact. Where gaps or missing samples preclude stronger conclusions, label those intervals as uncertain rather than allowing an attractive fitted line to imply observations that never occurred.

Herbert Kroemer, Peer Question: Mr. Davies, software timestamps are only one source of ambiguity. A receiver subjected to a nearby switching event can experience amplifier saturation, gain-control recovery, oscillator pulling or an apparent repeated burst caused by filter ringing. These physical effects may follow a regular industrial cycle, even if the source actually being investigated transmits irregularly. What laboratory controls would distinguish a true periodic external emission from a periodic receiver response caused by a stronger nearby disturbance? Would you alter input attenuation, preselection, gain state and antenna coupling, while preserving the original clocking chain? I am also concerned that inserting a synthetic test burst at the wrong point in the receiver hides front-end nonlinearities. How should the injection plane be specified so that the test genuinely covers

Copyright 2026, James M. Atkinson

the component suspected of creating the false beacon? A test that validates only the host software may miss the very circuit most responsible for the apparent observation.

Donald Watts Davies, Response: Professor Kroemer, the test must be designed around the complete physical path. If the suspected phenomenon arises in the antenna, preselector or first active stage, injecting a clean test signal after those components can prove only that the downstream detector responds as expected. It cannot exclude front-end overload, mixer intermodulation or antenna-coupled impulse contamination. The injection plane should therefore be recorded in a block diagram, and multiple planes used when a particular stage's influence must be isolated. A known test source introduced ahead of a preselector exercises a different collection of mechanisms from a source introduced directly at the analogue-to-digital converter's input.

Begin with measured linear operation. Vary the received level of a lawful reference burst while monitoring the relationship between input power and recorded sample amplitude. Then introduce a separately controlled strong interferer or pulse source, within equipment safety limits, and watch for threshold changes, gain recovery and repeated response. Change attenuator state and RF gain, but do not interpret the mere disappearance of a trace at lower gain as proof of its cause; an ordinary weak transmission can disappear too. More informative is a measurable change in apparent interval, waveform shape or recovery sequence that tracks the interferer's physical timing and the receiver's nonlinear state. An independent wide-dynamic-range reference chain can help identify whether the candidate RF energy truly existed before the first receiver distorted it.

Copyright 2026, James M. Atkinson

Preserve acquisition timestamp provenance throughout these changes. A gain-control operation may alter the detector's crossing time by moving the effective threshold relative to the envelope, even when physical emission onset is fixed. A receiver may also blank its output during retuning or overload, creating structured missing observations. The event detector should therefore report a time uncertainty that includes amplitude-dependent triggering and blanked periods. If the same laboratory source is measured through two analogue paths with different front-end behaviour, differences in their event lists are valuable evidence that the observation process matters.

The final report should distinguish three layers: the actual applied laboratory stimulus, the voltages delivered to the receiver's digital sampler, and the software events reported by the detector. A periodic pattern at the software layer can be produced by a periodically changing analogue response even when the target emission lacks that period. The experiment narrows the candidate mechanisms by controlled alteration of individual stages. It does not rely upon generic labels such as 'beacon' to replace that physics. Once the path-specific behaviour has been characterised, the investigator may cautiously infer which part of the observed pattern is consistent with source timing and which part remains instrument-dependent.

Donald Watts Davies, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, an automated survey system uses a repeatable detector and can export thousands of apparently beacon-like event intervals. Its configuration file specifies one threshold, but another threshold is calculated dynamically after the scanner changes frequency, and a background process may apply

Copyright 2026, James M. Atkinson

a refractory period before another event is counted. A programmer argues that repeatability of the software proves that the RF schedule is real. Would you explain how version control, threshold provenance, sample-counter continuity and adversarial software tests should be organised so that repeatability is not confused with truth? I ask particularly about a regression test which deliberately inserts missing blocks, duplicate records and delayed queue deliveries. What outputs should the instrument produce, and what should it refuse to infer when those artificial artefacts make a neat interval pattern? The resulting validation record must be intelligible to an independent engineering reviewer, not merely the original programmer. That reviewer should be able to reproduce the failure deliberately.

Richard Wesley Hamming, Cross-Peer Answer to Donald Watts Davies: Mr. Davies, reproducibility of a programme establishes that it applies its programmed rule consistently to the supplied input. It does not establish that the rule corresponds to an external transmitter's physical timing. A software system can consistently round timestamps to a coarse interval, impose a fixed refractory window, and transform packet delivery batches into apparent beacon events. The resulting records may look exceptionally tidy because the errors are systematic. An adequate verification programme must therefore challenge the software with inputs whose correct interpretation is known independently, including deliberately corrupted or incomplete inputs whose proper result is an uncertainty declaration rather than a confident classification.

Each event should retain a provenance chain: original sample range, acquisition counter, hardware status, threshold rule identifier, threshold value at the decision instant, candidate event boundaries, processing

Copyright 2026, James M. Atkinson

software version and any post-processing transformations. A dynamically selected threshold is not the same as a static setting saved in a configuration file. Store the actual history of the adaptive threshold, including the input measurements used to update it, its smoothing interval and any gain-state changes. If the detector has a refractory period, store that duration and the time during which further events would have been censored. A report of apparent physical intervals derived from these event records must account for the censoring the algorithm itself introduced.

Regression tests should include continuous clean reference bursts, irregular bursts, overlapping bursts, threshold-near events, zero-filled gaps explicitly marked invalid, discontinuous sample counters, duplicated blocks and out-of-order network messages. The programme should detect counter discontinuities and record them without silently manufacturing data. Duplicate records with identical source-range identifiers should not be counted as independent emissions. The result of a gap spanning a predicted beacon instant must be 'not observed because acquisition was unavailable', not 'the transmitter was silent'. A delayed metadata message must retain its original acquisition timestamp instead of inheriting the host delivery time as the physical event instant.

An independent examiner should receive the test inputs, known truth labels, source code revision or independently reproducible executable manifest, expected outputs and actual outputs. The distinction between assertion and observation should be visible in machine-readable data as well as narrative. Where the software detects an interval cluster, its classification can remain 'recurrent event candidate' until supplementary physical tests exclude instrumental patterns. I would not permit a regression test to pass merely

Copyright 2026, James M. Atkinson

because a graph looks like a beacon. The test must establish that the programme preserves evidential time meaning across the very disruptions most likely to corrupt that meaning in field acquisition.

Dr. James M. Atkinson, Moderator: Mr. Davies, thank you. Dr. Hamming, I pass the token to you to examine software validation, versioned event provenance and the risks of inferring physical recurrence from a programme’s own selection rules.

Richard Wesley Hamming, Fourth Principal Contributor: A robust event classifier should not be praised merely for emitting a reassuringly precise label. Its first duty is to preserve the measurements from which that label may be challenged. A burst record often begins as samples, is condensed into trigger times and envelope measurements, and is then presented as a concise set of intervals. At every stage information may be discarded. That loss can be acceptable for routine monitoring if it is declared, but it is hazardous when the final label implies a protocol identification not supported by the stored evidence. The software ought to distinguish facts such as 'threshold crossed at acquisition sample 18,443,120' from derived claims such as 'estimated period 0.25 seconds' and conjectures such as 'beacon of type X'. A change in confidence cannot transform a conjecture into a directly observed field.

The data model should separate physical acquisition, signal detection, interval estimation and interpretation. For acquisition, retain raw or legally permissible calibrated summary records, timebase status and gap masks. For detection, record the threshold and filtering rules, duration and envelope features, and the uncertainty of onset estimates. For interval estimation, retain the exact set of event identifiers admitted, missing-cycle

Copyright 2026, James M. Atkinson

assignments and the parameters of competing models. For interpretation, retain the proposition being evaluated and the evidence required to disprove it. A reviewer should be able to recompute the recurrence from primary event records without treating the original analyst's chosen period as an immutable fact.

Consider a hypothetical system that emits one real burst every 250 milliseconds but is observed by a receiver whose frequency scanner revisits the channel every 500 milliseconds. If the bursts and scanner are synchronised, the receiver may record every second event and report an apparent half-second recurrence. If the two schedules drift slightly in relative phase, the record can contain runs of detections followed by long gaps. A fixed-period estimator may then invent abrupt changes in source behaviour that actually arise in the observation schedule. The correct software design retains the scan eligibility function and either models its effect explicitly or refuses to infer a source period from a sparse record lacking adequate observations. It must not patch missing cycles by assuming the hypothesis it is supposed to test.

Another hypothetical system emits irregular broadband switching impulses. An energy detector imposes a 100-millisecond refractory period after every trigger. The observed intervals will contain no values shorter than that limit, creating a sharp lower bound and sometimes a misleading peak near the boundary. A histogram with such a feature may resemble timer quantisation, even though the dominant timing mechanism lies in the detector. A quality-control rule should therefore run the classifier against known irregular event inputs through the actual detection firmware. If the output falsely develops a periodic peak, the test captures a systematic bias.

Copyright 2026, James M. Atkinson

A file containing only reported event times cannot resolve this after the fact unless the refractory policy and underlying data are preserved.

Software validation is especially important where the operator chooses what constitutes 'a similar burst'. Packet lengths, bandwidth estimates, detector onset times and burst clustering tolerances may be adjusted until a family of events looks consistent. Each adjustment changes the eligible population and may alter the inferred interval distribution. Report the feature definition before the final frequency or time window is selected, and distinguish exploratory optimisation from out-of-sample validation. The analyst should be able to ask whether a model trained on half the data predicts events in an untouched interval. Repeated tuning on the validation interval turns that interval into another development set, despite the filename used to describe it.

For a forensic-quality audit, an event record should carry not only time and frequency but a versioned reason for inclusion or exclusion. When a burst is omitted because its power falls below threshold, record that censoring as a sensitivity limitation rather than a statement of silence. When the acquisition fails, retain a gap marker and its duration. When sample counters jump, preserve both sides of the discontinuity. One should never generate interpolated events to make a plot pleasingly regular and then count those interpolations as physical detections. Such manufactured evidence could make an incorrect periodic model appear extraordinarily precise, while concealing the simple fact that the receiver did not observe the intervals in question.

The end product should be a layered conclusion. The software may find that eligible events are consistent with an interval near T under an explicit

Copyright 2026, James M. Atkinson

residual bound. It may also find that several models are indistinguishable after applying observed acquisition gaps. It can identify an instrument configuration capable of creating apparent regularity, or a controlled reference source whose recurrence survives those challenges. These are useful results. A named protocol, however, requires identifiable framing, modulation or other standard-specific structure established independently and lawfully. No amount of clever period fitting can supply features absent from the input. A carefully designed classifier must sometimes say 'not determined'; that output is a success when it prevents an inference which the evidence cannot carry.

Ralph Vinton Lyon Hartley, Peer Question: Dr. Hamming, a monitoring application reports a remarkably tight cluster of apparent intervals at 250 milliseconds, but its data have passed through several rounds of quantisation. The original converter uses a sample clock of uncertain accuracy, the digital detector records onset to the nearest block of 256 samples, and the database rounds timestamps to whole milliseconds. An analyst combines the resulting entries as though each were an independent timing observation to microsecond precision. How would you compute a realistic bound for the resolution and uncertainty of the interval estimate, and how could one demonstrate whether the observed quantised pattern belongs to the source or to the processing chain? Please distinguish the numerical resolution of an exported timestamp from the attainable physical time accuracy, which may be far worse. I also ask how to explain to a tribunal that a long sequence of identically rounded values need not imply extraordinarily stable emissions when every value has been forced onto the same grid.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Response: Mr. Hartley, the first correction is conceptual. A timestamp printed with six decimal places is not necessarily measured with microsecond accuracy. Its numerical resolution is a property of storage or display; its accuracy depends on clock calibration, acquisition synchronisation, detector onset uncertainty and the way the physical signal changes the threshold crossing. If the onset is rounded to a 256-sample block, the acquisition stage has already imposed a grid before the database rounds to milliseconds. The final export may therefore contain precise-looking numbers whose actual event uncertainty is dominated by one or more coarser mechanisms.

Let f_s be the nominal samples per second and B the detector block size in samples. The block interval is B/f_s seconds, subject to the actual oscillator's fractional frequency error. If onset is reported as a block boundary without interpolation, a plausible quantisation uncertainty may extend across much of that interval; its exact bound depends on whether rounding, truncation or a fixed detection delay is used. The database contributes another rounding term whose support and dependence must be specified. Two event times may have correlated clock error, so the uncertainty of their difference is not necessarily obtained by simply adding two independent error variances. A common offset cancels in an interval, whilst drift does not. The model must represent those relationships.

To locate the source of quantisation, change one parameter at a time using an authorised reference emitter whose start times are independently measured. Vary B while holding the physical source timing constant. Change the database resolution without altering the detector. Compare onset estimates from a second receiver with a different clock and event algorithm.

Copyright 2026, James M. Atkinson

If the supposed timer quantum follows B or the database field width, then it belongs at least partly to the measurement system. If it persists across independent calibrated chains, it becomes more plausible as a source-related feature, though not automatically a unique fingerprint or named protocol characteristic.

For reporting, retain the raw counter values and a transparent uncertainty budget. It is entirely possible for a hundred reported intervals to share exactly the same millisecond value because the software rounds them, even if the underlying physical intervals fluctuate within that grid. An average of those rounded values may estimate a central period, but it cannot recover fine-scale jitter that the instrument discarded. The proper statement is that events are recurrent within the temporal resolving power and uncertainty of the stated apparatus. That phrasing is rigorous and comprehensible: the uniformity belongs to what was recorded and may or may not describe the finer behaviour of the source.

Richard Wesley Hamming, Cross-Peer Question to Harry Nyquist: Mr. Nyquist, we have an apparent 250-millisecond burst recurrence collected by a clocked receiver which itself revisits the channel every 500 milliseconds, with occasional switching delays. Some analysts propose that seeing a regular interval in the event list proves that the external source's period has been measured. Would you explain the relation between physical source periodicity, the sampling of event opportunities and the alias-like ambiguities that follow from a periodic scanner? Please give a simple numerical counterexample and identify what extra observations break the ambiguity. I am particularly concerned that the analogy with sampling theory may be useful but should not be overstated: events are not a band-

Copyright 2026, James M. Atkinson

limited sinusoid, and a binary eligibility function can cause censoring rather than ordinary amplitude sampling. How would you frame this distinction so that the mathematics disciplines the inference instead of becoming another source of unjustified confidence? A hostile reviewer should be able to identify every interval in which the radio was actually blind.

Harry Nyquist, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, the analogy with sampling is valuable when its limitations are kept clear. A receiver that observes one channel only during scheduled dwell windows does not acquire a complete time history of physical events on that channel. It acquires a selected subset determined by the intersection of the source emission times and the receiver's eligibility windows. Different source schedules may produce the same subset under a given scan, especially when their periods bear simple rational relationships. The problem is therefore one of incomplete observation and non-unique inverse inference, not a claim that each burst has been reconstructed by the conventional theorem for band-limited waveforms.

Take a simple hypothetical case. A source emits at times 0, 0.25, 0.50, 0.75 seconds and so on, while a scanner observes only short windows around 0, 0.50, 1.00 seconds and so forth. If every visible event is detected, the recorded spacing is 0.50 seconds, even though the physical source period is 0.25 seconds. Another source emitting only at 0, 0.50, 1.00 seconds could create the same record. From these observed event times alone, no estimator can distinguish the two sources. The scanner's own half-second revisit interval has removed the distinguishing observations. A claim that the external period is exactly half a second would therefore be stronger than the evidence permits.

Copyright 2026, James M. Atkinson

Changing the observation schedule helps. One may hold the receiver continuously on the channel during an authorised calibration interval, or use an independent wideband reference receiver that observes the same frequency without synchronised gaps. Alternatively vary the scan revisit period and phase according to a documented test plan. If the pattern changes systematically with scanner timing while the reference source is stable, the original observation is selection-dependent. Where source and scanner timing are uncertain, collect enough independent phases to expose missing cycles and estimate the observation probability. None of these procedures requires recovering a protected payload; they concern lawful reception opportunity and event timing.

The analogy should be expressed precisely. A sequence of timestamps is not equivalent to periodic samples of a continuous band-limited voltage, so the classical sampling theorem does not directly produce a unique reconstruction of missing events. Rather, periodic observation can create indistinguishable hypotheses in both problems. The correct lesson is about information absent from a record: when an instrument did not observe a time interval, the analyst must not manufacture certainty about what occurred there. A report can describe observed half-second recurrence and its relationship to the receiver schedule while explicitly leaving the source's true physical periodicity unresolved.

Dr. James M. Atkinson, Moderator: Dr. Hamming, thank you. Mr. Nyquist, the token passes to you. Please address periodic observation, missed bursts and the difference between a sampled event list and a uniquely reconstructed source schedule.

Copyright 2026, James M. Atkinson

Harry Nyquist, Fifth Principal Contributor: Periodicity in a signal and periodicity in the act of looking for that signal are distinct properties. Where a receiver is continuously observing a channel, its event record may provide a fairly direct sample of the emission starts, subject to thresholding and timing error. Where a scanner dwells for brief intervals and then attends to other frequencies, its list is a filtered record whose contents depend upon the relative phase and frequencies of two clocks or scheduling systems. A regular event list in such a case cannot be attributed solely to the external transmitter. It is a result of an interaction, and one must measure both sides of that interaction before inferring an underlying source period.

We may express the observation opportunity as a time-dependent function w(t), equal to one when the receiver is adequately settled on the relevant frequency with sufficient sensitivity and zero when it is blind. More realistic models let w(t) take intermediate values reflecting probability of detection as a function of frequency, amplitude and receiver state. Physical emission starts occur at times s_i. Recorded starts are those for which the relevant emission overlaps an eligible interval and the detector successfully declares an event. If w(t) is periodic, it imposes a periodic selection process on the event stream. A burst shorter than the scanner's dwell can be missed completely when it occurs outside that dwell. Even a long burst may be partly clipped, shifting its apparent onset and measured duration. The period inferred from detected starts can consequently be a multiple, alias or phase-dependent distortion of the physical recurrence.

A numerical counterexample makes the ambiguity plain. Let a laboratory source emit short pulses every 0.20 seconds and let the receiver observe the channel only around times separated by 0.40 seconds. With source and

Copyright 2026, James M. Atkinson

scanner phases aligned, the receiver may record every second pulse and see gaps of 0.40 seconds. A different source emitting only every 0.40 seconds could yield the identical record through that scanner. Yet another source emitting every 0.10 seconds might yield the same observed detections if the dwell windows are short and the phase is arranged appropriately. The first event list alone cannot distinguish the three. Its temporal regularity is genuine as a property of the observation, but its relation to the physical source schedule remains underdetermined.

If the receiver has an independent continuous reference channel, compare the timestamps of detected events with that channel's event record. But the reference must itself be calibrated and sufficiently independent; a shared software processing clock can impose the same false pattern on both. If a continuous receiver is unavailable, change the scanner's revisit period under an authorised controlled experiment and observe how the detected interval distribution changes. Choose incommensurate revisit settings where practicable, while preserving receiver bandwidth, threshold and relevant RF sensitivity. A source period hypothesis predicts certain changes in which emissions become visible; an artefact tied to scanner scheduling predicts others. These expectations should be written before examining the next test data, avoiding a post-hoc explanation that can accommodate any result.

One must not misuse the vocabulary of sampling theory. The traditional result about reconstructing a band-limited waveform from samples under specified conditions is not a theorem that allows recovery of all missing event times from sparse detections. Event intervals form a point process observed through a censoring window. Its reconstruction needs a source model, a detection model and enough observation diversity to discriminate

Copyright 2026, James M. Atkinson

competing explanations. If the source is arbitrary, many hidden event sequences share the same observed subset. A mathematical calculation may estimate plausible periods under a model, but a model-conditioned estimate is not proof of uniqueness. That distinction should be central to any technical surveillance countermeasures training because the operator may otherwise confuse the elegance of a frequency estimate with a measurement that was never taken.

The clock itself requires scrutiny. The converter clock, scanner control oscillator, host processor and source timer may each have offset, frequency error and short-term fluctuations. A nominal revisit interval of 0.40 seconds need not stay exactly at that value, and temperature or processing load may alter the schedule. Record the actual time at which the receiver entered and left an eligible dwell, not merely the commanded values in configuration software. Calibrate settling time after retuning; a channel nominally selected by software may not yet be delivering accurate amplitude or timing estimates. Mark acquisition gaps and overload intervals separately. If the source interval appears to drift, compare its phase against an independent physical reference before attributing the drift to the transmitter. Two clocks drifting relative to each other can produce phase walks and alternating patterns of detections even when each clock is individually orderly.

Finally, the report should not call a waveform a named beacon merely because a number matches a familiar nominal heartbeat period. Many technical systems use round-number intervals chosen for convenience, so an apparently familiar 100-, 200- or 500-millisecond schedule carries little identity information in isolation. Describe the measured recurrence, interval uncertainty, receiver eligibility and compatibility with multiple physical

Copyright 2026, James M. Atkinson

explanations. Report what was seen when the scan schedule changed, including negative and ambiguous results. If a waveform has additional public structural features, those can be considered separately in a lawful and controlled inquiry, but timing alone must not borrow evidential strength from them without analysis. The most valuable finding may be that periodicity survives an observation challenge, or that it disappears when the receiver's own clocking is changed. Either result is more defensible than an unsupported protocol label.

Irving S. Reed, Peer Question: Mr. Nyquist, suppose several observation schedules have been used and each produces a different set of burst timestamps. An analyst might try to combine them by assigning every detected event to an integer cycle number under a hypothetical source period. When a long blind interval occurs, many assignments of that cycle number may be possible, especially if the oscillator has drift and the trigger threshold shifts with pulse amplitude. How should the investigator distinguish legitimate integer-cycle inference from circular selection in which the period determines the missing counts and the missing counts are then cited as proof of that same period? I ask also how measurement error should affect the reporting precision, and whether a second receiver that shares the same antenna amplifier and timing reference genuinely supplies independent validation. Please identify a minimal controlled experiment that can reject a false reconstruction, not merely accommodate a successful one. A useful evidential method should remain capable of proving the attractive hypothesis wrong.

Harry Nyquist, Response: Dr. Reed, the safest course is to separate the directly observed event identifiers and timestamps from the inferred cycle

Copyright 2026, James M. Atkinson

numbers. An assignment of an integer count through a blind interval is a hypothesis about unseen events, not an observation. The programme should retain all assignments compatible with the declared uncertainty and show how the fitted period changes across those choices. Where several physically plausible counts yield nearly the same residual fit, the result should report that ambiguity. Choosing the count which maximises regularity and then using that same fit as independent evidence for regularity is indeed circular. A validation interval or a changed scanner schedule can supply genuinely new constraints on the candidate assignments.

A model can express an observed gap g as approximately kT + d, where k is an unknown positive integer, T a proposed source period and d a residual reflecting clock differences and timing error. The admissible range of k depends on the acquisition gap duration and independently measured bounds on T and d. If the receiver was continuously eligible during a portion of the interval, some cycle assignments may be excluded by the absence of detected events only if detection probability was high enough for that absence to carry information. If the receiver was blind, no such exclusion is justified. Uncertainty intervals should contain the effect of ambiguous cycle counts, oscillator drift and measurement quantisation rather than being calculated only from the tiny residuals of the favoured model.

An independent reference receiver is valuable when it contributes distinct physical evidence. Two acquisition streams that share a saturated front-end amplifier, a time-stamping programme or the same replayed data packet may agree because they share a defect. Record the topology of common components and design tests that vary those components. One receiver

Copyright 2026, James M. Atkinson

might use a separate antenna and analogue chain, with its own stable counter and a separately calibrated relation to common time. Both can observe an authorised synthetic pulse source whose programmed starts are independently triggered. Agreement after the chains are challenged by deliberate scanner phase changes offers stronger support than agreement obtained by merely duplicating the software output.

A minimal falsification test is to choose two candidate source periods that fit the discovery record but predict different event windows during a future interval in which the receiver will be continuously eligible. Freeze the test windows, timing tolerances and detector threshold before the future record is taken. If one predicted event pattern is absent despite a demonstrated capacity to observe it, that model is weakened or rejected. If both continue to fit, more discriminating observation is needed. In either case, the report should keep the weaker inference separate from protocol identification. The observation of regularity can become well established without entitling the analyst to attach a particular device class or named standard to the signal.

Dr. James M. Atkinson, Moderator: I thank the contributors. The panel distinguishes an empirically recurrent observation from source-driven periodicity, protocol classification and physical identity. Repetition should be documented with its observation windows and uncertainty; it should not be named as a protocol unless independently discriminating lawful evidence is obtained.

QUESTION 087

Copyright 2026, James M. Atkinson

Can power-on transients support transmitter-class inference without unique fingerprinting?

SCHOLARLY RECONSTRUCTION. The historical contributors named below did not take part in this meeting. Their dialogue is an expressly fictional scholarly reconstruction, not an authentic quotation or a claim of endorsement. All experimental designs concern authorised reference transmitters, known test envelopes, calibrated receiving systems and non-content waveform measurements.

Dr. James M. Atkinson, Moderator: Dr. Kroemer, please examine which semiconductor and bias-network processes can be associated with an RF power-on transient, and why such an observation cannot by itself identify an individual transmitter. I pass the token to you.

Herbert Kroemer, Principal Contributor: The question is not whether a transmitter exhibits a transient when electrical power is applied. The difficulty is deciding which features of the recorded transient arise in the source's semiconductor devices, which arise elsewhere in the radio-frequency circuit, and which belong to the receiving instrument. An isolated turn-on trace is a joint result of all three. A power-amplifier stage can traverse a sequence of bias points before its intended steady condition is reached; during that transition the small-signal gain, junction capacitances, device conductances and thermal loading may change. One ought not attribute a spectral shoulder or a short amplitude overshoot to a particular transistor family without considering the matching network and the manner in which its bias rail arrives. A battery-powered source and the same design

Copyright 2026, James M. Atkinson

operated from a current-limited laboratory supply can present different early envelopes. They are not thereby two different transmitter identities.

The language of semiconductor band structure is useful because it demands identification of the physical state variables. In a heterojunction device the distribution of carriers across barriers and the effective transport time can depend upon device construction, temperature and applied potential. This does not mean that a field observer can reconstruct the band diagram from a brief radio transient. Instead it means there are several hidden states capable of producing similar observable behaviour. We may write a schematic input-output relation y(t)=H_R{H_P[x(t;theta_S,u(t),T)]}+n(t), in which x is the source's intended electrical excitation, theta_S represents unknown source parameters, u(t) represents the bias and power-supply history, T is temperature, H_P represents antenna and propagation coupling, H_R is the receiving chain, and n is measurement noise. This notation is a bookkeeping device rather than a fitted physical model, and the operator H_R need not be linear during overload.

Suppose two authorised reference transmitters use the same general semiconductor technology and have nearly identical programmable power ramps. One unit operates with a different output matching network and sees a more reactive antenna. The resulting ramp in detected power may be slower than the nominal transistor bias transition, because energy is being exchanged with stored reactive fields and the amplifier's output network. Conversely, when the receiver is operated close to gain compression, a slower physical ramp may look abruptly clipped. If an analyst sorts recordings by the width of the first detected pulse, a classification experiment can succeed under one receiver configuration yet fail when the

Copyright 2026, James M. Atkinson

input attenuator is changed. That failure does not reveal a mysterious change in the transmitter. It identifies the classifier's dependence upon the laboratory chain in which it was trained.

A proper experiment therefore varies the transmitter, receiver and coupling path independently. First measure repeated authorised switching events from a fixed source, with the supply voltage, source temperature, antenna termination and trigger instant recorded. Hold the source constant while changing receiver preselection, analogue gain and sampling rate. Next hold a calibrated receiver fixed while changing the source design, its power control state and its termination. Finally exchange the receiving antenna or controlled coaxial coupling path without changing either unit. These crossed comparisons supply within-source, between-source and between-chain distributions. The experimental unit is a physical power cycle, not each digital sample within a single waveform: thousands of adjacent samples from one event cannot legitimately masquerade as thousands of independent transmitter trials.

I would distinguish onset latency, spectral-centroid evolution, instantaneous occupied bandwidth, amplitude trajectory and carrier-frequency settling. None is an intrinsic device signature without a declared observation method. Onset latency measured from a receiver's threshold crossing has a different meaning from latency measured between a source-side trigger and an independently sampled RF envelope. The first mixes source delay with threshold, noise and channel gain. The second, while more useful, still includes trigger instrumentation uncertainty and cable-path propagation. A source whose amplitude climbs through a fixed threshold at a different speed will seem to start earlier or later even if the actual physical activation

Copyright 2026, James M. Atkinson

instant is unchanged. A robust record must therefore retain raw time series, calibrated thresholds and the source-trigger reference rather than reduce the evidence immediately to a single nominal start time.

Temperature deserves a separate factorial test. The semiconductor junction, oscillator resonator and output matching components may respond on very different thermal time scales. A cold start after a long interval is not equivalent to a warm restart after two seconds. The experiment must record off-time and thermal history, then use held-out physical cycles at both conditions to test whether a proposed feature remains discriminating. If temperature is unrecorded, an apparent family distinction might simply reflect that one set of reference events was collected at breakfast in a cold laboratory and another after the rack had warmed through the afternoon. The remedy is not merely to normalise traces until they look alike; normalisation may remove real changes as well as nuisance variation. The remedy is to measure and report the relevant environmental factors.

Where a classifier is proposed, its claim should be phrased at the level its validation warrants: for example, under the tested supply, load, temperature and receiver settings, the chosen features separate two reference transmitter classes better than a declared chance baseline. The result does not identify an individual unit, prove a design lineage, or make a forensic attribution to a source outside the experiment. Confidence intervals belong to independent power cycles and separate hardware instances, not merely random samples partitioned from the same recording. One should also test a receiver-only trigger, a dummy load and an externally injected calibration pulse; without them, a repeatable step response of the measurement system can impersonate a repeatable transmitter transient.

Copyright 2026, James M. Atkinson

My recommendation is to maintain a causal inventory. One column records physical hypotheses concerning the semiconductor, bias circuit and output network; another records independent observable predictions; a third records receiver or propagation alternatives capable of producing the same observation; and the last identifies the intervention that distinguishes them. A claim that survives changed attenuators, altered receiver hardware and controlled source operating states earns more confidence than a striking photograph of a single trace. The object of the exercise is defensible transmitter-class inference, not a fingerprint obtained by silently treating unmeasured electronic states as known.

Egon Sharpe Pearson, Peer Question: Dr. Kroemer, your proposed factorial design recognises that a measured turn-on envelope is produced by several interacting physical systems. Yet a forensic examiner may have only a small number of authorised reference transmitters, and the distributions of their switching transients may be skewed or multimodal because bias controls change state during startup. What would count as a properly defined statistical comparison under those conditions? I am particularly concerned that an investigator might select the most visually distinctive feature after inspecting every waveform, then report a very small error probability derived as though that feature had been specified beforehand. Would you distinguish a development collection used to choose features from a genuinely independent confirmation collection?

The accompanying challenge is interpretive. Even an excellent separation of laboratory classes may fail when an unmodelled receiver chain or antenna coupling configuration appears. How should an uncertainty interval acknowledge that the tested devices were not randomly sampled from every

Copyright 2026, James M. Atkinson

possible member of their purported class? What evidence would justify the cautious expression 'consistent with a design class', and what additional evidence would be needed before one made a categorical statement about the origin of an unknown field recording?

Herbert Kroemer, Response: Professor Pearson, a useful first distinction concerns the observational unit. Each separately initiated physical power cycle is a candidate unit, whereas adjacent samples and overlapping time-frequency tiles from that cycle are repeated measurements of substantially the same event. The true number of independent transmitters is smaller still. The examiner should tabulate variability at several levels: variation between samples within a start, between starts on one unit, between units of the same declared design, and between designs. A model fitted only to sample-level fluctuations can be impressively precise about the wrong population. Resampling must respect the clustering. Leave-one-unit-out or leave-one-receiver-out evaluation is more relevant to transportability than randomly splitting the individual waveforms of one instrument between training and testing sets.

Selection after observing the data is a distinct and serious hazard. If the analyst calculates twenty candidate transient features, examines which one most separates two reference collections, and then estimates its error using those same collections, the reported performance includes a hidden selection advantage. One may use nested validation to separate feature choice and evaluation, but the stronger experiment preserves an independently collected confirmation set whose devices, receiver configuration and environmental schedule have been declared before the final test. The relevant false classification rates should be accompanied by

Copyright 2026, James M. Atkinson

uncertainty intervals and explicit operational conditions. They do not automatically extend to unobserved products, altered bias firmware or unknown antenna systems.

The phrase 'consistent with a design class' should be coupled to specific exclusions. One might establish that an unknown waveform lies within the distribution of several authorised reference devices under matched observation conditions, while also acknowledging that competing designs were not exhaustively represented. A categorical source claim would require a far stronger discrimination experiment, a controlled set of plausible alternatives and independent corroboration that addresses transmitter hardware rather than receiver response alone. In most technical surveillance countermeasures settings, the defensible product is a ranked set of hypotheses and a plan for lawful further measurements, not a named manufacturer or individual transmitting apparatus. The report should state clearly whether the statistical comparison was exploratory, confirmatory or only illustrative.

Finally, no confidence interval can transform a convenience sample into a random sample of a population that was never defined. We may estimate repeatability for the collected units and tested conditions, and construct sensitivity analyses for plausible environmental shifts. The resulting inferential boundary should be written in ordinary language as well as equations. One may report that a calibrated feature differed in the tested two-class laboratory experiment and that it remained stable across held-out power cycles, without implying that every untested emitter must obey the same relationship.

Copyright 2026, James M. Atkinson

William Ralph Bennett, Peer Question: Dr. Kroemer, let us imagine a known reference source whose bias rail is ramped with a digitally controlled regulator. A receiver records a high-frequency shoulder during the first few microseconds, followed by a flatter plateau. Its operator believes the shoulder reflects carrier transport within the amplifier's transistor. Yet a supply lead, an output matching network, and the receiver preselector each possess a frequency-dependent response capable of converting a sharp transition into overshoot or ringing. What intervention would best identify the physical origin of that shoulder without assuming the receiving instrument is transparent? Should one begin by changing the source supply waveform, by substituting a non-radiating termination, or by inserting calibrated test transients directly ahead of the receiver?

I also ask how the examiner should handle nonlinear switching. A single linear impulse response cannot reproduce a receiver whose limiter, automatic gain controller or analogue-to-digital converter is driven beyond its operating range. Which measurements must be performed before any fitting of a supposed source-specific transient, and how could a deliberately varied input level expose the hidden threshold or compression behaviour?

Herbert Kroemer, Response: Mr. Bennett, those proposed interventions answer different questions, and they should be ordered to prevent a circular interpretation. Begin by verifying that the receiver can reproduce a known injected RF envelope at several power levels without unexpected amplitude-dependent deformation. A calibrated signal generator or controlled laboratory modulator should deliver a rise and decay with known bandwidth and independently recorded timing. If the purported shoulder appears on this injected waveform as well as on the source under study, there is

Copyright 2026, James M. Atkinson

immediate evidence that some part of the recorded feature may belong to the receiving chain. That does not by itself exclude a source shoulder, because the mechanisms can coexist, but it prevents claiming a unique transmitter origin without further testing.

Next vary the controlled source supply ramp while holding the output load and receiver settings fixed. If the shoulder follows bias-rise time or regulator mode transitions, a causal supply connection becomes more plausible. Substitute a matched non-radiating termination, within the source's permitted operating conditions, to reduce uncontrolled antenna and propagation effects. Observe the amplifier output through an appropriately rated, calibrated directional coupler if that laboratory access is available. Do not connect measuring equipment in a way that changes the amplifier load or violates source safety limits. A loading-dependent shoulder suggests an output-network or feedback contribution; a receiver-gain-dependent shoulder suggests measurement-chain distortion.

Nonlinearity should be tested explicitly. For a nominally linear receiver, scaling an injected reference by a known voltage factor should scale the recovered signal proportionately, with predictable noise effects. If changing RF input amplitude alters the normalised shoulder shape or onset time, the analyst must investigate limiting, automatic gain response, detector log compression and converter saturation. A record of attenuator state, gain setpoint and observed ADC headroom is therefore evidence, not a mundane administrative detail. Where several operating regimes are present, a single impulse-response correction is invalid. Instead, the examiner may stratify by regime or fit a bounded nonlinear model validated on held-out injected tests.

Copyright 2026, James M. Atkinson

It is equally important to preserve the raw complex samples and trigger timing where lawful and technically feasible. An energy detector may smooth the transient until its peak position depends upon the smoothing window rather than the original RF event. Spectrogram colour maps can conceal saturation because they normalise each frame independently. A stable causal interpretation must survive changes in display scale and feature extraction. The eventual conclusion should identify a class of potential mechanisms and the measurements that distinguished them. It must not transform a visually distinctive oscilloscope trace into the unique identification of a semiconductor technology.

Herbert Kroemer, Cross-Peer Question to William Redington Hewlett: Mr. Hewlett, your pioneering oscillator design makes the control and stabilisation of amplitude a matter of deliberate circuit dynamics. Suppose a modern authorised test transmitter exhibits a reproducible envelope overshoot, while its carrier frequency simultaneously moves toward a steady value. The engineer treats both observations as proof of a distinctive active device. I suspect that the regulator, amplitude-control feedback, oscillator startup and RF load each contribute, with potentially different time constants. Would you explain how a circuit designer distinguishes those coupled control loops experimentally, without pretending that their dynamics can be read uniquely from a single received waveform?

A second question concerns universality. Two independent designs may have nearly the same feedback bandwidth or soft-start programme, and one design may change dramatically with firmware revisions. In what circumstances can the shape of a transient support a broad oscillator or power-control class, and what would be necessary to show that it belonged

Copyright 2026, James M. Atkinson

to an individual apparatus? I should particularly value a proposal that identifies the possible contributions of receiver stabilisation rather than regarding the receiver as a passive observer.

William Redington Hewlett, Cross-Peer Answer to Herbert Kroemer: Dr. Kroemer, an oscillator ordinarily includes both a frequency-selective mechanism and an amplitude-regulating mechanism. The former determines what frequencies enjoy sufficient loop gain and phase alignment for oscillation; the latter restrains growth into a stable operating condition. At power application, those loops need not settle on the same time scale. Even a relatively simple resistance-capacitance network with a slow amplitude-control element can display overshoot before the control element catches up. A received amplitude shoulder is therefore not, by itself, evidence of unusual transistor transport. It may reflect ordinary feedback during the passage from open-loop growth to controlled oscillation.

The decisive measurements would alter one physical parameter at a time while recording more than a single dependent variable. In an authorised laboratory generator, vary the amplitude-control time constant within safe design bounds and measure envelope overshoot, settling delay and frequency drift. Independently vary the reference resonator or oscillator tuning state, where the apparatus permits, and compare the resulting carrier motion. Then repeat with a different but characterised receiver. If the envelope transient persists when the receiver changes but responds predictably to the source feedback adjustment, its attribution to the source control system becomes more persuasive. If the shoulder changes with receiver gain or detector settings, measurement-chain contributions remain important.

Copyright 2026, James M. Atkinson

A control-system representation can help organise the experiment. Write A(t) for envelope amplitude and e(t)=A_ref-A(t) for the control error relative to a declared desired amplitude A_ref. The gain-control actuator has its own response time, while the oscillator's growth rate depends upon instantaneous loop gain and losses. Such a simplified model should not be fitted with more parameters than the observed data can identify. Its purpose is to predict the consequences of a controlled intervention, not to recreate a mysterious signature using arbitrary constants. Identical-looking envelopes may emerge from different combinations of gain, load and feedback delay.

Consequently I would regard the observation as evidence of a general operating regime only when several authorised reference designs display corresponding behaviour under matched and varied conditions. A claim of individual source identity would require a separate population study demonstrating low within-unit variation, distinctive between-unit variation and robustness across independent receivers and environmental states. Such a claim is rarely established by the limited evidence available to a defensive field survey. The more valuable finding is often that a transient is compatible with feedback-controlled startup, accompanied by a clear account of the alternative mechanisms not yet excluded.

Dr. James M. Atkinson, Moderator: Dr. Kroemer, thank you. Mr. Hewlett, the token passes to you. Explain oscillator start, amplitude-control dynamics and the receiver measurement chain as independent contributors to the observed trace.

William Redington Hewlett, Second Principal Contributor: An observer seeing a radio signal turn on must resist the temptation to imagine that the

Copyright 2026, James M. Atkinson

entire apparatus has one start time. A power supply energises particular stages; an oscillator builds from noise or an imposed seed; a level-control loop responds to changing amplitude; a buffer or frequency-conversion stage becomes conductive; and an output-control circuit may deliberately postpone radiation until a frequency or output-power condition has been met. Each transition can have its own time constant and measurement uncertainty. A single received envelope is the aggregate result of those internal events, combined with filtering and time selection at the receiver. From the standpoint of instrumentation, an attractive curve is a prompt to design discriminating measurements rather than a certificate identifying the oscillator or transmitter that produced it.

It helps to distinguish loop start-up, loop stabilisation and transmitted-signal onset. In a feedback oscillator the small-signal loop gain must initially exceed the loss to sustain growth; when amplitude increases, some mechanism reduces effective gain or increases attenuation toward an equilibrium. The amplitude's rate of increase will depend on loop gain, available energy and nonlinear limiting. The oscillation frequency is influenced by the frequency-selective network and may change during thermal or electrical settling. Yet a radio transmitter can suppress its RF output until a control circuit asserts readiness. The receiver then observes the opening of an RF gate, not the startup of the hidden oscillator. Another design may let the unsteady oscillator radiate immediately. The same final carrier frequency can therefore be accompanied by very different beginning traces without requiring a unique device signature.

Measurement instrumentation can impose equally persuasive false structure. An IF filter with a narrow passband stretches a rapid input

Copyright 2026, James M. Atkinson

transition into a longer response. A detector with a finite averaging window shifts the apparent start time. An automatic gain controller may briefly amplify the start, then reduce gain as the input rises, creating an envelope with a pronounced peak even if the actual source output rose monotonically. If an instrument captures only after a software-selected energy threshold, its first stored sample may be much later than the first physical emission. If the firmware pretrigger buffer is too short, the observer may never see the beginning. One must record the complete timing chain, including RF input, analogue filter, detector, trigger condition, sample storage and software event timestamp.

A controlled way to separate these effects employs a known RF pulse generator and a splitter feeding two different receiver chains with traceable timestamps. Apply a calibrated pulse envelope spanning the observed rise times and bandwidths, and repeat at several levels from clearly linear operation to a safely characterised near-compression regime. The output of each receiver is a measurement of its response to the reference, not merely a photograph of the pulse. Where a simplified linear regime applies, the recorded complex voltage can be modelled as the convolution of the source waveform and an effective impulse response, with additive noise. Near limiting or gain-control transitions this representation is inadequate; the test must deliberately identify that boundary instead of correcting the result by a mathematically convenient but physically false deconvolution.

I would also compare the same source with two activation methods. One method supplies electrical power from zero. Another keeps the oscillator and power amplifier biased but opens a separately controlled RF switch. If the recorded features are dominated by the abrupt switching element, the

Copyright 2026, James M. Atkinson

second method may reproduce an apparent 'power-on' signature without a genuine oscillator start. A third controlled test may enable the oscillator but delay amplifier bias, allowing the investigator to separate frequency settling from power-amplifier ramp. These are laboratory interventions only, performed on authorised equipment whose operation can be safely modified. They demonstrate mechanisms; they do not establish what an unknown external transmitter did unless independent evidence identifies the corresponding architecture.

The distinction between timing and frequency stability is especially important. Suppose the observed carrier frequency drifts by a few kilohertz during a brief startup. It may reflect a source oscillator warming or a synthesiser loop acquiring lock. But a receiving local oscillator settling after its own retuning can produce a similar frequency trajectory. With a shared reference and a stable calibration source, one can determine whether the receiving converter is drifting. The experiment should preserve raw I/Q data and record the reference-clock state rather than infer physical frequency solely from the trend drawn by a display. A disagreement between two independently disciplined receivers is not a minor nuisance. It is powerful evidence against prematurely attributing the displayed motion to the emitter.

Class inference is possible when its meaning is carefully bounded. For example, a set of reference devices with continuously operating oscillators and gated outputs might show less startup frequency wander than devices that energise their oscillators at each event, under a specified time resolution and noise floor. The class label in such an experiment describes a known operating architecture, not a protected communications protocol or

Copyright 2026, James M. Atkinson

a named commercial device. The result must be tested with devices unseen during feature selection and with different receiving configurations. A source-to-source comparison should not be made from an instrument whose own gain, bandwidth and trigger threshold have quietly changed between sessions. Before reporting classification accuracy, the analyst should establish whether the class feature survives a receiver exchange.

Finally, the record must be reproducible. Keep a diagram of the measurement topology, reference generator settings, cable and antenna coupling losses, input protection state, clock source, sample rate, bandwidth, filter coefficients and gain. Record the interval since previous power application, because stored charge and temperature can cause two successive starts from the same apparatus to differ. Preserve the trial-level raw evidence and the calculation code version, then repeat a random subset blind. Where calibration uncertainty and between-unit variability remain large, a statement that the transient is 'compatible with gated-output startup' may be the strongest justified conclusion. It would be scientifically indefensible to convert that into an individual fingerprint merely because a classifier makes a confident numerical prediction.

Claude Elwood Shannon, Peer Question: Mr. Hewlett, you describe a physical oscillator's behaviour and a receiver's reaction as two possible sources of the same apparent transient. I should like to press the question of which random variable the investigator is actually estimating. Suppose a classifier receives only three features: the delay to first detected power, the slope of a short frequency trace, and a short-time spectral-width estimate. Those features arise after thresholds, filtering and sampling. How should the investigator demonstrate that they contain information about an authorised

Copyright 2026, James M. Atkinson

source class beyond information already contained in the receiver configuration, power level and triggering procedure? Would merely balancing the number of recordings from each transmitter type be sufficient, or must the acquisition conditions be crossed with both classes?

Please also distinguish a model that predicts which file belongs to which experimental session from a model that predicts transmitter architecture in a new measurement environment. I ask because a very successful predictive algorithm may be exploiting the microphone-like individuality of the measuring instrument, rather than the radio apparatus supposedly under investigation. What held-out tests would reveal that distinction without requiring observation of protected messages?

William Redington Hewlett, Response: Dr. Shannon, the measured random vector can be defined as Z=(L,S,B), where L is the delay from the declared reference trigger to the detector's first qualifying observation, S is the estimated early frequency slope in hertz per second, and B is bandwidth under a stated estimator and window length. Its distribution is conditional on more than transmitter class C. It depends on receiver configuration R, received power P, source-state history U, temperature T and the detection algorithm D. A useful probability statement therefore takes the form P(Z|C,R,P,U,T,D), even if an applied model approximates that distribution rather than estimating every variable exactly. Reporting P(C|Z) as though the nuisance conditions were absent invites unwarranted generalisation.

Balancing the number of recorded files per class does not address this problem when one class was measured on Receiver A and another on Receiver B. In that design, class and receiver are perfectly confounded. The analyst cannot tell whether a detected difference belongs to the source or to

Copyright 2026, James M. Atkinson

the instrument. The experiment should measure multiple devices from each class on multiple receiver chains, over controlled power ranges and power-cycle conditions. The resulting crossed data support tests that hold out entire hardware units and entire receiver sessions. If performance collapses when the receiver is changed, the purported class feature is not sufficiently invariant for the intended purpose, even if it reliably separated files in the original training collection.

There are two practically distinct validation goals. One asks whether the system can organise recordings from an already known laboratory configuration. The other asks whether it can classify a new reference emitter under conditions reasonably similar to a future authorised survey. The second requires a difficult transportability test. One can train on one group of units and receivers, then assess on newly collected devices and a separately configured chain whose calibration is recorded but not used to tune feature selection. The held-out assessment should include deliberately similar devices from competing classes and tests near the detection threshold, where waveform distortions can be strongest. The analyst should present the confusion matrix and uncertainty intervals, not just an average percentage.

None of this requires reading a message. A reference generator can emit an agreed test envelope or a dummy modulated signal whose contents are irrelevant. The examiner can retain waveform energy, instantaneous frequency estimates, receiver state and time references without extracting protected traffic. The conclusion should distinguish classification under a specific measurement model from attribution to a unique physical transmitter. Even a highly informative statistical feature cannot prove an

Copyright 2026, James M. Atkinson

identity when the set of plausible competitors has not been defined and tested.

William Redington Hewlett, Cross-Peer Question to John Bardeen: Dr. Bardeen, we agree that a received power-on curve is an interplay of electrical states. Yet there is a practical tendency to treat all semiconductor switches as the same fast ideal device, and then to attribute any unexpected shoulder to a radio-frequency amplifier's design. Could you explain how charge storage, junction capacitance and device bias history complicate that ideal picture? What feature would you expect to vary systematically when a known source is restarted quickly rather than after a long unpowered interval, and what measurements could distinguish that variation from thermal drift in the receiver or its local oscillator?

I am also interested in the evidential meaning of resemblance. Suppose two physical transistor designs give nearly identical received envelopes because each is governed by a digitally imposed output-power ramp, while a third instance of one design differs after an unusually warm restart. Would the semiconductor construction remain identifiable from that one envelope? How should an examiner prevent a convenient circuit model, fitted after the fact, from turning into a claim of device fingerprinting without a genuine intervention that tests the model's predictions?

John Bardeen, Cross-Peer Answer to William Redington Hewlett: Mr. Hewlett, the ideal switch model is adequate for some circuit calculations but unreliable as a literal description of a semiconductor passing between operating states. Electrical charge is stored in depletion regions, device junctions and external capacitors. Its distribution depends upon the previous bias condition and the rate at which applied potential changes.

Copyright 2026, James M. Atkinson

Some devices also exhibit minority-carrier storage and recovery effects; their importance depends on the specific technology and circuit topology. A transistor that was only briefly de-energised may retain a different thermal and electrical starting state from a unit left unpowered for an hour. The resulting voltage and current trajectories can differ without implying any change of hardware identity.

The first measurements should therefore be local and physical, where authorised reference equipment permits. Record the bias rail waveform with an instrument of sufficient bandwidth and known loading. Record the output envelope through a characterised coupler and compare it with the timing of control signals that govern amplifier enable and RF gating. A family of tests with varied off-time can then distinguish reproducible bias-memory effects from changes correlated only with the receiver's own warm-up. A stable external RF reference, measured before and after each test cycle, can identify changes in receiving local-oscillator behaviour. If the same output transient changes while the source input state is held constant but the receiver gain is altered, the source-only explanation is incomplete.

The mathematical point is one of non-unique inverse inference. Several arrangements of device physics and control circuitry may yield the same observed amplitude trajectory once the receiving chain has filtered and thresholded it. Even if a mechanistic model fits every point, other models with different internal states may fit equally well. The useful test is a prediction under an intervention not used in the fit. For example, the model might predict how the early shoulder changes when the controlled bias ramp is lengthened or when a known load reactance is adjusted safely. If that predicted change occurs across independent source units and

Copyright 2026, James M. Atkinson

receivers, confidence in a mechanism may increase. It still does not imply that the measured pattern is unique to an individual unit.

A sensible classification claim should thus be modest: a transient may be compatible with a broad architecture involving stored-charge recovery, gated RF output, or controlled ramping. Which explanation is favoured depends on interventions and uncertainty, not on the visual novelty of the trace. The examiner ought to record failures of the model openly, because those failures identify conditions under which it should not guide future surveillance-countermeasure decisions. The mere existence of microscopic differences between physical transistors does not establish that the chosen observation system can measure those differences robustly, much less attribute an unknown emitter to a unique device.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, thank you. Dr. Bardeen, kindly accept the token and examine semiconductor state, stored charge, source history and the inferential limits of indirect remote observation.

John Bardeen, Third Principal Contributor: A classification scheme based upon a turn-on transient is only as sound as its account of the device states that can affect that transient. Semiconductor materials contain mobile carriers and electric fields whose distribution changes as electrical potentials are imposed. But the radio envelope emitted into space is many stages removed from those microscopic events. It includes switching controls, bias networks, resonant elements, coupling components and the load presented by the antenna. It would be an error to assume that a waveform recorded at a distant receiving antenna is a direct picture of the semiconductor's internal motion. We must take care not to substitute a charming analogy

Copyright 2026, James M. Atkinson

between an oscilloscope trace and a crystal's physics for evidence that the trace reveals its construction.

Consider a power amplifier whose output is controlled by an enable signal and a bias regulator. At early times, the regulator may bring a transistor gradually through operating points with different gain and effective capacitance. The amplifier's output filter stores and exchanges energy. If the enable signal arrives before the oscillator has settled, a short frequency transient may coexist with the rising envelope. Conversely a design may allow its oscillator to stabilise before the RF output is enabled, hiding almost all oscillator movement from a field receiver. Observed similarity between these arrangements can arise when an envelope controller imposes the same ramp on both. Observed difference can arise when the input source level, antenna impedance or receiver threshold changes. Neither result identifies the semiconductor by itself.

One should write an explicit hierarchy of states. Let b(t) denote the measured bias voltage, i(t) the amplifier supply current, a(t) the output-envelope amplitude measured at a calibrated laboratory coupler, and z(t) the complex samples recorded by the receiving apparatus. These observables have different locations in the causal chain. In a reference experiment the investigator can study whether changes in b precede and predict changes in a while z follows in a manner consistent with the independently measured receiver response. If all that is available is z, the inverse inference is much less constrained. Unobserved states can produce the same z, especially after filtering, quantisation and threshold selection. A classification scheme must distinguish what its instruments observe from what the engineer hypothesises about the inaccessible circuit.

Copyright 2026, James M. Atkinson

A repeated startup can also carry memory of its recent history. Capacitors discharge according to their time constants. Semiconductor junctions and the surrounding circuit may cool on longer time scales. A synthesiser may retain configuration state, while an output stage receives a programmed ramp independent of oscillator acquisition. Therefore the off-interval should be treated as an experimental variable rather than as an idle administrative detail. Randomise the order of short and long off-intervals, monitor temperature, and record the source's operating mode. The first start after overnight cooling may belong to a different within-unit distribution from the tenth start in quick succession. A model that interprets these populations as two transmitter designs has committed a basic causal error.

Bias and temperature measurements also require care to avoid changing what is being tested. A probe with appreciable capacitance on a sensitive node may alter the startup response. A coupler placed at an amplifier output changes the impedance presented to the system unless it is chosen and installed appropriately. A thermal probe may be too slow to resolve junction conditions even when the external case temperature appears constant. These limitations do not invalidate a controlled laboratory experiment, but they qualify its observations. A defensible paper will state the effective measurement bandwidth, loading and calibration and refrain from claiming a physical variable has been measured merely because a proxy was recorded.

For an example, imagine twenty independent authorised power cycles on each of four amplifier modules, repeated across a cool and a warm condition, with two receiving chains. The resulting number of digital samples might be millions, but the number of independent modules

Copyright 2026, James M. Atkinson

remains four. The uncertainty of a class-separation result is governed in part by the small number of physical modules and by how their conditions were selected. A random train/test split of samples from all eighty cycles would not test generalisation to an unseen module. Leave-one-module-out validation and separate receiver-condition tests are more honest, although they may reveal that the available evidence supports only a broad mechanism hypothesis rather than a stable classifier. One should report those limits instead of hiding them in a large sample count.

If microscopic device physics is invoked, its predicted macroscopic consequences should be stated before examining the final comparison data. A hypothesis about stored charge might predict a dependence on off-time but not necessarily on receiver bandwidth; a hypothesis about receiver ringing predicts dependence on filter design, even when the source is unchanged. An antenna mismatch hypothesis predicts a change when a calibrated termination replaces an uncertain load. A digital RF-gate hypothesis predicts a stable output onset relative to the gate command but may permit variable earlier oscillator behaviour. These predictions can be distinguished using authorised equipment. The historical achievement of semiconductor physics was to connect mechanisms with measurable consequences, not to establish that an unknown circuit can be uniquely reverse-engineered from one remote trace.

I would reserve the expression 'fingerprint' for an actually validated uniqueness proposition involving the relevant population of devices, environments and observing equipment. Even then, the term risks suggesting forensic individuality when only a narrow laboratory population was examined. For defensive technical-surveillance investigations, the

Copyright 2026, James M. Atkinson

necessary distinction is usually between a known transient artefact, a broad class of switching or transmitter architecture, and an unexplained emission requiring further lawful examination. Careful measurement can support the middle statement. It need not, and ordinarily cannot, jump to unique identification. The strongest evidence often comes not from an unusually sharp feature but from a falsifiable prediction about how that feature changes under a controlled intervention.

Harry Nyquist, Peer Question: Dr. Bardeen, your account includes several simultaneous electrical time constants, but the radio-frequency measurement chain has its own limited bandwidth and group delay. A colleague may claim that the initial carrier transient lasts twenty microseconds because the amplitude crosses a chosen detection level for that period. Suppose the receiver's intermediate-frequency filter has a comparable response time and the sampled output is digitally smoothed. What is the proper relationship between the bandwidth available to resolve a transition and the claims that can be made about the transmitter's underlying rise time? Would you set a lower bound on resolvable events using a calibrated step response rather than relying on a nominal receiver bandwidth printed on the instrument panel?

I also ask how you would test a proposed class distinction in frequency settling when its slope is estimated over a window that changes with the receiver's threshold crossing. The selection rule may itself correlate with signal strength and bias conditions. What independent time origin and observation schedule would prevent the analyst from manufacturing an apparent oscillator trend through inconsistent window placement?

Copyright 2026, James M. Atkinson

John Bardeen, Response: Mr. Nyquist, the response of the measurement chain determines the class of source changes that can be resolved. A narrow analogue filter cannot reproduce an arbitrarily abrupt input transition, and a software smoothing operation may increase that limitation or shift the apparent peak. A nominal bandwidth figure is therefore not an adequate substitute for measuring the effective response under the actual gains, preselection and detector settings. We should inject reference signals with rise times on both sides of the expected source transition and record the resulting complex samples. Where the measured output changes little as the injected rise time becomes shorter, the instrument has reached a practical resolution limit. An apparent source rise faster than that limit cannot be reliably estimated from the trace without additional validated assumptions.

The receiver's step response should be reported with sufficient detail to reveal ringing, overshoot and latency. A frequency-swept calibration tone addresses selectivity but may not expose time-varying gain and buffering in the same way. Separate reference pulses of known duration and level should test the response across the actual operating range. If saturation or gain adjustment occurs, the effective response depends on amplitude; then a single deconvolution kernel cannot be applied indiscriminately. One may characterise several regimes and restrict inference to a regime in which validation errors are acceptably bounded. Where the source transient and receiver response have similar scales, a measured width should usually be stated as an unresolved or model-dependent estimate rather than as an intrinsic material property.

Copyright 2026, James M. Atkinson

Window placement requires an independent origin. When possible, use the reference transmitter's hardware enable signal and an independently sampled trigger, and preserve a pretrigger record at the receiver so that the onset algorithm does not decide where the analysis begins. If the source trigger is unavailable in a defensive field observation, retain a fixed predeclared rule for choosing windows and report its selection uncertainty. Do not change the frequency-slope window after inspecting which segment looks most linear. A threshold crossing that occurs later for weaker signals can select a different portion of the oscillator's real trajectory, giving the appearance of a changed frequency-settling law even if the underlying path is unchanged.

The right scientific claim therefore has explicit temporal resolution and selection conditions. One might find that the received waveform is consistent with a frequency change lasting no longer than a stated measurement bound under a verified filter configuration. That statement is narrower but more meaningful than pretending to have measured an inaccessible transistor's intrinsic startup. A well-calibrated failure to resolve two proposed mechanisms is a legitimate result. It protects the eventual source-class conclusion from precision that the apparatus could not supply.

Ralph Vinton Lyon Hartley, Peer Question: Dr. Bardeen, the technical report may contain a striking spectrogram at startup and a table of feature values, but the features are computed after several operations that discard information. The analyst averages power, applies a log scale, divides by a windowed spectral estimate and retains only a few largest peaks. Would you explain how information lost through such transformations restricts the reversibility of the inference? If a particular spectral ridge is absent from the

Copyright 2026, James M. Atkinson

retained display, can the examiner infer that it was absent at the antenna, or merely that it was below the transformed display's sensitivity? Which original measurements must be preserved to permit a different examiner to test an alternative physical explanation?

My further concern is that a source may differ in electrical construction while producing a deliberately standardised ramp. To what extent can a classifier rely on a distinctive feature that an ordinary control system may remove? Should a source-class conclusion be framed as an observation of the programmed outward behaviour rather than as a claim about the hidden semiconductor design?

John Bardeen, Response: Mr. Hartley, the transformations you describe are generally many-to-one. Averaging erases the ordering of fine fluctuations, magnitude conversion discards phase, logarithmic compression changes how small and large differences are perceived, and choosing a handful of spectral maxima suppresses the remainder of the record. None of these operations is improper for a defined measurement purpose, but their outputs cannot usually reconstruct the original complex voltage. If a ridge is absent from the display, the absence may reflect finite resolution, thresholding, smoothing, insufficient dynamic range or a genuinely absent component. The displayed image alone cannot distinguish those explanations. The examiner must preserve the measurement chain's settings and the unprocessed data accessible under the lawful survey scope.

A reproducible evidence packet should include raw complex I/Q samples if legitimately captured, sample counts and dropout flags, time reference and clock stability, centre frequency, analogue bandwidth, input gain, attenuator settings, any preselection changes, calibration records and software version.

Copyright 2026, James M. Atkinson

It should also describe how the spectrogram was formed: window, overlap, normalisation, FFT length, display floor and colour mapping. A second examiner can then recompute the early feature using another defensible estimator and determine whether the claimed distinction survives. If only a screenshot remains, the appropriate qualification is that the inference was made from a derived display whose omitted information cannot be recovered.

A standardised ramp can conceal information about hidden hardware. That is precisely why visible emission behaviour must not automatically be equated with semiconductor construction. Two quite different amplifiers may be governed by the same gate and digital envelope programme. Conversely two instances of the same amplifier may behave differently if one control sequence enables the output before the oscillator settles and another waits. A classifier may validly distinguish those outward operating regimes, provided the regimes are defined and the result generalises to new authorised samples. It should then call them operating regimes, not manufacturers, individual units or semiconductor material classes. The name of the category is part of the scientific claim and must match the evidence actually present.

Where one suspects a physical class difference, design a test with known apparatus capable of changing the relevant operating variable. A programmed ramp hypothesis predicts differences when the ramp command changes; a semiconductor-storage hypothesis predicts relationships with off-time or bias history; a filter-ringing hypothesis predicts changes when receiver bandwidth changes. These are not interchangeable predictions. The advantage of preserving raw evidence is that competing

Copyright 2026, James M. Atkinson

predictions can be evaluated without having to trust a single selected picture. Even the best evidence may support several mechanisms. A report that makes those alternatives visible is stronger than a confident but unsupported identification.

John Bardeen, Cross-Peer Question to Sir Martin Ryle: Sir Martin, a laboratory engineer may control a transistor's bias and measure its output through a cable, yet the defensive examiner observes the same class of signal through an uncertain environment. Reflections from building surfaces, antenna orientation, movement and multipath delay may change the waveform received at a particular point. Which features of a power-on transient could survive reasonable changes in path, and what independent observations would show whether a spectral shoulder belongs to the transmitter or to a delayed replica arriving at the antenna? In particular, can one compare two receiving antennas in the same room without mistakenly assuming their paths are independent?

I should also like you to address spatial selection. If an operator moves an antenna until a startup feature looks unusually sharp, then takes that location as representative, the apparent source class may be influenced by the selection itself. How could the survey record the search geometry and its uncertainties so that later investigators can assess whether a distinction is robust across positions rather than an artefact of the chosen observation point?

Sir Martin Ryle, Cross-Peer Answer to John Bardeen: Dr. Bardeen, propagation is an essential part of the measured event. In an approximate linear time-invariant channel one may write r(t)=sum over k of alpha_k s(t-tau_k)+n(t), where s is the emitted complex baseband signal, alpha_k are

Copyright 2026, James M. Atkinson

complex path gains, tau_k are relative propagation delays, and n is aggregate noise. This model is not universally valid in moving or nonlinear environments, but it makes the ambiguity clear. A short source transient may be lengthened by delayed components; its amplitude may be enhanced or cancelled at particular frequencies. A shoulder appearing at one location can vanish a modest distance away because the complex path contributions have changed. One receiver at one point cannot distinguish all these mechanisms from source-intrinsic effects.

Two receiving antennas do not automatically supply independent experiments. If they share nearly the same multipath geometry, the same local oscillator or the same analogue chain, their errors and channel responses may be correlated. Their value depends on documented separation, polarisation, calibration, timing and channel diversity. An authorised reference source placed at known locations can probe the site response without guessing which environmental components created each reflection. Where possible, use a controlled conducted or shielded coupling test to isolate the source and receiving instruments from the variable room channel. Then compare that laboratory baseline with field measurements as a constrained analogy, not as a direct identity proof.

The operator's search procedure also matters. Selecting the spatial point that maximises a desired feature and then using that same point to claim exceptional distinctiveness introduces selection bias. Record the actual antenna path, elevations and orientations, the detector's settings, and every observation location examined, including unsuccessful ones. A predefined spatial sampling grid or independently repeated survey reduces the temptation to turn an extreme selected trace into an intrinsic property. If a

Copyright 2026, James M. Atkinson

sharp early shoulder appears only at a narrow set of positions, that pattern is evidence of path sensitivity. If it persists across sufficiently distinct paths and receiving systems, a source contribution becomes more plausible, though not uniquely identified.

The defensible conclusion would identify which aspects of the transient were stable under measured path changes and which remained dependent upon the environment. A class hypothesis that requires one lucky receiving position is not ready for forensic attribution. The proper analogy from radio astronomy is that the instrument's spatial response and the environment's propagation structure must be accounted for before an observed feature is assigned to the object being observed. That principle is equally applicable to a defensive survey of an unknown RF transient.

Dr. James M. Atkinson, Moderator: Dr. Bardeen, thank you. Sir Martin Ryle, I pass the token to you to account for propagation, antenna geometry and the independence of receiver-based corroboration.

Sir Martin Ryle, Fourth Principal Contributor: A radio observation is the result of a source, a path and an instrument. The measured turn-on trace can be strikingly detailed while remaining incomplete as evidence about the source itself. At a particular antenna position a short emission may arrive by a direct path and several reflected paths with different delays and phases. Their combination can produce a transient amplitude shoulder, a notch or a frequency-dependent ring that does not exist in the emitted field at the source. At a second position those path contributions may interfere differently, altering the apparent opening seconds or microseconds of a transmission. The investigator should not call every reproducible feature an

Copyright 2026, James M. Atkinson

intrinsic signature, because the room itself can reproduce it whenever the antenna returns to the same place.

In a simplified description of a stationary multipath environment, the channel is a sum of delayed and weighted versions of the source waveform. That model explains why a rising envelope can appear longer or more complicated than the original. It also explains how a frequency-dependent channel can alter the estimated early spectrum. However, an indoor environment may not remain stationary when doors open, people move, machinery starts or a handheld antenna is repositioned. A classification model trained in one static room might therefore fail elsewhere. The appropriate question is not whether a particular complex trace looks repeatable, but whether the source-class feature remains stable after the likely path and instrumentation differences are deliberately introduced.

Our first concern should be observability. A receiving antenna has a pattern, polarisation response, impedance and coupling to nearby structures. An attenuator or preselector changes the effective observation chain. If an operator changes antenna orientation while pursuing the strongest signal, the resulting trace is sampled from a selected region of the channel's spatial response. Selecting a spectacular transient after inspecting dozens of locations is not equivalent to a predeclared test at a random location. The final record must include the selection history, including positions where the proposed feature was weak, inconsistent or absent. Otherwise the reader is shown a curated result without the denominator of failed observational opportunities.

A useful controlled experiment uses an authorised reference emitter with a known trigger and envelope, placed at documented positions. Record the

Copyright 2026, James M. Atkinson

signal simultaneously through two independently calibrated receiving systems, preferably with independent clock and analogue chains. Keep the location, polarisation, antenna height, filter settings and input level documented for each observation. Conduct a second experiment through a calibrated shielded or conducted coupling path, within the source's safe operating constraints. Comparing the freer propagation path with the controlled baseline helps determine which early features are sensitive to the environment. It does not fully reconstruct every reflection, but it challenges a source-only explanation with an alternative that is experimentally observable.

Independence between channels is often overstated. Two receivers may be fitted with separate antennas yet share the same timing reference, processing software or preselector design. Their recordings can agree because they share a calibration error. Conversely two physically different receivers may have different analogue impulse responses, making source-consistent events appear different. The test should classify which elements are truly independent: RF front end, oscillator reference, analogue-to-digital converter, processor, event-detection algorithm and physical antenna path. Where practical, use a known calibration emitter through each system before and after the experimental run. A agreement of two derived spectrograms is weaker than agreement of calibrated raw event features measured through genuinely different chains.

Consider a quantitative example. A hypothetical source has an envelope rising over 5 microseconds, and a reflection arrives 2 microseconds after the direct signal with a complex gain whose magnitude is 0.4 of the direct path. Depending on phase, the reflected contribution may enhance or partially

Copyright 2026, James M. Atkinson

cancel the direct field during the rise. The delay is 2 microseconds by assumption, not by any asserted measurement. The spatial response can therefore alter the apparent transient on a scale comparable to the source rise, particularly where reflections are appreciable. No universal curve can be inferred from those illustrative values because building geometry, frequency, antenna pattern and bandwidth determine the actual response. A controlled experiment should vary path conditions and demonstrate whether the chosen features are stable in spite of such changes.

Frequency stability is subject to its own propagation qualifications. A static multipath channel does not ordinarily create a genuine carrier-frequency drift, but it may distort instantaneous-frequency estimates when the signal is weak, when paths interfere, or when the receiver algorithm follows an amplitude notch rather than the true carrier. Moving scatterers may introduce additional Doppler components. A local oscillator drift in the receiver introduces yet another competing explanation. If the analyst sees a brief frequency excursion alongside an amplitude dip, the report should compare raw phase continuity, receiver clock records, amplitude-dependent estimator failures and independent receiving observations. One should not interpret the mathematical phase of a noisy, near-zero complex sample as if it were an exact measurement of a physical oscillator's state.

For lawful defensive fieldwork, the purpose is often to sort observed events into plausible broad categories so that the survey can choose further measurement methods. One may report that a transient is stable across certain antenna positions and receiver configurations, and that it resembles the controlled startup of a known class of reference sources. This supports prioritisation, not a unique source label. A substantial change after

Copyright 2026, James M. Atkinson

repositioning the antenna suggests that the observed feature is path dependent. A substantial change after exchanging the receiver suggests instrument dependence. The investigation advances by treating these changes as information, not as inconvenient anomalies to be concealed beneath a class label.

Finally, the documentation must make the measurement geometry recoverable. Record room location, antenna separation, orientation and distance estimates with appropriate uncertainty, equipment state, environmental movement and trial times. Preserve null observations as well as detected ones, because a disappearing feature may be more discriminating than an especially attractive positive trace. Distinguish repeated measurements at one fixed point from independent configurations in which the physical path has changed. The aim is not to reconstruct a transmitter's unique identity by some form of remote clairvoyance. It is to exclude competing propagation and receiver explanations before treating a transient as evidence about a transmitter class.

Richard Wesley Hamming, Peer Question: Sir Martin, your insistence on documenting antenna location and path suggests that software metadata may be as important as the RF samples themselves. Suppose two independent receivers appear to agree on the first ten microseconds of a reference transmitter's startup, but both streams pass through the same event assembler. That programme aligns captures on the detected peak, removes any event whose pretrigger buffer is incomplete, and normalises the stored amplitude. The resulting files could show an artificial similarity. Which metadata and independent processing tests would let an examiner

Copyright 2026, James M. Atkinson

determine whether agreement is genuinely physical or created by the common software? Would you regard independent RF hardware as sufficient when the comparison pipeline itself is not independently controlled?

I should also ask how to preserve negative observations. A receiver that was blind during a scan gap has not disproved an emission, and an event filter may silently discard weak or distorted starts. What records of eligibility, buffer completeness, sample loss and software rejection should accompany the archive so that a later examiner can distinguish a true absence from a missing opportunity to observe?

Sir Martin Ryle, Response: Dr. Hamming, independent RF hardware is an advantage but not a substitute for independently validated processing. If both data streams are peak-aligned by the same event assembler, shared preprocessing can create a common shape even when raw onset times and amplitudes differ. The data package should therefore preserve the original sample indices, acquisition timestamps, trigger records, pretrigger depth, complete input level information and the exact transformation code used to prepare each display. A second analyst should be able to reconstruct the comparison from independently sampled raw data without trusting the first assembler's alignment decisions. The analysis should disclose rejected events and the reasons for rejection, not quietly count only those starts that already look clean.

To test the pipeline, inject synthetic reference events into recorded noise at known offsets and amplitudes, then run the software without revealing the insertion labels to the analyst. This identifies whether peak alignment systematically shifts the onset or whether incomplete buffers are discarded

Copyright 2026, James M. Atkinson

disproportionately for slow-rising pulses. Process a separate set through a second independently implemented algorithm, and compare not only final feature values but event selection and sample indices. The aim is not perfect agreement between programmes; a disagreement identifies assumptions that must be resolved. If two programmes use the same input buffer created by a common flawed driver, they are not independent at the acquisition level, so the hardware path must also be audited.

The negative observations require an eligibility log. A sweep receiver should record tuning position, dwell intervals, settling periods, sampling gaps, gain changes and detector thresholds. A null in an eligible, calibrated observation window has a different evidential meaning from a null during a retune or data loss. Similarly, a waveform discarded by a quality filter is not absent from the antenna merely because it was excluded from the class comparison. Reports should state the population of physical trials, the subset visible to each receiver, the subset successfully captured, and the subset finally analysed. A classification rate calculated only on the cleanest selected events may tell us little about general detection performance.

I would ask for an audit trail with immutable raw records, hashes, software versions and a reproducible sequence of transformations. The examiner should confirm that the class result persists under reasonable alternative alignment and normalisation methods. If not, the evidence supports at most a processing-dependent descriptor, not a robust RF-source feature. Such caution is especially important in forensic circumstances, where the apparent certainty of two agreeing instruments can conceal a shared computational decision. A source class ought not be inferred from concurrence manufactured by a common file-handling routine.

Copyright 2026, James M. Atkinson

Sir Martin Ryle, Cross-Peer Question to Edwin Howard Armstrong: Mr. Armstrong, an unfamiliar startup trace may be influenced by both the emitting apparatus and the receiving chain, and the receiving chain may include conversion, limiting and strong selectivity. Suppose a weak laboratory transmitter radiates an amplitude ramp with a short frequency excursion, while a superheterodyne receiver retunes during acquisition. Its display shows a pronounced spectral hook. Would you explain how frequency conversion and IF filter response might generate or magnify such a hook, and what comparative experiment would distinguish that instrument effect from an actual source frequency trajectory?

I also wish to press the difference between stable reception and stable evidence. A receiver design that beautifully suppresses interference may nevertheless discard information about the true instantaneous startup waveform, particularly when a limiter or detector responds nonlinearly. Which parts of the measured transient remain physically interpretable after those operations, and how should a countermeasures report avoid identifying a supposed emitter type merely because the spectrogram is visually characteristic of one receiver architecture?

Edwin Howard Armstrong, Cross-Peer Answer to Sir Martin Ryle: Sir Martin, the superheterodyne receiver is a chain of deliberate frequency transformations. A received carrier is mixed with a local oscillator, passed through selectivity and eventually detected or sampled. If the receiver's local oscillator changes frequency during capture, the frequency of the intermediate signal may move even when the transmitting carrier is steady. An IF filter with nonuniform amplitude and group-delay response may then alter the early envelope and spectral shape. A visually striking hook can

Copyright 2026, James M. Atkinson

therefore arise from the instrument's own dynamics. One must not regard the instrument as a transparent window merely because its steady-state frequency scale is well calibrated.

A discriminating test begins with a stable, traceable reference signal whose startup and frequency are independently known. Inject it at an appropriate point ahead of the receiver, with level and bandwidth matched to the intended experiment, and repeat the capture across the suspected retuning states. If the reference acquires a hook under the same receiving configuration, the receiver must be implicated. A second independently stabilised receiver can then monitor the actual radiated laboratory source continuously while the first retunes. Agreement in the source's physical frequency excursion across both chains strengthens a source-side interpretation; disagreement, particularly one following the first receiver's tuning transitions, weakens it.

Limiting and detection deserve separate notice. A limiter deliberately removes amplitude variations beyond its operating range. This can improve reception of a frequency-modulated signal but also makes the original amplitude ramp unrecoverable from the limited output alone. A narrow IF channel may suppress parts of a rapidly changing startup spectrum, causing the apparent shape to depend upon alignment and bandwidth. Thus a receiver suitable for listening may not be suitable for measuring every aspect of transient source behaviour. The report should declare at which measurement point the samples were acquired and whether relevant amplitude and phase information survives the intervening stages.

As to identification, I would restrict the conclusion to the features independently established. One might say that the observed startup in two

Copyright 2026, James M. Atkinson

calibrated chains contains an early frequency excursion beyond the measured uncertainty and that the excursion is compatible with particular oscillator-settling architectures. One should not identify the transmitter as a certain make or unique apparatus without separate population evidence and controlled exclusion of competing designs. The receiver that makes the trace attractive also provides reasons to question it. The proper use of sophisticated radio instrumentation is to expose those dependencies and narrow the uncertainty, not to hide them beneath a confident label.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, thank you. Mr. Armstrong, the token passes to you. Address superheterodyne conversion, filtering, detection and a defensible source-class rather than individual-source conclusion.

Edwin Howard Armstrong, Fifth Principal Contributor: An RF receiver is not a neutral pair of eyes. Its selectivity, gain, conversion stages, oscillators and detectors determine the portion of a transmitter's behaviour that reaches the examiner. A receiver optimised for recovering a message can be especially unsuitable for examining the exact transient amplitude that preceded steady transmission, because its filters and limiters deliberately reshape the signal. In a superheterodyne system, an apparent early shift in frequency may reflect motion of the receiving oscillator, motion of the transmitting oscillator, or both. The surveyor should ask where in the chain a measurement was made, how its time reference was established, and which components of the original waveform can survive the chosen path. Without that information, an apparently characteristic power-on transient can easily be a characteristic of the receiver.

Copyright 2026, James M. Atkinson

Consider a controlled transmitter that begins with an oscillator settling through a small frequency excursion while its power amplifier gradually opens. A narrow receiving IF filter may initially pass only the portions falling near its centre, making amplitude appear to rise and fall as the carrier crosses the passband. A wider IF filter may show a smoother amplitude envelope and a broader short-time spectrum. If the analyst receives only a log-power waterfall from the narrow channel, the observed pattern may look like two separate startup events. Yet a wideband complex recording could reveal a single continuous physical event. The correct comparison must therefore consider whether the proposed classifier is attached to the receiver's selected output representation rather than to a transmitter mechanism.

I would classify the instrument operations by their effect on evidence. Frequency conversion changes the reference frequency and incorporates local-oscillator stability into the measurement. A finite IF filter introduces amplitude and phase response, potentially extending the duration of transients. Limiting can erase amplitude information. Automatic gain control changes the apparent envelope according to earlier input power. Squelch and energy thresholds can remove the weakest beginning samples. Digital resampling, timestamp assignment and spectrogram windows introduce further time and frequency selection. The fact that these operations are deliberate and useful for ordinary reception does not make them appropriate for every forensic measurement. Their role must be declared before a physical cause is inferred from a derived feature.

The distinction between modulation and startup dynamics is also worth making. A signal may show changing instantaneous frequency because the

Copyright 2026, James M. Atkinson

source is intentionally modulated, because a frequency-control loop is acquiring stability, because a receiving converter is drifting, or because a phase estimator becomes unstable during low amplitude. The mere existence of a brief frequency slope does not reveal which explanation applies. If a known test source can hold its oscillator steady while its RF output is gated, the resulting capture supplies a useful receiver-control condition. If another reference source intentionally sweeps its oscillator under known control, the measuring system's ability to recover that sweep can be tested against independent timing and frequency references. Neither experiment should require decoding an unknown communication.

An investigator may gain much by deliberately changing receiver architecture. Record the same authorised power-on event through a sufficiently wideband direct-sampling receiver and through a superheterodyne chain whose analogue bandwidth, filter shape and oscillator reference are characterised. If the distinctive spectral hook follows the superheterodyne but not direct sampling, it is unsafe to claim that the source intrinsically generates that hook. Conversely, if a calibrated frequency excursion appears in both chains at corresponding source-trigger times, with uncertainties accounted for, a source-side mechanism becomes more plausible. It may still be shared by many transmitter classes, and its presence is not a unique fingerprint.

A basic numerical illustration emphasises bandwidth. Suppose the useful part of a startup feature changes over 10 microseconds, and a receiver's effective impulse-response decay extends over 30 microseconds. The output may be dominated by the receiver's longer response, and no sound inference can distinguish a 5-microsecond source feature from a 10-

Copyright 2026, James M. Atkinson

microsecond one without additional validated information. Those times are purely hypothetical. The engineer should measure actual step and pulse responses for the operating conditions and disclose whether an attempted distinction lies inside the instrument's resolution. Higher nominal sample rate does not cure inadequate analogue bandwidth or a gain stage operating in compression. The sampling converter cannot recreate portions of the waveform already removed by the front end.

Physical source classes remain useful if they are defined by mechanisms and supported by comparative measurements. A gated continuous oscillator, a free-running oscillator enabled with the power stage, and a synthesiser whose output is withheld until lock may produce different patterns under controlled laboratory conditions. But a programmer can impose the same output ramp on more than one architecture, and different receiver chains can make one architecture appear varied. A valid study should therefore use more than one hardware unit per proposed class, varied receiving chains, held-out power cycles, source-state metadata and explicit tests for alternative causes. Error rates calculated from non-independent samples or from a single instrument should not be generalised to the entire population of unknown transmitters.

For a defensive field report I would present the observable record first: calibrated amplitude and frequency trajectories, time origin, signal-to-noise ratio, instrument state, detection threshold and uncertainty. Then I would list supported interpretations in descending order of evidential compatibility, including receiver and propagation artefacts. Finally I would specify what authorised experiment would discriminate the remaining hypotheses. An antenna movement, independent receiver, controlled

Copyright 2026, James M. Atkinson

attenuation series or known source-side trigger can be more valuable than a more elaborate pattern-recognition algorithm. We should be rigorous about the limitations imposed by actual circuitry, because transmitter identity is not a prize awarded to the most complicated looking trace.

The study of transient RF behaviour should therefore be a study of measurement provenance as much as of transmitter circuits. No single waveform feature is automatically intrinsic, universal or unique. A reliable class inference survives experimental changes that should affect nuisance mechanisms but not the claimed source mechanism, and it remains uncertain where those interventions are unavailable. The engineer who writes that a startup pattern is compatible with a broad oscillator-control class, under stated conditions, has served the examiner better than one who pronounces a precise identity without demonstrating that the instrument could support it.

Irving S. Reed, Peer Question: Mr. Armstrong, I should like to raise a statistical concern about the feature vector that survives your receiver chain. If a limiter erases most amplitude variation and an IF filter shapes the opening spectrum, a classification algorithm may still find highly repeatable coded patterns in the remaining sample sequence. But repeatability in a derived representation is not evidence of uniqueness in the physical source. Which held-out experiments should be required before a radio survey calls those features transmitter-class evidence? Would you insist on independent receivers with different analogue architectures and on source devices not seen during feature selection, even when the first system shows exceptionally low apparent error?

Copyright 2026, James M. Atkinson

A second concern is the analyst's temptation to repair disappointing results by changing thresholds, window boundaries or normalisation after inspecting the errors. What should a defensible protocol specify before the confirmation experiment begins, and how should the outcome be reported if performance deteriorates substantially when the measurement chain is changed?

Edwin Howard Armstrong, Response: Dr. Reed, a classification experiment has to be designed to test the scope of the proposed claim, not merely the ability of a programme to recognise the recordings it has already seen. If the claim is that early RF features identify an oscillator-control architecture, the test should use several authorised examples of that architecture and several plausible competing architectures. The receiver chains should differ enough to challenge a common artefact, and the physical transmitters used for final evaluation should not have been used to choose features or tune thresholds. One may conduct preliminary development on known hardware and still reserve a genuinely independent confirmation set. Without that separation, excellent apparent classification can simply be excellent memorisation of instrument and laboratory conditions.

The experimental protocol should name its observation variable, time origin, analogue bandwidth, frequency estimator, signal-level range, capture eligibility and classification rule before the confirmation data are examined. If the protocol uses an automatically selected early window, that algorithm and its parameters must be fixed in advance. Tests should include reference pulses that challenge the analogue response and signals near the detector's actual operating threshold. Every rejected physical cycle should remain in the accounting, with the reason recorded. An evaluator that silently discards

Copyright 2026, James M. Atkinson

difficult events cannot claim the same performance on the entire authorised survey population as it has on a chosen clean subset.

If performance deteriorates when a receiver is exchanged, that failure is not merely an inconvenience; it narrows the claim substantially. It may establish that the classifier organises recordings for the original receiver architecture, while failing to distinguish transmitter classes independently of that architecture. Report the failure alongside the original success. Show confusion matrices by receiver, device and environmental stratum and include uncertainty that respects physical-unit clustering. A high score on repeated digital samples is not equivalent to independent evidence from new transmitter units. Even where a feature remains stable, the result supports a class distinction only within the evaluated reference population and operating conditions.

No manipulation of protected communications content is necessary. The experiment may use known authorised training signals, dummy modulation or controlled RF gating, retaining only lawful waveform measurements and instrument logs. A defensible report would state which physical explanations have been challenged, which remain plausible and what future authorised measurement could distinguish them. A scientific programme gains credibility from acknowledging that its first attractive feature failed an independent hardware test. It loses credibility by redefining the test after seeing the result and then reporting the amended trial as though it had been planned from the outset.

Dr. James M. Atkinson, Moderator: I thank the contributors for the careful handover of the token. The panel finds that measured power-on behaviour can inform cautiously defined architectural classes when source,

Copyright 2026, James M. Atkinson

propagation and receiving-chain alternatives have been challenged independently. No transient recorded by one instrument is an intrinsic individual transmitter identity in the absence of a separately validated uniqueness and attribution experiment.

QUESTION 088

Copyright 2026, James M. Atkinson

How does antenna switching affect bearings of a moving or rapidly duty-cycled source?

Copyright 2026, James M. Atkinson

SCHOLARLY RECONSTRUCTION. The historical scientists named below did not meet for this discussion. All remarks are newly composed fictional scholarly reconstructions rather than historical quotations. The techniques are restricted to lawful, authorised defensive RF measurements.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, I should like to begin with the distinction between observing a radio wave at several receiving elements simultaneously and switching one receiving channel between antennas at different times. If a source moves or transmits in brief intermittent bursts, can a sequence of individually credible antenna measurements form a false composite bearing? Kindly take the token and account for the time, geometry and instrumental qualifications before we invite the other specialists to examine the measurement.

Copyright 2026, James M. Atkinson

Sir Martin Ryle, Principal Contributor: An antenna system provides information about direction only to the extent that its spatial observations can be related to a common state of the source and receiving environment. If receiving elements observe a sufficiently stationary wavefront at the same instant, comparisons of their signals may exploit phase and amplitude differences attributable to geometry. If, however, the equipment selects one antenna, records a brief interval, disconnects it and only later connects a second, the two measurements refer to different instants. An estimator that then treats them as simultaneous implicitly assumes that the source's direction, emission amplitude, frequency, propagation channel and polarisation have not changed in the meantime. For a moving or short-duty-cycle transmitter, that assumption must be defended experimentally rather than inherited from a conventional stationary-source bearing calculation.

Copyright 2026, James M. Atkinson

Let theta(t) denote the true direction of an authorised reference transmitter relative to an instrumented array, a_j(theta) the complex directional response of receiving element j, and s(t) the complex transmitted field under a simplified far-field model. Let w_j(t) be one when element j is eligible to receive and zero when the switch or receiver is blind, and let n_j(t) represent measurement noise. The recorded sequence may be represented schematically as y_j(t)=w_j(t)a_j(theta(t))s(t)+n_j(t). In practice the responses include frequency dependence, polarisation, multipath and receiver memory, which the simple expression omits. Even this elementary model makes the central error visible: if the switch records element one at t_1 and element two at t_2, the ratio y_2(t_2)/y_1(t_1) does not generally estimate an antenna-pattern ratio at a single bearing. It also contains changes in the transmitted field and in the source's direction between t_1 and t_2.

Copyright 2026, James M. Atkinson

Suppose a controlled laboratory source crosses a known angular trajectory at 20 degrees per second relative to the receiving array. A sequential scan requires 150 milliseconds to collect its nominal set of antenna observations. Over that scan the true direction changes by 3 degrees. These illustrative numbers do not claim a measured system accuracy; they show that the assumption of a common source direction already contains a potentially material error before considering receiver noise. If the source emits only during one part of the 150-millisecond interval, the missing channels may be filled by the next burst at a still later direction. An algorithm can produce an apparently precise bearing from these assembled measurements, while the purported physical angle never existed at a single instant. Increasing the number of samples at each antenna does not repair the fundamental temporal mismatch.

Copyright 2026, James M. Atkinson

The switching operation itself introduces additional blind intervals and transients. A receive front end may require time for RF switches to settle, the first intermediate-frequency filter to recover, or automatic gain control to respond after the antenna path changes. Those intervals must be measured with authorised reference pulses, not inferred solely from a switching-control bit. A nominal dwell of five milliseconds may contain less than five milliseconds of eligible observation if the first part is consumed by settling. A duty-cycled source can then emit while the receiver is physically unable to acquire it. An empty recording from that antenna is not evidence that the source's radiation pattern had a null in that direction; it may be evidence only that the two time schedules did not overlap.

Copyright 2026, James M. Atkinson

A simultaneous calibrated array supplies an important reference, but it too demands careful calibration. The receiving channels must have known relative phase, gain, timing and frequency responses, and their antennas must have documented spatial and polarisation properties. Common reference clocks can help establish simultaneous timing; they can also create shared errors if the reference itself is faulty. The distinction is not between an infallible simultaneous receiver and a defective switched receiver, but between two measurement architectures whose assumptions and failure modes can be tested. A controlled comparison can determine how far sequential scanning departs from a simultaneously measured benchmark under different source speeds, burst duty cycles and receiver settling times.

Copyright 2026, James M. Atkinson

A useful experiment moves an authorised test transmitter along a measured track while imposing bursts at controlled, concealed time intervals. The source position, orientation, power and burst eligibility are recorded independently of the receiving equipment. Repeat the track with different switch schedules and start phases, including schedules randomly displaced with respect to the source bursts. Some trials will contain a complete set of antenna observations, others only one or two and others none. Every trial should remain in the accounting. Estimating bearing error solely from the successfully completed scans would select for cases in which the source happened to be cooperative; the result could exaggerate the instrument's performance in the very intermittent regime that concerns the investigator.

Copyright 2026, James M. Atkinson

The analysis should distinguish measured error conditional on a complete antenna sequence, probability that a sequence is complete, and total probability of producing a defensible bearing per authorised observation interval. These are different quantities. A switched system may yield excellent directional estimates in the subset of slow, continuously radiating sources, yet have poor acquisition reliability when bursts are short and moving. Another algorithm may return a bearing on nearly every trial by combining observations from different events, but its apparent completeness is gained at the cost of a hidden stationarity assumption. The proper report should show the distribution of angular error, the distribution of observation latency and the rate of unqualified bearings, each as a function of motion, duty cycle and receiver configuration.

Copyright 2026, James M. Atkinson

I would not allow a final plot that connects successive bearing estimates with an unbroken curve unless the estimates have timestamps, uncertainties and declared observation windows. A line between a 20-degree observation and a later 30-degree observation may suggest continuous tracking even if there was no eligible reception between them. The examiner should display missing intervals, the actual antenna-selection sequence and any source events used more than once in an estimate. If the environment contains reflections, a bearing drawn from selected amplitude maxima may respond to a changing reflected path instead of to a changing source location. Independent observations through different geometries can help challenge such alternatives, but they should not be described as independent merely because a pair of antennas looks different.

Copyright 2026, James M. Atkinson

The conclusion must therefore be conditional. A sequential antenna switch can support a bearing for a moving, duty-cycled source when timing, source stationarity during the applicable observation window, receiver settling and spatial response have been sufficiently bounded. Where those conditions fail, the system may provide only a set of partially observed directions or a hypothesis requiring another measurement architecture. It is entirely legitimate to decline a precise bearing rather than to manufacture simultaneity from measurements taken at different times. The strongest scientific result may be the explicit determination of the speeds, dwell periods and burst occupancies under which the selected instrument ceases to be an adequate observer.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Peer Question: Sir Martin, the proposed data set contains both ordinary directional measurement error and missing observations that depend upon whether a transmitter happened to be radiating while the selected antenna was eligible. Suppose the instrument succeeds in collecting a full antenna sequence only when bursts last longer than the switching cycle, but its developers report the angular accuracy calculated from those successful sequences without accounting for the short-burst trials. Would you distinguish the probability of obtaining a bearing from the accuracy of the bearing conditional on its existence? How should an analyst compare a system that refuses to return a bearing in uncertain circumstances with a system that always returns a number by combining samples from different emissions? A single average angular error may conceal the decisive difference between reliability and forced completeness.

Copyright 2026, James M. Atkinson

I would also ask whether randomising the switch order is enough to eliminate bias. If the source's motion and duty cycle are correlated with the observation schedule, the missing-data mechanism is not automatically independent. Which independently logged variables and external controls would be required before the examiner could assert a defensible uncertainty distribution for those unobserved bursts?

Copyright 2026, James M. Atkinson

Sir Martin Ryle, Response: Dr. Shannon, the two performance dimensions must be reported separately. Let E denote the event that the receiver had adequate, temporally compatible observations to construct a bearing under a predeclared validity rule, and let A be the angular error of a returned bearing. A report of the conditional distribution P(A|E) tells us how accurate the selected successful estimates were; it does not tell us how often they were available. The acquisition probability P(E) is a different statistic. Both should be estimated from all authorised source trials, with the denominator and observation-eligibility conditions stated. A system whose reported bearings are excellent but rare may be entirely unsuitable for monitoring brief intermittent emissions; a system that always returns a point estimate may instead have very poor physical validity when its input sequence combines incompatible source states.

Copyright 2026, James M. Atkinson

The comparison should therefore include at least three declared outcomes for each trial: a valid estimate supported by adequate observations, an explicit abstention because required data are missing or inconsistent, and a rejected or demonstrably invalid estimate. The last category must not be hidden by silently removing its cases. One may plot angular-error distributions for valid estimates and acquisition frequencies for the entire trial population. Where a system fabricates completeness by borrowing observations from separate bursts, evaluate those estimates against the independently recorded source track at the relevant timestamps. A bearing with no single defensible reference instant is not made valid by choosing whichever true angle minimises its apparent error after the analysis.

Copyright 2026, James M. Atkinson

Randomising the antenna switch sequence can reduce systematic alignment with a periodic source, but it cannot guarantee unbiased sampling. The source's burst duration, start time, power, direction and polarisation may all affect detectability; the receiver's settled gain and detection threshold can interact with those factors. The independent ground-truth logger should therefore record source emission timing and physical trajectory without relying on the scanning receiver. A second continuously observing calibrated reference channel can identify bursts missed by the switch system, and the trial record must include intervals when each antenna was ineligible. These controls allow the analyst to estimate how many unobserved events were lost to the sampling schedule rather than to the absence of radiation.

Copyright 2026, James M. Atkinson

If several receiver configurations are compared, preserve the same authoritative physical-trial definitions. Do not change the definition of a successful source burst to favour one architecture. Report uncertainty across independent trajectories, different source units or trial sessions where available, rather than treating thousands of overlapping time samples from one track as independent replicates. The cautious scientific conclusion may be that sequential switching yields satisfactory conditional angular accuracy within a restricted motion and duty-cycle range but substantially lower availability outside it. That is a valuable finding. It is better than a single impressive bearing-accuracy statistic that silently excludes the very events the survey was intended to observe.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Bracewell, Sir Martin has identified the central danger of making observations at different instants and treating them as a single spatial measurement. I now ask you to examine the corresponding problem in array mathematics. In particular, please distinguish a physical array manifold, the sampling operator used by a switched receiver, and the hidden stationarity assumptions under which sequential measurements can be combined into a bearing. The token is yours.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Principal Contributor: A directional receiving instrument does not measure an angle directly. It collects electrical observations that are interpreted through a model of the antenna geometry and the incident field. In a simultaneous, narrowband array the complex samples at several elements may be represented by a spatial steering vector whose entries describe phase and amplitude at a single reference instant. Such a representation is useful precisely because it separates an assumed source direction from the characteristics of the measurement apparatus. The mathematical simplicity, however, depends upon coherent observations: the entries of the vector must correspond to substantially the same wavefront or to a demonstrably stationary process over the interval involved. When one receiving chain is connected to successive antennas, the recorded sequence is no longer the ordinary spatial vector unless additional temporal conditions are imposed.

Copyright 2026, James M. Atkinson

Let a(theta) be the vector of calibrated complex receiving responses for a plane wave arriving from direction theta, and let x(t) be the complex amplitude of that wave. Under a deliberately simple one-source, narrowband model, the simultaneous array observation is y(t)=a(theta(t))x(t)+n(t), where n(t) contains receiver noise and unmodelled contributions. A switching receiver instead delivers separate observations z_j=a_j(theta(t_j))x(t_j)+n_j(t_j), with t_j denoting the acquisition instant for antenna j. Even when every antenna response a_j has been measured perfectly, it is not generally correct to place these z_j into one vector and evaluate a conventional simultaneous-array direction estimator. The source amplitude, position and propagation transfer function may have changed between t_1 and t_j. That change can masquerade as spatial phase or amplitude structure.

Copyright 2026, James M. Atkinson

Consider two antennas separated by a baseline of length d and a source whose arrival direction evolves at angular rate omega. For a conventional far-field phase comparison, the instantaneous path-induced phase difference is approximately (2 pi d/lambda) sin(theta), with lambda representing wavelength and theta measured relative to the chosen baseline normal. But if the first element is sampled at t_1 and the second at t_2, their measured phase difference also includes the source's own phase evolution between those instants, oscillator drift, carrier-frequency offset and the differing propagation channels. The resulting number is not simply the path phase difference at some average direction. A switched receiver that supplies an apparently stable phase-bearing under these circumstances may merely be reporting the timing relationship between its switching oscillator and the signal source.

Copyright 2026, James M. Atkinson

The problem is not confined to phase-based methods. An amplitude-comparison direction finder selects the direction most consistent with observations from antennas having different directional patterns. If an intermittent source radiates at one power during the first antenna dwell and another during the second, the inferred amplitude ratio combines true directional response with unknown source variation. A receiver that records a strong signal on a forward-facing antenna, then sees silence on a side-facing antenna, may infer an angular null even when the second antenna was simply switched in after the emission ended. The system must identify the missing second observation as an absence of eligible data, not treat it as a measured zero field.

Copyright 2026, James M. Atkinson

It is useful to define a temporal-compatibility condition before applying a direction estimator. Suppose the total switching aperture is Delta, the interval between the first and last antenna observations in the group. Let omega_max be an independently justified upper bound on absolute angular speed of the source relative to the array, and let epsilon_theta be an angular-change budget that the analysis can tolerate. The necessary kinematic condition omega_max Delta <= epsilon_theta constrains the duration of the sequence. It is not sufficient by itself. One must also bound changes in emitted power, oscillator phase, polarisation and multipath over Delta, together with the front end's settling interval. For example, if a reference emitter can change at 12 degrees per second and the allowable unmodelled motion is 0.6 degrees, Delta must not exceed 0.05 second under the constant-bound assumption. An attractive half-second scan does not become compatible merely by applying a more elaborate estimator to the same samples.

Copyright 2026, James M. Atkinson

The choice of a reference instant should be explicit. A sequential bearing may be assigned to a declared acquisition centre only if the statistical model can translate each element's observation to that time using independently supported motion and signal models. Extrapolation introduces uncertainty that depends on the age of each observation. A direction-finding programme should retain the original t_j values, measured dwell duration, RF-switch state and signal-detection eligibility, rather than replace them with a convenient common timestamp. When reporting results to another investigator, it is important to provide the source's possible angular displacement during the aperture along with the ordinary estimator variance.

Copyright 2026, James M. Atkinson

A simultaneous receiving arrangement can act as a controlled comparator, but its own array manifold must be calibrated for frequency, mutual coupling, cable phase, gain and polarisation. A comparison should not be called independent if both receivers share the same untested timebase or use identical correction constants derived from the switched system. Ideally, the experimental reference includes a separately measured source track, a continuous monitor of actual emission times, and a coherent array with its own integrity checks. The switched system should then be exercised over a range of source speeds and burst patterns, with the switch start phase varied independently of source emission timing. Trials in which the switched system fails to form a bearing remain in the denominator for availability statistics.

Copyright 2026, James M. Atkinson

A difficult but consequential point is that the selection of successful scans may itself distort reported accuracy. Complete antenna sequences disproportionately occur when bursts are long, source motion is slow, or received power is favourable. A histogram of error calculated only from these convenient cases describes conditional performance. It must not be offered as an unconditional accuracy statement for fast, intermittent sources. An estimator can legitimately return no bearing where observations do not satisfy the declared compatibility rule. Indeed, an abstention with correct timing and traceable cause may be stronger evidence of instrument integrity than a persuasive but physically unsupported compass angle.

Copyright 2026, James M. Atkinson

A robust report must separate three things: the physically observed sequence, the mathematical model used to join observations across time, and the classification of the resulting directional estimate as valid, provisional or unavailable. There is no single algorithm that can reconstruct information the receiver never acquired without invoking assumptions. In controlled research, such assumptions can be tested against an independently instrumented transmitter. In a real defensive survey, the limitations should remain visible to the reader. The texture of a smooth track drawn across a screen is not a substitute for the discontinuous, timestamped records from which the track was computed.

Copyright 2026, James M. Atkinson

John Daniel Kraus, Peer Question: Dr. Bracewell, your steering-vector formulation assumes a calibrated receiving response as a function of source direction. A practical array, particularly one assembled from antennas having markedly different polarisation patterns, can have directional changes that resemble variations of the transmitted field. Suppose a moving reference source turns its antenna as it traverses a path, while the direction finder sequentially switches between a horizontally sensitive element and an element with a different polarisation response. A difference in recorded power might arise from motion, polarisation, transmitter activity, mutual coupling or a temporal gap. Which of these should be incorporated into the predeclared validity criteria, and how would you design a reference experiment that could distinguish them rather than selecting a single favourable explanation after the event? I should also ask how the laboratory would prevent a common calibration error in the simultaneous reference array from making the sequential method appear more accurate than it actually is. A defensible result must specify whether the proposed angle describes arrival direction, dominant polarisation response, or an unstable combination of both quantities.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Response: Dr. Kraus, the calibration cannot properly be a scalar gain attached to an antenna name. The receiving response is a vector function of direction, frequency and polarisation, further altered by nearby conductors, antenna coupling and receiving cable characteristics. If the reference transmitter rotates, its radiated field can change in polarisation as well as amplitude. A switched comparison of unlike receiving elements therefore becomes ambiguous unless the experiment independently records the transmitter orientation and controls the radiated polarisation. We should first characterise each receiving path with stable authorised sources at known positions and polarisation states, documenting both the principal response and important cross-polar sensitivity. That permits the investigation to distinguish a measured amplitude ratio expected from the geometry from one that could be caused by a changed illumination state.

Copyright 2026, James M. Atkinson

I would employ a factorial controlled experiment rather than a sequence of convenient examples. Use both stationary and moving emitters; vary source orientation and emitted burst schedule independently; and test multiple switch sequences at each setting. Keep raw per-antenna observations and actual switch-state timing. To expose mutual coupling, compare elements in the installed array with suitable isolated or reconfigured reference measurements, and record whether a nearby antenna's termination changes the response of its neighbour. For a receiver whose patterns are intentionally dissimilar, an amplitude ratio must be calculated only for bursts with eligible observations from each required path, and only within the independently supported interval of source stability. A missing observation should be labelled missing, not inserted as a zero-power measurement that manufactures a pattern null.

Copyright 2026, James M. Atkinson

The simultaneous array reference requires its own blind checks. Its phase and gain calibration should be verified against independently positioned sources whose positions were not used to tune the directional estimator. At least one alternate calibration sequence and an independently timed record of the moving transmitter should be maintained, so a shared incorrect correction cannot drive both systems towards the same erroneous answer. If the reference itself lacks enough confidence, the proper outcome is a widened uncertainty interval or an unresolved comparison, not the declaration that whichever system yields the narrower angular histogram must be correct.

Copyright 2026, James M. Atkinson

For every trial we should report the eligibility of each antenna observation, the measured polarisation controls, the source's trajectory and the delay between observations. Directional uncertainty should be conditional on those facts. In some cases the measurements may constrain only a region of possible arrival directions because an unknown source orientation introduces a family of equally plausible antenna-pattern ratios. A scientifically responsible instrument ought to be capable of reporting that region or abstaining altogether. This is especially important in a defensive survey, where the apparent sharpness of a plotted bearing can encourage greater confidence than the instrument's actual information content warrants.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Cross-Peer Question to Sir Martin Ryle: Sir Martin, I wish to return the token to you on an important experimental issue. The reference array and the switched receiver may both be driven by the same clock distribution, while the moving source's independent logger uses another timebase. It would be tempting to attribute any discrepancies to switching alone, yet clock skew, delay asymmetry and an unrecognised common-mode calibration error could affect both systems. How would you establish a genuinely independent time reference, and how would you specify the angular-motion uncertainty associated with each element's acquisition interval? More particularly, if an analyst chooses a single fitted reference time after observing the results, does that constitute a valid physical bearing or an instance of fitting away the very temporal mismatch the experiment was designed to expose? I would be grateful for a protocol that can still produce a clear result when the transmitter emits too briefly to illuminate every antenna in a cycle. Your distinction between refusing a measurement and returning a qualified one is crucial here.

Copyright 2026, James M. Atkinson

Sir Martin Ryle, Cross-Peer Answer to Ronald Newbold Bracewell: Dr. Bracewell, the experiment must separate synchronisation accuracy from the observation itself. A common receiver clock may provide excellent relative timing while simultaneously hiding a shared frequency or phase error. An independent reference should include a transmitter event log produced through a separately checked timing chain, with measured clock offsets and uncertainty before and after the trial. The experimenter must preserve enough raw timing information to reconstruct the onset and end of each authorised burst without assigning a convenient common time after the bearings are calculated. For each antenna element the record should carry the acquisition start and end times, the switch-control transition, the empirically measured settling period and the actual interval during which received samples were eligible for estimation.

Copyright 2026, James M. Atkinson

If the motion rate is independently bounded by omega_max and an observation is Delta_t seconds from the chosen reference instant, the simplest possible contribution to angular uncertainty is bounded by omega_max times Delta_t. The bound is conservative and does not address changes in propagation or transmitter radiation. If source acceleration is material, a second-order bound or a track model with explicitly justified uncertainty must replace it. The reference instant and its selection rule should be fixed before looking at the directional estimates. Choosing it afterwards to make a weak array comparison appear coherent is not an independent demonstration of simultaneity; it is a model-fitting step that needs its own declared assumptions and validation data.

Copyright 2026, James M. Atkinson

An emission too brief to illuminate all required switched elements cannot by itself provide the full spatial comparison demanded by that architecture. It can support an event timestamp, a detection on one element, and perhaps a restricted directional likelihood if independent information constrains the missing elements. But the analysis must not relabel the unobserved channels as though they had been measured. The simultaneous reference array can test whether the source truly existed at the corresponding instant and which direction the reference observations support. Across many trials, the comparison should give both the fraction of events for which the switched system had the requisite observations and the angular errors among events for which a bearing was legitimately returned.

Copyright 2026, James M. Atkinson

Finally, the analyst should conduct deliberate negative controls. Shift the declared switch-to-source alignment by amounts greater than the measured timing uncertainty, inject known gaps in the acquisition record, and repeat the calculation using an intentionally incorrect clock offset. A defensible estimator should flag these conditions or show a predictable degradation of performance rather than preserve the same implausibly precise direction. Such failures of measurement validity are results, not embarrassments to be erased from the report. They give the reader evidence that the system's uncertainty statements respond to actual experimental contradictions instead of remaining a decorative number beside each bearing.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Kraus, the discussion has so far concentrated upon time alignment and array processing. I now invite your examination of the antennas themselves, including pattern calibration, polarisation and the way a moving emitter can turn an apparently well-timed amplitude comparison into a physically misleading bearing. Please take the token.

Copyright 2026, James M. Atkinson

John Daniel Kraus, Principal Contributor: A receiving antenna is not a passive arrow pointing towards a transmitter. Its terminal response depends on the electric field incident at that location, the antenna's geometry and orientation, frequency, polarisation and the electromagnetic environment. A direction finder that uses two or more antenna patterns can infer an arrival angle from differences in the received signals, but only when the comparison corresponds to a sufficiently common incident field. Antenna switching breaks that commonality in time. The physical quantity that enters an amplitude comparison is not a direction alone; it is the product of the changing field and the changing directional receiving response, with additional contributions from reflections and receiver gain. An examiner who omits these factors can convert an innocent change in illumination into a fictitious movement of the source.

Copyright 2026, James M. Atkinson

Let $g_j(\theta,\psi,f)$ represent the complex response of antenna j at arrival direction theta, polarisation state psi and frequency f. For a source field with complex amplitude E(t), a simplified settled observation may be written $y_j(t_j)=g_j(\theta(t_j),\psi(t_j),f(t_j))E(t_j)+n_j(t_j)$. The expression is not a complete Maxwell-equation solution. It deliberately leaves out mutual coupling, scattering and gain-control memory. Its purpose is to prevent the false inference that a ratio of two readings taken at different times isolates only the ratio of antenna patterns. Even if the source direction were fixed, a change in the source's polarisation or field strength could alter the ratio. When direction, polarisation and emission duty cycle all vary, the ambiguity becomes more serious.

Copyright 2026, James M. Atkinson

A practical measurement should separate the radiation pattern from the switching schedule. First characterise each receiving path with a reference signal at a series of known directions, frequencies and polarisation orientations, retaining both principal and cross-polar responses. Next install the antennas in their working geometry and repeat the relevant measurements, because the final array may differ materially from the isolated antenna. Nearby conductors, common housings, ground planes and transmission lines can change the current distribution and therefore the pattern. It would be a mistake to copy a manufacturer's nominal free-space diagram into an operational programme and then interpret every deviation as the movement of an unknown emitter.

Copyright 2026, James M. Atkinson

A moving reference transmitter introduces an additional distinction between orientation and location. A vehicle travelling around the receiver may change its position while the transmitting antenna maintains a particular orientation relative to the vehicle. In another trial the transmitter may move on the same path but rotate its radiating element. The receiver may observe different polarisation and signal-strength histories even though the source's geographical track is identical. An amplitude-only sequential direction finder that seems accurate during the first trial can fail badly in the second. The test matrix must vary source track, antenna orientation and burst timing independently if one wishes to establish which of those dimensions the instrument can actually observe.

Copyright 2026, James M. Atkinson

The role of frequency should not be neglected. Different antennas and feed lines may have dissimilar frequency responses, and a broad or frequency-agile signal may illuminate them differently. If the front-end switch selects an antenna and then the receiver retunes, the observed amplitude is conditioned on both operations. A nominal gain correction measured at one frequency does not establish validity over the full band. Moreover, receiver filters, preamplifiers and automatic gain control can retain state from the previous antenna. The resulting amplitude change may be an electrical memory effect rather than an electromagnetic difference at the antenna terminals. Direct recording of settled reference samples after measured switching intervals is essential for separating these effects.

Copyright 2026, James M. Atkinson

One controlled test would use a continuous reference array and a separate switched receiver while an authorised source moves through a measured trajectory. Every radiated burst would have an independent event identifier and timestamp, so the evaluator could determine whether a switched antenna sequence drew its samples from the same emission or from successive emissions. A simultaneous reference receiver should record the actual field's amplitude and polarisation characteristics to the extent practicable. The switched system should retain its dwell schedule and distinguish a physically sampled value from an estimated value propagated across a gap. Randomise the source's orientation and switch start phase according to a recorded plan, keeping the analysis blind to the source's true bearing until the estimation rules have been frozen.

Copyright 2026, James M. Atkinson

It is important to make uncertainty dependent on observation geometry. A pair of antenna patterns may have very little difference over some angular regions and therefore provide almost no directional discrimination there. At other bearings a small amplitude uncertainty may translate to a much smaller angular interval. Thus an apparent direction error cannot be evaluated by using a single constant conversion from decibels to degrees. If the pattern-ratio function is r(theta), then for a local perturbation in measured ratio delta_r the linearised angular error is approximately delta_theta=delta_r/r'(theta), provided that r'(theta) is nonzero and the linearisation is valid. Where the derivative is close to zero, uncertainty can become large or the inversion nonunique. Source variability across switched observations increases delta_r beyond ordinary thermal noise.

Copyright 2026, James M. Atkinson

Suppose an example antenna-pattern ratio changes at 0.2 decibels per degree near one test angle. A one-decibel ratio discrepancy could then correspond, under a purely local linear approximation, to five degrees of angular error. Near a region where the pattern-ratio slope is only 0.02 decibels per degree, the same discrepancy corresponds to fifty degrees, and the linear approximation itself may no longer be credible. Neither estimate is a general empirical performance claim. Both demonstrate why a bearing uncertainty must be tied to the locally measured directional response and the relevant observation conditions, rather than printed as a uniform number for every point on a track.

Copyright 2026, James M. Atkinson

A final report should therefore include the patterns actually used, their calibration uncertainty, the transmitter orientation in controlled tests, the observation window for each element and the confidence rule by which a bearing was accepted or rejected. Where a fast intermittent source affords only one valid antenna observation, it may be sound to report a signal detection and the receiving element's broad directional sensitivity, without calculating a single bearing. Where several compatible observations exist, the reported bearing should carry a traceable likelihood or uncertainty interval that accounts for frequency, polarisation and temporal compatibility. It is an engineering virtue to preserve what was measured and to distinguish it from what the inversion algorithm supplied. The graphical neatness of the final bearing line should never outrun the quality of the electromagnetic evidence.

Copyright 2026, James M. Atkinson

Antony Hewish, Peer Question: Professor Kraus, I would like to examine the distinction between antenna-pattern discrimination and the receiver's detection threshold. If a brief burst is recorded on the antenna with favourable polarisation but not detected on the other antenna after switching, the absence of a detection may reflect an imperfect receiver, not a true null in the pattern. How would you define the detection eligibility of each dwell, and how would you separate a below-threshold signal from an interval during which the source had already ceased transmitting? Would you require the evaluator to retain raw recordings even when the signal detector does not issue an event marker? In transient radio astronomy we have learnt the importance of distinguishing genuine short events from instrumental coincidences and missed acquisition. It seems possible that a bearing method trained only on successfully detected bursts would inherit a substantial selection bias. Please explain which negative controls would reveal that defect and whether the report should contain the number of pulses that were known to exist but that the switched receiver never had a fair opportunity to acquire.

Copyright 2026, James M. Atkinson

John Daniel Kraus, Response: Dr. Hewish, the absence of an event marker is not a measurement of zero incoming field. It is a decision made by a detector under a particular gain, noise floor, threshold, state of settling and length of observation. I would keep separate records for periods when the source was known to radiate but the selected antenna was not connected, periods when that antenna was connected but the receiver had not settled, and periods when the path was fully eligible but the detector did not cross threshold. The first two are observation-opportunity failures; the third is a valid nondetection under declared instrument sensitivity. All three are materially different from a measured directional null, which itself would require calibration and uncertainty bounds.

Copyright 2026, James M. Atkinson

The trial record should include pre-trigger or continuous raw samples wherever legally and technically appropriate, with preserved timing and receiver configuration. If recording bandwidth is constrained, the acquisition policy and resulting blind intervals must be explicitly documented before the data are examined. The independently timed reference emitter can establish the actual burst population. The fraction of known bursts intercepted by each receiving state then provides an empirical encounter rate, while the amplitude distributions for eligible dwells help establish the conditional detection probability. These statistics should not be merged into a single claim of direction-finding accuracy.

Copyright 2026, James M. Atkinson

A revealing negative control is to change the phase of the switch schedule relative to the reference burst timing without changing source direction. If the reported bearings move when only the timing schedule changes, the estimator is sensitive to selection effects and cannot claim a purely angular response. Another control is to insert a calibrated test field at fixed direction and vary its polarisation, so that the method must distinguish known cross-polar loss from movement. I would also deliberately suppress detector event markers on a subset of otherwise intact recordings and verify that the processing chain distinguishes a missing marker from a missing physical signal, rather than treating the two as interchangeable evidence.

Copyright 2026, James M. Atkinson

The report should state the full number of independently logged source events, the number that overlapped each antenna's fully settled observation interval, the number detected above threshold, and the subset that supplied sufficient compatible data for a bearing. These denominators provide transparency about selection. When a source exists but never illuminates the switched receiver's qualifying windows, the correct conclusion is that the receiving architecture failed to observe that event. It is not appropriate to draw a directional conclusion from the absence. Similarly, when only one element detects a burst, a broad sector constrained by that antenna pattern may be reasonable, whereas an exact bearing would require additional information and assumptions. Such restraint is a necessary condition for credible forensic reporting.

Copyright 2026, James M. Atkinson

John Daniel Kraus, Cross-Peer Question to Antony Hewish: Dr. Hewish, permit me a final examination of the event-selection mechanism before we turn to operational doctrine. In an antenna-switching direction finder, a short burst may appear on a favourable antenna and escape the second channel because its dwell occurred later, after the burst had ended. The software may then select a subsequent burst for the second channel, perhaps one whose signal envelope and centre frequency resemble the first closely enough to appear compatible. Would you distinguish a physically measured common emission from an event association inferred solely through spectral similarity? How could an authorised test transmitter with a documented but concealed burst sequence expose spurious associations, and what safeguards should prevent a strong signal from causing a less sensitive receiving path to be treated as though it had observed the same event? I am particularly interested in whether a large number of correctly detected individual pulses might nevertheless produce a misleadingly precise bearing when the pulse-pairing process is systematically wrong. Please address the limits of the directional claim rather than the mere correctness of each detector event.

Copyright 2026, James M. Atkinson

Antony Hewish, Cross-Peer Answer to John Daniel Kraus: Professor Kraus, the question identifies a distinction that should be built into the test design before any measurement is made. The physical burst is an emission interval that exists independently of the receiving programme. An event association is a hypothesis that two or more recorded observations correspond to that same interval. Spectral similarity may support a hypothesis, but it cannot establish identity when a source emits repeated or nearly identical bursts. A switched receiver that observes one pulse on an antenna and another pulse on a different antenna has not acquired simultaneous spatial information merely because their bandwidths and centre frequencies agree. Their relationship depends on measured timing compatibility and a source-stability model that must survive independent challenge.

Copyright 2026, James M. Atkinson

For controlled evaluation, the authorised transmitter should maintain a ground-truth schedule whose burst identifiers are hidden from the receiving algorithm but preserved for later scoring. Vary burst spacing, duration and envelope shape, including runs in which repeated emissions are intentionally indistinguishable to a simple spectral detector. Compare the receiver's proposed event groupings with the transmitter's actual event identifiers. The result can be presented as an association confusion matrix showing correctly paired observations, falsely joined bursts and genuine common bursts that were separated by the algorithm. This test measures the pairing stage independently of directional estimation, so an attractive bearing cannot mask incorrect reconstruction of the input observations.

Copyright 2026, James M. Atkinson

I would also introduce deliberate changes of source position between successive bursts, while holding nominal waveform characteristics as constant as possible. If the algorithm joins them into one virtual array snapshot, its resulting bearing may correspond to neither actual position. The error may appear especially deceptive where source movement and switch order interact to produce a plausible phase or amplitude pattern. A second simultaneous reference receiver can observe whether those physical bursts occurred at distinct times, but it should have an independently verified clock and its own detection-eligibility record. A common processing timestamp does not establish that two RF observations referred to the same source event.

Copyright 2026, James M. Atkinson

The final estimator must propagate the uncertainty of event association. Where an association is not independently defensible, the report can retain the separate detections and state that no compatible spatial sample set was acquired. It should never feed an arbitrarily paired vector into a direction algorithm and then report the algorithm's narrow conditional standard error as though the physical association were certain. If several plausible pairings remain, one may evaluate the alternative bearing hypotheses as an exploratory analysis, explicitly recording that they are model dependent. The evidential statement must be weaker than a verified same-burst bearing and should disclose the source-event assumptions that would need further testing. The strength of the investigation lies in distinguishing a true repeated observation from a convenient resemblance between two radio transients.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Hewish, the discussion now requires an explicit account of intermittent emissions as events rather than as an ideal continuous field. Please consider how a direction finder knows whether a burst existed, whether the receiver could acquire it and whether observations from different bursts may properly be joined. I pass the token to you.

Copyright 2026, James M. Atkinson

Antony Hewish, Principal Contributor: The detection of a transient radio signal is an event in an observing system, not an assertion that the signal existed only for the duration of the recorder's event marker. A receiver has finite bandwidth, noise, integration time, sensitivity and scheduling constraints. A burst that arrives while an antenna is disconnected or the filter is settling may escape detection entirely. A different burst may be registered with a timestamp delayed by detector integration or software buffering. The distinction between the incident physical signal and its representation in the instrument is particularly consequential when a sequence of transients is used to infer direction. A switched array can produce readings that appear to form a spatial comparison although the observations actually belong to different bursts from a moving emitter.

Copyright 2026, James M. Atkinson

In an experiment with a known source, let B_k denote the time interval occupied by emitted burst k. Let W_j denote the union of settled observation intervals for antenna j, and let D_{jk} indicate whether the receiver issues a valid detection for burst k on that path. The intersection B_k with W_j is a necessary but not sufficient condition for a detection: received power, noise, polarisation and detector threshold also matter. For a direction-finding method requiring observations from antennas one through m during the same sufficiently stationary source interval, eligibility cannot be established from a single positive D_{jk}. It requires a documented set of compatible observations and a rule for rejecting events that are too sparse. A missing positive marker should not be silently converted into an amplitude zero.

Copyright 2026, James M. Atkinson

The comparison between a simultaneous array and a switched arrangement must preserve burst identity. A recurring source may send nearly identical emissions and tempt the analyst to assemble one virtual array snapshot from several cycles. Such assembly is permissible only under a model whose stability assumptions have been tested. If the source moves at a known angular velocity, repeated bursts at different times illuminate the array from different directions. If the source changes polarisation or output power, successive bursts may also have different amplitudes unrelated to the receiving antenna. Without independent tracking, a direction estimate produced by mixing these bursts is an inference about an assumed trajectory, not a direct measurement of one instantaneous bearing.

Copyright 2026, James M. Atkinson

Consider a source radiating bursts of ten milliseconds duration every one hundred milliseconds while an antenna switch requires thirty milliseconds for a complete cycle. Some switch phases may place all of a burst inside the dwell of one antenna, with no compatible observation on the others. Other phases may divide the burst across two eligible dwells, though neither has enough integrated signal for robust detection. If the operator analyses only the cases where the detector has found two useful readings, the apparent error distribution can favour fortunate alignments. Randomising the source burst phase relative to switching exposes the dependence of acquisition probability on timing, but randomisation does not itself recover missing measurements. The trial register should include the source bursts that the receiver did not detect.

Copyright 2026, James M. Atkinson

The observation process should be characterised before source motion is introduced. Feed the receiver with authorised calibrated reference pulses of known duration and amplitude, at many offsets relative to the switching cycle. Measure the probability that each pulse produces a valid sample for each antenna, the distribution of timestamp offsets, and the time to recover normal operation after a switch transition. Repeat at several signal levels around the detection threshold, because an apparently small change in noise or gain can alter which part of a burst is labelled present. Only after these functions are measured should one combine them with a moving-source experiment. Otherwise physical motion and receiver-selection behaviour can become indistinguishable in the record.

Copyright 2026, James M. Atkinson

The timebase used for eligibility deserves independent verification. A detector timestamp may correspond to the moment the threshold was crossed, the centre of an integration window, the end of a digital buffer or the time a software worker processed the data. These are not necessarily interchangeable. A high-level log saying that an event occurred at a particular time does not establish when individual RF samples were acquired. Whenever possible retain sample counters, raw complex recordings and separately validated acquisition clocks. A negative control can inject fixed pulses while varying software load; if event timestamps shift but sample counters do not, the processing delay should not be misinterpreted as source motion.

Copyright 2026, James M. Atkinson

A careful experiment compares instruments according to two separate outcomes. The first is availability: for what fraction of independently known emitted bursts, or declared observation intervals, does each architecture have the observations required to make a valid bearing? The second is accuracy conditional on availability: how large is the angular error for those cases that satisfy the declared validity rule? The two should be reported together. A simultaneous system might be more available but suffer a calibration error, whereas a switched system might return fewer but more accurate estimates in favourable conditions. Neither can be declared superior from a single average angle calculated after the least convenient cases have been omitted.

Copyright 2026, James M. Atkinson

For the unknown field source, we ordinarily lack the luxury of independent burst ground truth. That limitation should be made prominent rather than hidden by a neat track. A continuous auxiliary channel may reveal emissions missed by the switched path, but it is not infallible, and a shared antenna or gain path can introduce dependence between the two monitors. If the auxiliary channel has its own sensitivity and completeness record, its observations can constrain what the switched system missed. If not, the examiner can report only the detections actually made and the monitoring windows during which acquisition was physically possible. A failure to see a burst does not establish that no burst occurred.

Copyright 2026, James M. Atkinson

The ethical and forensic significance of these distinctions is plain. A series of compass readings may look compelling when placed on a map, but the evidential value depends on the underlying acquisition record. Reports should disclose the number of independent bursts identified, the number used for each direction estimate, the timestamps and identities of those bursts, and any assumptions made about stationarity or repeated transmission. When the data support only a broad directional region, or no direction at all, the report should say so. Intermittent radio science gains credibility from explicit non-observation and uncertainty, not from filling every blank interval with an attractive inferred bearing.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Peer Question: Dr. Hewish, a direction finder may have an internal event detector which assigns a timestamp to the centre of a time-frequency tile rather than to the physical onset of the source burst. If a burst straddles two such tiles, it may be entered twice in the event log, and those two entries could be mistaken for separate transmissions illuminating different selected antennas. How would you test the identity of a burst without relying solely on a decoder or on the detector's own event counter? Further, suppose one reference receiver uses a narrower filter than the switched receiver. The two instruments would then have different transient responses and nominal timestamps. How would you preserve independence while determining whether they observed the same underlying emission? I would be particularly concerned about a processing rule that treats closely spaced detections as equivalent merely because their spectral centroids are similar. A lawful defensive observation must retain ambiguity when the acquisition chain cannot resolve the true event boundary.

Copyright 2026, James M. Atkinson

Antony Hewish, Response: Dr. Shannon, the detector's event identifier is a data-processing convenience rather than a physical truth. A useful controlled trial begins with the authorised emitter's independent trigger or modulation log, which records the burst interval before it reaches either receiver. The experiment can then determine how many detector entries arose from each emitted event and whether the detector split one burst across analysis windows or merged neighbouring bursts into one marker. Where no independent emitter log is available, the analysis should compare raw sampled time intervals, energy envelopes and receiver states, while keeping event matching provisional. The rule used to associate records from different antennas must be fixed before reviewing the final bearing errors.

Copyright 2026, James M. Atkinson

Filter bandwidth and group delay require calibration with reference pulses. One can inject known test signals into each acquisition chain and measure the onset-time bias and uncertainty under several pulse durations and signal-to-noise ratios. Differences in bandwidth alter the envelope and may shift threshold crossings, so a common timestamp cannot simply be imposed on both channels. For directional inference, use acquisition-time intervals with declared uncertainty rather than a single unexplained detector timestamp. If the possible event intervals overlap but cannot be shown to refer to the same burst, classify the association as uncertain; do not convert a likely correspondence into verified simultaneity.

Copyright 2026, James M. Atkinson

Receiver independence must be qualified. Two instruments can have separate processors but share an antenna, clock or RF distribution amplifier; they may then inherit common artefacts. A stronger challenge uses a separately calibrated reference signal path and a known emission schedule, or compares the same controlled source with altered antenna and receiver configurations. Intentionally varying filter bandwidth, detector integration and software load can expose whether inferred burst identities change with the measurement process. A genuine source event should remain linked to the independently recorded emission even if its detector markers shift in time within measured limits.

Copyright 2026, James M. Atkinson

When evaluating field data without an emitter log, I would preserve multiple candidate event associations if they are scientifically plausible. One may calculate directional hypotheses conditional on each association, but the final evidence report should identify that dependency. It should never present a single narrow angular interval while suppressing the event-matching ambiguity that made several incompatible bearings possible. The correct statement may be that the source was detected in a given time span and that the switched observations are insufficient to associate all detections with one emission. That conclusion preserves the distinction between observing radio activity and resolving a physical direction.

Copyright 2026, James M. Atkinson

Richard W. Hamming, Peer Question: Dr. Hewish, you distinguish source events from detector markers, but a software implementation could still destroy that distinction by assigning every observation a timestamp when an event record is written rather than when RF samples were acquired. Suppose a ring buffer wraps during a burst, the programme copies samples in two parts, and the downstream detector reports two detections with plausible timing. How should the test laboratory examine buffer indices, sample counters and missing-data markers to establish whether the apparent pair of events is genuine? I also wonder whether it is sufficient to monitor a single diagnostic counter. A counter can be continuous while samples are duplicated, reordered or replaced by stale data after an acquisition fault. What independent assertions would you require before such event timestamps could be employed to assemble an antenna-switching bearing? A direction finder may be mathematically elegant and still be invalid if its data provenance has been corrupted by an unnoticed software failure.

Copyright 2026, James M. Atkinson

Antony Hewish, Response: Dr. Hamming, the acquisition chain must be tested as a system that can fail in ways not visible from the final event list. A monotonically increasing sample counter is useful but insufficient. The laboratory should record buffer sequence numbers, antenna-selection state, acquisition clock state, actual write and read positions, and explicit flags for overflow, underrun and discontinuity. Controlled test waveforms containing known time-varying reference features can reveal duplicated or reordered segments even where the counter appears continuous. It is important to compare acquisition-layer logs with the raw sample record rather than accept the application layer's account of what occurred.

Copyright 2026, James M. Atkinson

One test should deliberately stress the software. Vary CPU load, disk throughput, memory pressure and communications latency while the authorised reference source sends pulses at known times. Determine whether samples are dropped, repeated or associated with the wrong antenna after each switch transition. If a processing fault occurs, the resulting record should be marked ineligible for direction estimation until the failure mode has been corrected and the affected interval identified. A timestamp attached to a copied data structure does not restore the physical timing of samples that were never captured or whose ordering is unknown.

Copyright 2026, James M. Atkinson

Independent assertions can include an external test receiver, a separately monitored switch-control signal, or injected acquisition test marks whose positions can be checked against the recorded sample indices. Where feasible, the instrument can produce cryptographic integrity checks over stored data blocks and preserve acquisition metadata alongside them. Such checks can demonstrate that an existing file has not changed after capture, but they do not prove that the capture originally represented the physical signal correctly. The latter question must be answered by hardware and software validation under known stimuli.

Copyright 2026, James M. Atkinson

For every bearing estimate I would preserve a chain from the output angle back to the actual sample ranges used, their antenna identifiers, the timing uncertainty and the event-association rule. If any range is discontinuous or lacks a defensible switch state, the estimate should be rejected or expressly qualified. These controls should be exercised with negative trials containing deliberate buffer gaps and duplicated segments. A correct implementation ought to detect or flag them rather than continue returning believable but unsupported directions. The lesson is that the forensic quality of a bearing depends on the provenance and completeness of its samples as much as on the apparent precision of its estimator.

Copyright 2026, James M. Atkinson

Antony Hewish, Cross-Peer Question to John Daniel Kraus: Professor Kraus, I should like to return to the physical interpretation of a burst that is measured on only one antenna. Your earlier comments suggest that a receiving pattern may support a broad directional sector even when a complete switched comparison is unavailable. Yet the detector has selected that burst because its signal crossed a threshold under a particular polarisation response and local noise state. Is it legitimate to treat the pattern's nominal gain contour as a likelihood over possible source directions without accounting for the probability of detection at each direction? In other words, a burst seen through the most sensitive part of an antenna pattern will be overrepresented among detected events even if the source distribution is uniform. How would you convey that selection effect in a report without imposing an unjustified prior distribution over unknown transmitters? I am asking especially about defensive surveys where the operator knows neither the emitter's power nor its polarisation.

Copyright 2026, James M. Atkinson

John Daniel Kraus, Cross-Peer Answer to Antony Hewish: Dr. Hewish, one must distinguish an antenna's calibrated response from a probability distribution over source direction. A gain contour tells the investigator how the antenna responds to an incident field of a specified frequency, polarisation and direction. It does not by itself say how likely it is that an unknown source occupies any particular direction. That latter claim requires assumptions about the distribution of source power, position, orientation and the receiver's detection process. A single detected burst on one antenna can constrain possible arrival directions under declared amplitude and polarisation assumptions, but those constraints may be extremely weak.

Copyright 2026, James M. Atkinson

In a controlled study, the detection-selection function can be estimated. Present an authorised test source at known angular positions with varied power and polarisation, record the fraction of bursts detected during fully eligible dwell intervals, and construct a detection probability conditional on those parameters. This produces an empirical measure of what the receiving architecture tends to notice. A report about an unknown emitter can then show how directional conclusions change across reasonable power and polarisation ranges rather than silently fixing the values most favourable to one bearing. Where no defensible prior exists, avoid a posterior probability map that appears objective while embedding an arbitrary source distribution.

Copyright 2026, James M. Atkinson

The laboratory should also preserve nondetections from qualifying observation intervals. They can constrain a source hypothesis only through the calibrated sensitivity and detection function; they are not proof that the source was absent. If the receiver's threshold or noise level changes, those constraints must be recalculated. For a burst detected on one element and missed by another, ask first whether both were eligible during the same emission, and then whether the second channel had sufficient expected sensitivity. If the two antennas observed different emission intervals, there is no valid amplitude-ratio bearing to calculate. A pattern null cannot be inferred from a missing sample.

Copyright 2026, James M. Atkinson

In the final account, I would distinguish three statements: the burst was physically detected by antenna j; the calibrated antenna response is compatible with certain broad directional regions under specified assumptions; and the full array lacks enough simultaneous observations to return a unique bearing. This is not an unsatisfactory scientific result. It conveys the actual information that survived the measurement process. A narrower map can be produced only if the examiner adds independent evidence, such as a second site, a continuous array observation or a controlled source track, with the corresponding new uncertainties fully explained.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Sir Robert Watson-Watt, I invite you to bring these laboratory distinctions into operational direction finding. How should a defensive survey be conducted when sources are moving, transmissions brief and the available receiver must switch between antennas rather than observe them all simultaneously? Please take the token and identify the minimum records required before any bearing can responsibly be placed into a final evidence report.

Copyright 2026, James M. Atkinson

Sir Robert Alexander Watson-Watt, Principal Contributor: The purpose of a direction-finding system is not to manufacture an answer to every radio event but to obtain information that is reliable enough to guide subsequent observations. An operational operator may possess a receiver with a graduated dial, an antenna switch and a display that offers a numerical bearing, but those conveniences do not relieve the investigator of examining what the apparatus actually observed. A moving, intermittent source imposes severe constraints upon a sequential measurement. The source may radiate while only one antenna is selected, may move appreciably before the next dwell, or may disappear altogether during a period that the programme interprets as an antenna-pattern null. A compass value derived from those incompatible observations can be precise in appearance while being physically false.

Copyright 2026, James M. Atkinson

I would insist first upon a distinction between detecting a source, estimating a line of bearing, and identifying or locating an emitter. The detection of a brief RF event establishes that the receiver encountered energy satisfying its declared detection conditions. A line of bearing requires an antenna or array observation whose directional relationship to the incident field is supported by calibration and timing. Position estimation generally calls for additional geometry, such as multiple independent sites or known movement with adequate reference information. None of these claims is interchangeable, and a repeated set of apparent bearings should not be offered as proof of transmitter identity merely because it forms a plausible track on a map.

Copyright 2026, James M. Atkinson

Before a field survey starts, document the actual switching schedule. Record the antenna identifiers and their physical orientations, the receiver mode and tuned frequency, the length of each settled observation interval, and the time taken to change paths. Verify the timing by an independent instrument where practicable. Operators often assume that a nominal dwell begins when a control command is issued; the RF path may not be usable until mechanical switching, amplifier recovery, filter settling and gain-control transients have ceased. The difference between command time and scientifically eligible acquisition time belongs in the measurement budget. Where a short emission falls wholly within that gap, the instrument has not measured its direction.

Copyright 2026, James M. Atkinson

Operational practice must also allow for changing geometry. A distant moving transmitter may shift angle slowly during a scan, whereas a nearby source moving across the receiving site's line of sight can change its bearing rapidly. One should not specify a universal safe switching interval without reference to possible angular speed. The source's true range and lateral velocity may be unknown in a defensive survey, so the examiner should state a conditional limit rather than pretending to know them. If a test geometry bounds the apparent angular rate by omega_max and the scan aperture lasts Delta seconds, the possible angular movement during the acquisition is bounded in a simple constant-rate approximation by omega_max Delta. The bound is a screening device, not a complete propagation model. Reflection and transmitter orientation may change independently of the physical angle.

Copyright 2026, James M. Atkinson

Consider a controlled moving source whose direction changes at 8 degrees per second. A sequence of antenna observations extending over 0.25 second spans a potential two-degree angular change, even before receiver bias or multipath is considered. If the device reports an angular confidence of a fraction of a degree based only on high signal-to-noise ratio, it has failed to include the uncertainty arising from assembling observations taken at different times. Conversely, if the source is sufficiently slow, the antenna response stable and the reference bursts long enough to illuminate every required dwell, sequential observations may be useful. The proper question is whether the assumptions have been demonstrated for the event under consideration.

Copyright 2026, James M. Atkinson

An operational direction finder should preserve alternative outcomes rather than force each event into the same display category. A detection with one antenna and no valid others belongs in an event register without a bearing. A set of observations acquired from the same sufficiently stable emission may support a provisional angle and its uncertainty. A complete, independently calibrated set with defensible timing can support a stronger bearing claim. If the software's classification is unable to express these distinctions, the operator should maintain an accompanying observation ledger rather than let a single output field govern the evidence. A system that declines a doubtful bearing can be more useful than one that always returns a number.

Copyright 2026, James M. Atkinson

I would compare a switched instrument against a simultaneous reference array during controlled exercises. The authorised source should follow independently measured paths and emit bursts under schedules not disclosed to the bearing operator in advance. Repeat runs with the switch cycle started at different phases relative to the bursts. Include intervals in which the source is not transmitting and intervals in which it radiates but the switched receiver cannot observe it. A field instrument's performance should be described using all reference events. Separate the probability of an eligible bearing from the error distribution of bearings actually returned. Otherwise an attractive average error may merely describe the convenient subset of continuously illuminated antenna sequences.

Copyright 2026, James M. Atkinson

The record should also reveal whether a bearing is a new measurement or a propagation of a previous estimate. A display that maintains the last known angle through a period of silence may be operationally convenient, but the displayed number becomes increasingly stale. It must carry the timestamp of the actual source observation, not the time at which the screen was redrawn. When two sequential measurements are joined into a track, state the interval and the motion assumptions connecting them. The map should distinguish measured points, interpolated segments and periods without eligible observations. A smooth line is a hypothesis about motion, not a substitute for samples.

Copyright 2026, James M. Atkinson

The receiving environment further complicates interpretation. A nearby reflection can produce a strong signal from a direction unrelated to the source's geometric bearing; the dominant reflection may change as the source moves or as the receiver switches between differently situated antennas. The result may resemble a credible directional change, especially if only amplitude maxima are used. Repeat observations from independently located positions, rotate the receiving system when feasible, and compare different polarisation states. Such challenges may expose multipath sensitivity but cannot guarantee a unique correction. A defensible report should identify the geometry of the observations and state whether each angle describes a direct-path estimate or a dominant incoming-field direction under the stated model.

Copyright 2026, James M. Atkinson

In a legal or administrative setting the most serious danger is an overconfident conclusion detached from acquisition conditions. I would require the investigator to retain the raw or suitably preserved RF samples, the switching and timing logs, the calibration record, the original event decisions, and the estimator settings in effect when a bearing was produced. An independent reviewer must be able to reconstruct which physical observations supported each reported angle and to identify the trials discarded under the predeclared validity rule. If that reconstruction is impossible, the attractive precision of the final output should be viewed with caution. The objective of responsible defensive surveillance countermeasures is not to locate a source at any cost but to report faithfully what the available radio measurements can and cannot establish.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Peer Question: Sir Robert, your proposed operational ledger distinguishes detections, provisional bearings and stronger calibrated estimates. But consider an investigator who collects an intermittent emitter's supposed bearings while walking around a building. The receiving platform moves, the antenna array changes orientation, and different parts of the environment reflect the signal. A later analyst may attempt to triangulate these bearings as though each were an independent line drawn towards a fixed source. What independent information about platform attitude, acquisition time and channel stability must be retained before that triangulation is mathematically defensible? Would you permit an algorithm to treat a bearing without complete antenna observations as a weighted line, provided it attaches a large numerical uncertainty? Or can the absence of a valid spatial comparison make the statistical distribution itself ill defined, such that uncertainty weighting cannot restore what the receiver failed to measure? The distinction matters where a plausible intersection might be mistaken for corroboration.

Copyright 2026, James M. Atkinson

Sir Robert Alexander Watson-Watt, Response: Dr. Bracewell, triangulation cannot create valid evidence from lines whose origin and physical meaning were never established. The investigator must record the receiving platform's position and orientation at the time of each qualifying observation, not merely at the time the screen was updated. If the operator walks or turns during an antenna-switching cycle, that movement should be included in the response model or the cycle rejected when it exceeds the instrument's validated limits. A fixed building or ground reference can help determine platform orientation; an independent positioning record may document movement. Both must carry uncertainty, and their timestamps must be reconciled with the RF sample acquisition times.

Copyright 2026, James M. Atkinson

The significance of a broad or incomplete observation depends upon whether a defensible likelihood can be formed. If a receiver detects one burst through an antenna whose directional response is known but lacks the other observations, it may be possible to state that some directions are more compatible with that detection under declared assumptions about source power and polarisation. Such a statement is a conditional sector or likelihood, not a measured narrow line. It should not be introduced into a triangulation routine that expects full-array bearings unless the routine has been designed to handle the weaker observation type and its uncertainties. Simply attaching a large standard deviation to an arbitrary point angle can imply an error distribution for which there is no physical basis.

Copyright 2026, James M. Atkinson

Where valid bearings exist from several independently positioned observations, their error structures must be examined. Shared calibration errors, common propagation reflections and source movement can make the lines dependent. A narrow intersection of several biased lines is not independent corroboration. The analyst should identify whether source motion between observations makes the fixed-source triangulation model untenable. If a moving-source model is used, its trajectory assumptions and sensitivity must be reported separately. Measurements made from a moving platform need a consistent coordinate transformation and explicit propagation of attitude and timing uncertainty; without them the apparent geometry is a drawing convention rather than a verified physical reconstruction.

Copyright 2026, James M. Atkinson

An operational record should therefore distinguish direct measured angles, broad directional compatibility regions and absent bearings. The final map may show these with different symbols and different supporting tables. If a large number of transient events lack qualifying spatial observations, reporting those missing bearings honestly is essential to understanding the coverage of the survey. The investigator must be free to conclude that the data support only the presence of intermittent RF activity, despite the temptation to join incomplete observations into a persuasive source location.

Copyright 2026, James M. Atkinson

John Daniel Kraus, Peer Question: Sir Robert, suppose the operator has several directional antennas of unequal patterns mounted on the same mast, and a survey vehicle traverses a region with strong reflections. A detected pulse arrives on one antenna while two subsequent pulses appear at markedly different strengths on the others. The software interprets the three amplitudes as one pattern ratio and displays a bearing that changes as the vehicle passes a metal structure. Could that sequence arise entirely from variations in reflected propagation and polarisation, even if the true transmitter direction barely changed? What controlled tests would you recommend to distinguish an actual change of geometric bearing from a change in the dominant arriving field? I should like you to address the temptation to make the display more stable by temporal averaging. Averaging may reduce random noise but it can also conceal short-term changes in the physical channel and combine different emission events under a false assumption of common direction.

Copyright 2026, James M. Atkinson

Sir Robert Alexander Watson-Watt, Response: Professor Kraus, the sequence you describe is consistent with several competing explanations. The receiving system may have observed different source bursts, each affected by distinct fading, polarisation or reflected paths. The mast and nearby vehicle structure may alter the antenna patterns in ways absent from their original calibration, while the software treats the installed system as though it were operating in free space. The true geometric source direction may be nearly unchanged while the dominant received arrival direction moves because a reflector changes its relative contribution. None of these possibilities can be resolved by smoothing the displayed angle alone. Smoothing can make the plot look more stable without showing that the underlying physical model is correct.

Copyright 2026, James M. Atkinson

I would begin by recording the same authorised test source from controlled known locations and orientations, using both the switched installation and a reference receiver with a continuous observation path. Repeat the test with the vehicle stationary, then at known positions and speeds. Change the switch start phase and, when practicable, compare observations from a different receiving site where the reflection geometry changes. Measure the installed antenna responses with the mast and vehicle present. If the reported bearing depends strongly on a nearby structure or on switch schedule phase, that dependence must be described as an instrument-and-environment sensitivity, not attributed to motion of the source without further evidence.

Copyright 2026, James M. Atkinson

Averaging may legitimately reduce zero-mean noise under a stationary and appropriately modelled signal, but it must not convert incompatible bursts into synthetic simultaneous samples. The aggregation window should be declared in advance and related to the source's possible angular movement, emission changes and environmental variability. The software should preserve the underlying individual event decisions, so an independent analyst can determine whether a smooth output concealed large contradictory bearings. Use experiments in which the reference source moves through the region while the receiving geometry is held constant, and separate experiments in which the receiving platform moves while the source remains fixed. These comparisons help identify whether apparent movement follows the source or the measurement apparatus.

Copyright 2026, James M. Atkinson

If the evidence remains ambiguous, the report should state that the instrument estimated the direction of the dominant received field under specified conditions, not necessarily the direct geometric direction to a transmitter. That distinction is meaningful in a survey. It warns later reviewers that a highly precise displayed bearing could be materially affected by reflections or time-separated observations. The investigator's responsibility is to retain the uncertainty and competing explanations rather than to make the evidence fit an aesthetically pleasing map.

Copyright 2026, James M. Atkinson

Sir Robert Alexander Watson-Watt, Cross-Peer Question to Ronald Newbold Bracewell: Dr. Bracewell, I should like to question the assumptions behind a computed confidence interval. An array algorithm may return a narrow statistical uncertainty when a direction estimator has high numerical curvature around its optimum. Yet if the input vector was assembled from bursts recorded at different times, the algorithm may be solving the wrong physical model. What practical validation would distinguish a narrow conditional uncertainty within an invalid model from a genuinely reliable bearing? Could one formulate a predeclared rejection test based on the predicted changes of source direction during the antenna cycle, the measured spread of source amplitude and the residuals of an independently calibrated array manifold? I also ask whether the procedure should explicitly quantify the probability of refusing to issue a bearing, since an estimator that gives only a few defensible results may nevertheless look exceptionally accurate when the rejected observations have vanished from the published sample.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Cross-Peer Answer to Sir Robert Alexander Watson-Watt: Sir Robert, the numerical sharpness of an objective function is not a certificate that its model describes the physical observations. A narrow interval derived under the assumption of simultaneous reception conditions only the answer upon that assumption. To validate the estimate, first examine the timestamps and eligibility of the observations used to construct its input vector. If the source could have moved beyond the declared angular-change budget during their acquisition, or if the observations came from separate bursts whose relative amplitude and phase stability has not been established, reject the simultaneous-array interpretation before evaluating the estimator's reported variance. An accurate numerical optimiser can faithfully produce an incorrect answer to an invalid physical question.

Copyright 2026, James M. Atkinson

A predeclared rejection rule can combine several checks. Require that each observation fall within a documented settled interval, that the source emission association satisfy an independently tested timing rule, and that potential motion over the entire acquisition aperture remain within the accepted bound. Evaluate the residual between the observations and the calibrated antenna manifold, but do not treat a small residual as sufficient proof of validity: a physically wrong model can sometimes fit contaminated data remarkably well. Where possible, compare against simultaneous reference observations and a known moving-source trajectory. Deliberate counterexamples, including a fixed source with changing power and a moving source with short bursts, can test whether the estimator incorrectly returns the same narrow bearing in situations where its assumptions fail.

Copyright 2026, James M. Atkinson

The probability of a valid estimate is an essential output, not a nuisance statistic. For each independently known reference event, record whether the switched system collected qualifying samples, whether its estimator returned a candidate, whether that candidate passed the declared validity checks, and how accurate the accepted bearing was against the source track. A report can then state the availability fraction and the angular-error distribution conditional on accepted estimates, with their respective denominators. If the successful fraction becomes small in short-burst regimes, the instrument's limitations are visible even if its accepted bearings remain precise. This prevents statistical selection from turning a sparse but favourable subset into a misleading general statement about operational performance.

Copyright 2026, James M. Atkinson

In a defensive field investigation without external truth, confidence must be correspondingly modest. The analyst may establish that observations are temporally compatible and consistent with an array response, yet still face unresolved reflections, source polarisation and movement. The reported interval should identify the modelling assumptions and any systematic error budget, and the final location claim must not exceed the evidence supplied by actual receiving geometry. One may state that the receiver is unable to provide a defensible bearing for a particular transient without thereby failing the survey. That abstention is a correct expression of the instrument's information limit.

QUESTION 089

Copyright 2026, James M. Atkinson

When does a public synchronisation field become unreliable evidence of a particular transmitter?

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Hamming, I invite you to distinguish what a published synchronisation sequence establishes about a received waveform from what an investigator would need to establish the identity of its transmitting instrument. Please begin with coding structure, observed errors and the possibility that entirely independent sources radiate the same public sequence. I pass the token to you.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Principal Contributor: The central error is a confusion of categories. A synchronisation sequence is chosen to enable a receiver to find the beginning of a frame or estimate a parameter of a channel. It is generally constructed so that many compliant devices can emit it and many compliant receivers can recognise it. It cannot logically serve as an individual signature merely because the investigator's correlator produces a large peak. In a controlled experiment I would start by acquiring published sequences from three separately assembled reference transmitters, using different oscillator components and RF front ends, but identical standard-compliant framing. The resulting payload-free synchronisation records would often match at the nominal digital-sequence level. That is what interoperability requires. Their physical waveforms may differ in amplitude, timing, frequency offset, transient behaviour or analogue impairment, yet none of those distinctions may be ascribed to the public sequence itself. The distinction between code agreement and source agreement must be maintained in every data table.

Copyright 2026, James M. Atkinson

A code can be described as a set of allowed symbol sequences, but an individual source is a physical object with a state. Let c[k], for k from zero to N minus one, denote a known complex training sequence of N symbols. Let y[k] be the receiver's measured complex samples after its declared timing and filtering, and let h represent the channel response. A simplified observation y[k]=a c[k-d] exp(j(2πΔf k/Fs+φ))+w[k] assumes a scalar complex channel a, integer delay d, frequency offset Δf in hertz, sample rate Fs in samples per second, phase φ in radians and additive disturbance w[k]. The simplified scalar model is invalid where multipath requires a convolution, where symbol and sample clocks drift or where front-end distortion is significant. Most importantly, the expression contains no unique transmitter identity variable. To infer a device from it, the examiner would have to introduce, test and independently validate further source-dependent features. Writing an instrument name beside a correlation peak does not supply those missing premises.

Copyright 2026, James M. Atkinson

The matched-filter statistic R[d]=sum over k of y[k+d] times the complex conjugate of c[k] is useful for finding candidate timing offsets. Its absolute value is not a posterior probability that a particular source was responsible. A peak can be enlarged by received power, integration length, favourable antenna orientation or a close match to the common published code. A distinct but protocol-compatible reference source can produce a similar peak. Conversely, the actual source may produce a weak or misleading peak because the receiver is saturated, its frequency error exceeds the correlator's accommodation, or interference damages part of the training interval. Thus a larger R can provide better evidence of sequence presence under a calibrated signal model without being evidence of a named transmitter. That asymmetry should be explained to every student who has admired a bright vertical stripe on a spectrum waterfall and heard the false certainty in an automated device-identification alarm.

Copyright 2026, James M. Atkinson

Even an error pattern requires an explicit generative model. Suppose a candidate segment differs from an expected 64-bit public sequence in four positions after legitimate demodulation of a laboratory test. The Hamming distance is four, and the observed bit mismatch fraction is four divided by 64, or 0.0625. This measured fraction does not reveal whether the cause was fading, a frequency offset, a receiver threshold, a synchroniser slip, a hardware malfunction, or deliberate alternate encoding. Nor does it turn the 60 matching positions into the identity of one radio. The bit-error event may be burst-correlated rather than independent, particularly in a narrow fading notch or a clipped acquisition. A laboratory should archive not merely the decoded or sliced 64 bits but the receiver configuration, raw authorised measurement window when permitted, acquisition clock, and ambiguity information needed to reproduce the result without recovering protected payload content.

Copyright 2026, James M. Atkinson

Consider a second experiment with two independent emitters whose permitted training fields are identical. Place one emitter at a fixed distance and another at a different azimuth, both operating one at a time under concealed random allocation. Before seeing the trial labels, require the analyst to report whether the data support only the public training-field class or support a reliably distinguishable RF implementation class. The equipment's location, transmission timing, antenna rotation and chosen receiver should be balanced over emitters. A classifier that succeeds only when one reference source is physically closer has learned propagation or signal strength, not intrinsic manufacturing features. Likewise, a model that succeeds only on a particular receiver may have learned that receiver's oscillator or quantisation peculiarities. Proper interpretation demands a held-out receiver and fresh recording session, not merely a random split of neighbouring samples from the same burst.

Copyright 2026, James M. Atkinson

The public code often appears in frames generated by many products under different regulatory and operational conditions. That breadth is a deliberate engineering virtue; it creates a serious forensic limitation. A code-family hypothesis can be tested by changing the sampling frequency, channel impairment or code acquisition length in a controlled setting and examining how the statistic behaves. Individual-source attribution is a different proposition requiring source-discriminating features, false-match rates measured over relevant alternatives, stability across environmental conditions and a clearly defined population. If the target population includes radios not represented in the experiment, then a closed-set classification rate cannot be read as the probability that an unknown field transmission came from the one device already on the investigator's bench.

Copyright 2026, James M. Atkinson

There is a deeper issue in the act of selection. An examiner who searches hundreds of offsets, multiple candidate standards, two polarisation settings and several filter configurations may eventually discover a very attractive match to a public sequence even under unrelated interference. The false-alarm probability for the chosen peak is not the same as the probability that an equally large peak would emerge from the entire search. The analysis must preserve all tested hypotheses and the parameters selected before examining the data. Otherwise the investigator presents an especially persuasive trace without the unglamorous history of how many alternatives were tried. This is a statistical error, not merely a question of courtroom vocabulary. The listener hears a compelling code name while the record conceals the noise against which the conclusion was chosen.

Copyright 2026, James M. Atkinson

I propose a hierarchy of findings. First, the receiver recorded energy in a stated bandwidth and time interval. Secondly, a calibrated synchroniser found a candidate sequence with a documented statistic and false-match assessment. Thirdly, the observations were compatible with one or several public frame formats under explicit assumptions. Fourthly, if justified by separately validated physical features, certain equipment classes may be favoured over declared competitors. Individual physical transmitter identity must remain unestablished unless there is independent, appropriately designed evidence. The report must also retain the possibilities of replay by authorised test equipment, implementation reuse, correlated receiver errors and multiple sources using the same format. A precise negative boundary is as valuable as a confident positive measurement: it prevents an instrument's ability to recognise shared structure from becoming a claim the evidence cannot bear.

Copyright 2026, James M. Atkinson

Jacob Ziv, Peer Question: Dr. Hamming, your division between public code structure and physical source is sensible, but I should like to press upon the treatment of a waveform whose training interval appears identical while the surrounding source statistics change between sessions. A compressor, data scrambler, variable-length frame builder or traffic scheduler can alter the apparent entropy and timing distribution of neighbouring regions without changing the public synchronisation field. Would you allow an investigator to treat joint resemblance of the preamble and adjacent non-content timing observations as cumulative evidence, or must the possible shared software and traffic model first be controlled? Please specify how one would separate the influence of the common code, of a deterministic encoder state, of receiver frame segmentation and of the particular source equipment. In particular, what result from a blind trial would falsify an attribution claim that seemed persuasive when both the sequence and frame cadence were viewed together?

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Response: Dr. Ziv, I would permit cumulative evidence only after testing the dependence between the measurements. The code-match event and a timing-cadence event are not necessarily independent; a common receiver synchroniser supplies the segmentation that defines both. If the synchroniser locks to the wrong offset, it may change the estimated start times and hence the cadence. If a single software implementation chooses both the public training format and a nominal beacon interval, many different hardware products can share those features. Multiplying the marginal false-match probabilities would then create an artificially impressive number, since the shared cause has been counted twice. I would begin with an explicit causal graph including encoder design, firmware schedule, RF hardware, propagation, acquisition clocks and the algorithm that marks candidate events. Conditional dependencies should be estimated or bounded rather than wished away.

Copyright 2026, James M. Atkinson

The blind trial you propose is particularly useful if the emitters vary independently in hardware and scheduling firmware. Repeat the identical training sequence under several controlled frame cadences for each source; then hold the cadence constant while exchanging sources. If the classifier's apparent ability to distinguish transmitters disappears when the cadence is reassigned, the supposed hardware inference was a learned scheduling convention. This is not proof that the classifier is worthless: it may remain a useful description of the observed traffic class. But the claim must be reduced to the proposition that survives the intervention. A third manipulation replaces the nominal encoder with a different implementation that preserves the public field. If this changes the other observed statistics, those changes cannot be attributed to the public training bits themselves.

Copyright 2026, James M. Atkinson

I would insist that the investigators predeclare whether the relevant question is format recognition, event grouping, product-family screening or individual-source attribution. The experiment that tests one need not test the others. Use a held-out recording day and a different calibrated receiver for the final evaluation, and include a deliberately unfamiliar transmitter. The unfamiliar source is a particularly severe challenge to an overly confident closed-set classifier. If it assigns the unknown source to the nearest known class with high confidence, we learn that the algorithm must have a rejection rule rather than being allowed to name a device whenever it sees a match. Finally, publish both confusion rates and abstention rates, with the expected costs of false attribution. The laboratory ought not convert a repeated interval and a common code into an accusation simply because their joint display looks orderly.

Copyright 2026, James M. Atkinson

Abraham Lempel, Peer Question: Dr. Hamming, imagine an authorised demonstration in which a programmable signal generator faithfully reproduces a publicly documented preamble and a modest portion of the analogue envelope of another reference instrument. The generator need not imitate a protected message; it transmits only a benign laboratory frame under the examiner's control. An analyst, unaware of this substitution, might observe the correct sequence and even several matching features after filtering. Would you regard the possibility of such reproducibility as a categorical obstacle to individual attribution, or only as a demand for a more restricted and experimentally qualified claim? Please address a specific issue: the emulated wave may pass through a different antenna, room and receiving chain from the original. How should that difference be prevented from providing a spurious means to separate the sources? What evidence would be necessary before the examiner could properly say more than that both trials used the same publicly specified training format?

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Response: Dr. Lempel, an authorised replay experiment demonstrates that code agreement alone cannot establish the emitting instrument's physical identity, because two sources can instantiate the same public bit sequence. It does not prove that all conceivable device-dependent measurements are uninformative. The proper conclusion is narrower and more useful: any proposed additional signature must resist plausible alternatives, including the replay or re-encoding of public symbols by a different transmitter. The experimental claim should specify the available adversarial or non-adversarial alternatives rather than suggest a universal uniqueness theorem. One can legitimately show that certain analogue features distinguish a set of carefully controlled reference units; that is not the same as identifying an unfamiliar emitter in the field.

Copyright 2026, James M. Atkinson

To avoid allowing the room to do the classifier's work, use physically balanced placements. Exchange the two test sources between each antenna position, randomise their transmission order, maintain independently measured powers where possible and repeat with different receiving orientations. Where safety and permissions allow, inject the controlled reference signals through a characterised cabled path to isolate the transmission hardware from over-the-air channel variations. Cabled tests still have connectors, amplifiers and filters that require calibration, but they provide an illuminating contrast to an uncharacterised radio path. If the distinguishing features vanish when the propagation paths are exchanged, a report about transmitter identity must be withdrawn or substantially qualified.

Copyright 2026, James M. Atkinson

The result should also be evaluated under deliberate receiver changes. A feature that is stable only at one sample rate, intermediate-frequency filter or automatic-gain-control setting may belong to the instrument and its digital processing. Separate precision from accuracy: repeated measurements can be extraordinarily consistent and yet systematically wrong about the generating physical cause. I would ask the examiner to preserve the uncorrected data, the transformation history, the nuisance-variable manipulations and the uncertainty for each reported feature. Only then may a reader distinguish a repeatable laboratory association from an identifying physical characteristic. The final report should say the public code was observed and that other independent features did, or did not, support a limited equipment-class distinction under specified conditions.

Copyright 2026, James M. Atkinson

A useful audit would also log the amplitude and duration of each neighbour event, since truncation of the observation window can otherwise create a false association between the shared preamble and the apparent cadence. The inference should remain conditional on the measured coverage.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, I pass to you the central inferential difficulty. A detector reports a clear match to a public preamble, yet there may be ten thousand compatible transmitters and no tested individual characteristics. How should conditional probability be expressed so that a reader does not confuse a high probability of the observed code under a candidate device with a high probability of that device given the code? Could you present a deliberately transparent numerical example with explicit prior assumptions, and then tell us whether adding receiver clock drift or multipath would improve the conclusion or merely increase the number of nuisance variables? I also ask you to distinguish a statement about a transmission's format from a statement about its owner, location or purpose, which are not variables specified by the public synchronisation bits.

Copyright 2026, James M. Atkinson

I am especially interested in whether an analyst who has already looked at the code match would be tempted to choose the source prior after seeing the result, rather than before collecting the evidence.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, the distinction is elementary in notation but frequently neglected in practice. Let D denote the hypothesis that a particular device emitted the tested frame, let C denote the observed synchronisation-field match, and let K denote the instrument configuration and conditions used for calibration. The quantity P(C given D,K) is a likelihood: if the candidate device transmitted the proper frame, how often would this receiver report the match? The desired attribution P(D given C,K) requires a prior P(D given K) and the aggregate likelihood of the same observation under all other devices that might be present. A large likelihood is therefore not an attribution probability. I would not allow a numerical likelihood to be called confidence in a device unless the alternative population and prior assumptions were explicitly identified.

Copyright 2026, James M. Atkinson

Consider a hypothetical pool of one hundred equally plausible independent, standards-compliant laboratory emitters. Suppose all use exactly the same public training field, and a calibrated receiver recognises that field with probability 0.90 regardless of which source is transmitting. On this model, P(D)=0.01, P(C given D)=0.90 and P(C given not D)=0.90. Bayes' rule gives P(D given C)=[0.90×0.01]/[0.90×0.01+0.90×0.99]=0.01. The exceptionally good match changes nothing about which of those one hundred emitters was responsible. If clock drift, channel distortion or receiver frequency error is then measured, those variables might contain additional source-related information, but one must model their distributions under competing hypotheses, not merely append adjectives such as 'distinctive' or 'precise'. If the variations are mostly propagation dependent, they can make identity inference worse, not better. Format compatibility remains the defensible conclusion from the public field alone.

Copyright 2026, James M. Atkinson

The same numerical reasoning applies to a thousand competing, equally likely sources: the field match can be highly significant relative to noise and still fail to distinguish among them. In that case a 90 per cent field-detection rate supports an acquisition-performance statement, not an individual-source finding. Further features must be evaluated on fresh records for all plausible candidates, and their conditional dependence with the initial synchronisation event must be accounted for. If the only additional feature is the receiver's own clock offset, the supposed new evidence is merely a re-expression of one nuisance parameter.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Thank you, Dr. Hamming and Dr. Shannon. The distinction between likelihood and attribution has been placed plainly on the record. Dr. Shannon, please take the principal token and examine the information-theoretic and probabilistic limits of synchronisation evidence.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Second Principal Contributor: In the communication problem, a synchronising sequence is part of the common language of transmitter and receiver. It is not a secret token proving who is speaking. Indeed, a properly designed public synchronisation field must remain sufficiently predictable that a receiver can acquire timing and phase before the receiver knows the subsequent message or the source's precise hardware implementation. The observer can infer that a received segment has certain structural properties, but the segment's usefulness for synchronisation does not endow it with a unique authorship. Consider a signal that contains a repeated preamble. Correlation may help find a symbol boundary; it does not generally distinguish a high-volume manufacturer, a laboratory synthesiser and another permitted source employing the same training design. Each may generate the identical ideal complex sample sequence before analogue impairments are introduced. A statistical model must therefore separate information about the shared format from information about an individual physical unit.

Copyright 2026, James M. Atkinson

I would write the observation vector as Y and distinguish three latent variables: F, the selected public waveform format; D, the transmitting device; and H, the aggregate channel and receiver state. An engineer may find that the mutual information I(Y;F), computed under a declared distribution, is substantial because the preamble helps classify formats. Yet I(Y;D given F) can be small or zero when all devices produce the same ideal training samples and the remaining measured variation is dominated by unrecorded H. Conditional mutual information is a property of the specified distribution, not a universal constant of a preamble. The investigator must state how source devices are sampled, how observations are formed and what environmental variation is represented. A laboratory dataset that gives each device a different frequency, location or measurement day may exhibit large apparent information about D only because D is correlated with those nuisance variables. Reducing the dimension of Y to a code-match score discards potentially useful diagnostic information while retaining no guarantee of individual identity.

Copyright 2026, James M. Atkinson

The original synchronisation task usually seeks an event in a family of correlated tests. If the receiver slides a known template across K possible sample positions and tests M competing public sequences, it creates many opportunities for an accidental resemblance. A numerical false-alarm probability estimated for one position does not directly describe the largest statistic selected among K times M comparisons. Let p denote an explicitly calibrated single-comparison probability of exceeding a fixed threshold under a declared null. If all T=KM tests were independent, the family probability would be 1−(1−p)^T. For p=10^(−5) and T=1000, that is approximately 0.00995, close to one per cent. But sliding correlations share samples and are ordinarily dependent; independence is not a sound substitute for measuring the actual maximum-statistic distribution. A calibrated synthetic noise experiment should reproduce the receiver's overlap, filtering and adaptive thresholds. The point is not to invalidate correlation as a method; it is to refuse to treat the most favourable match of a large search as though it had been specified alone in advance.

Copyright 2026, James M. Atkinson

Frequency and timing errors provide another source of confusion. An RF oscillator can carry a small fractional frequency offset, but what the receiver measures is usually relative frequency error between the source and local oscillator, mixed with sampling-clock and processing uncertainty. For a nominal carrier of two gigahertz, a ten-part-per-million relative offset corresponds to 20 kilohertz. That offset might appear impressively stable in a short recording, but its sign and magnitude can change when the receiver is replaced, the source warms or either oscillator is disciplined differently. A repeated measurement from one receiver does not prove a unique source oscillator. A proposed identity classifier should cross receivers, temperatures, signal levels and acquisition sessions so that source-related stability is tested instead of assumed. A public code remains unchanged by these complications, while the analogue estimate associated with its acquisition may be highly contingent.

Copyright 2026, James M. Atkinson

I would also separate signal recognition from signal provenance. A matched correlator can recognise a suitable training pattern when the analogue signal has been replayed, re-encoded, generated synthetically or produced by a standards-compliant source. It recognises structure in the observation, not the history of every component that generated it. Evidence of provenance requires an independently trusted chain: for example, a controlled transmitter trigger and a recorded assignment of an authorised test source, or corroborating observations from independent receiving locations with their own calibrated clocks. In forensic writing the word 'therefore' is dangerous when its antecedent is merely a format match. It can connect an innocuous common preamble to an unproved device name and then to a person's supposed conduct without any intermediate experimental support. The report ought to preserve the distinctions between compatibility, statistical discrimination and physical source proof.

Copyright 2026, James M. Atkinson

A fair assessment of evidential weight compares hypotheses that both genuinely could explain the record. The likelihood ratio for device A against device B is L=P(Y given A,K)/P(Y given B,K), where K includes the declared recording conditions and the calibration model. If A and B transmit the same public field through comparable channels and receivers, the ratio based solely on that field is approximately one. If the analyst discovers additional analogue differences, L may deviate from one, but only after estimating the distributions of those differences with independent trials. A single high similarity score does not reveal the denominator. Nor does a machine-learning classifier's high score prove that its hypotheses exhaust the possible transmitters. Open-set uncertainty, unobserved devices and environmental changes are not technical footnotes; they determine what question the evidence can actually answer.

Copyright 2026, James M. Atkinson

There is a disciplined way to use a public sequence without collecting private payload content. The investigator can record the timestamp, frequency, bandwidth estimate, code-match statistic, declared synchronisation hypothesis, signal level, relevant receiver state and a concise non-content diagnostic of timing or frequency uncertainty. If collecting a short authorised IQ segment is essential to review the training field, the acquisition window should be bounded and the reason for retaining it documented. Nothing about this statistical argument requires opening a private message or analysing its semantics. In particular, the presence of a recognised preamble should not be treated as permission to acquire everything that follows it. Scientific reproducibility can be served by laboratory reference captures and verified procedures, while field records remain minimised to the legitimate detection question.

Copyright 2026, James M. Atkinson

Finally, I would teach a sequence of refusals. Refuse to turn certainty about a known public template into certainty about the source. Refuse to combine dependent features as though their likelihoods were separate. Refuse to interpret a classifier trained on fixed receiver positions as evidence of generalisable hardware identity. Refuse to substitute an attractive correlation plot for a declared error model. And refuse to hide the candidate sequences and search windows that were tried before the selected match was presented. A serious RF report can still make a valuable claim: a particular observation is compatible with a documented physical-layer format, within measured uncertainty. The more limited sentence is not a failure of investigation. It is a correct statement of the information actually present in the recorded evidence.

Copyright 2026, James M. Atkinson

John Robinson Pierce, Peer Question: Dr. Shannon, I should like to examine the role of a receiver's acquisition algorithm in manufacturing apparent distinctiveness. Imagine two transmitters that radiate exactly the same published training symbols, while one is weak and the other strong at the receiving antenna. A practical correlator may use different gain states, unequal windows, clipped samples or different early-to-late timing estimates. The engineer then sees different peak widths and delays and perhaps calls them transmitter characteristics. Would you prefer a single standardised receiver processing chain, or several independently designed acquisition methods that ought to agree about the underlying signal? How should the experimental design separate the genuine effect of a channel from the correlator's selection of a winning offset? Please include the case of overlapping candidate peaks, where only the largest event is recorded and the discarded alternatives are no longer available for later inspection.

Copyright 2026, James M. Atkinson

I ask that the analysis also distinguish the uncertainty of the estimated start time from the latency of the software notification, for these are not interchangeable timestamps in a buffered receiver.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Response: Mr. Pierce, both a standardised chain and independent methods have distinct uses, and neither should be trusted alone. A frozen processing chain permits repeatability and quantitative calibration of its threshold behaviour; independently designed algorithms test whether the claimed feature is robust to the analytical choices that a different laboratory might reasonably make. The central mistake would be to assume that agreement within a single adaptive processing pipeline proves the physical reality of its intermediate outputs. If a receiver's automatic gain control shifts between captures, or if a strong burst clips a converter, the correlation peak may differ even where the radiated digital preamble is identical. Those receiver conditions must be stored as measurement metadata, and invalid acquisitions should be marked rather than silently converted into source features.

Copyright 2026, James M. Atkinson

For a controlled comparison I would acquire paired transmissions from two source units at several attenuations, swap their positions, and feed a second independent reference receiver when possible. Report correlation peak magnitude, shape, selected delay and the distribution of alternative delays. If the strongest peak is retained but the runner-up is discarded, the experiment loses information about ambiguity. A moving interferer or multipath echo can cause the selected peak to jump discontinuously between nearly equal candidates. The apparent timing signature of a device would then reflect a data-selection policy. Recording the top several candidate peaks with their relative magnitudes is a modest non-content measure that improves later review without collecting payloads.

Copyright 2026, James M. Atkinson

An inference about device identity should be assessed with a likelihood or classification rule trained on one set of independently acquired conditions and evaluated on genuinely separate sessions. A receiver hardware change should not be treated as a cosmetic inconvenience; it tests whether the feature actually survives a change of instrument. If an algorithm succeeds only on the equipment with which its reference templates were made, it may be a useful local alarm system but does not support general forensic attribution. In the final report I would state the receiver model, analogue gain configuration, sample rate, timing estimator, code search space, interference conditions and grounds for excluding ambiguous bursts. The honest result may be only that both candidates conform to the same publicly specified training-field class.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Question to Peter Elias: Dr. Elias, in framing a burst, the receiver must decide when the public synchronisation interval begins and ends. I should like you to examine what happens when a correlator's frame boundaries are wrong by a small number of samples, or when a bit synchroniser slips within a public sequence. Can an error burst produced by a receiver or channel be made to resemble a distinctive transmitter-specific defect? What laboratory counterexample would expose that mistaken claim? I am also concerned that an analyst might treat a public frame delimiter as a private device identifier simply because it has a rare bit pattern relative to random noise. Please distinguish rarity under an inappropriate random-noise null from rarity among the population of compliant devices, and propose a defensible way to record the competing synchronisation offsets without acquiring protected payload content.

Copyright 2026, James M. Atkinson

If two compliant transmitters use the same delimiter but different proprietary payloads, what minimum non-content observations could properly test the synchronisation claim without retaining or decoding those payloads?

Copyright 2026, James M. Atkinson

Peter Elias, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, a frame delimiter can be rare under a random-bit null and universal among transmitters implementing a particular format. Those observations are not contradictory because the underlying populations differ. A 16-bit public marker, if its bits are exactly specified, has probability one under the ideal compliant-device model and perhaps probability 1/65,536 at one predeclared position under an ideal independent fair-bit null. Searching many overlapping offsets changes the latter calculation, and transmitted or received bits are often neither independent nor fair. It would be improper to transpose the random-null rarity into a probability of device identity. The engineering function of the delimiter is to reduce frame-boundary ambiguity, not to proclaim the manufacturer's serial number.

Copyright 2026, James M. Atkinson

A one-sample timing error can turn a correct symbol sequence into a misleading sliced pattern after a nonlinear decoder, especially where the waveform has pulse shaping or unequal channel delay. In a multipath channel the correlation surface can contain several plausible peaks. An acquisition algorithm that always chooses the earliest above-threshold peak and one that chooses the greatest peak may therefore produce different time stamps and apparent bit-error locations from the same analogue capture. A controlled counterexample transmits a fixed public training sequence from one authorised source while deliberately varying receive timing, sampling phase and channel impulse response. If the supposedly device-specific mismatch pattern moves with the receiver conditions, it is not a stable source signature. Preserve a bounded acquisition quality record: candidate offsets, threshold exceedances, uncertainty intervals and the reasons that ambiguous intervals were accepted or rejected. That record allows review of the synchronisation decision without authorising the recovery of any protected message that might follow.

Copyright 2026, James M. Atkinson

A useful further stress test deliberately changes the number of candidate offsets while leaving the authorised transmitted sequence fixed. If the apparent certainty grows only because the algorithm has more opportunities to select a favourable maximum, the supposed increase in evidential strength is reversed: the analyst has changed the search selection process rather than obtained a more informative signal. This difference must appear in the report's false-acquisition calibration. In addition, the laboratory should separate correlator confidence from payload interpretation. A recognisable public delimiter and its timing uncertainty can be documented with bounded test windows and known synthetic references; nothing about that exercise requires retaining private message content or naming an individual device.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Elias, please take the token. We have discussed what can be inferred from recognising a known sequence. I ask you now to examine the frame-detection machinery itself: the relation between synchronisation markers, finite error patterns, receiver slips and the false appearance of an individual source signature.

Copyright 2026, James M. Atkinson

Peter Elias, Third Principal Contributor: One can regard synchronisation as an agreement about where to begin interpreting symbols, whereas channel coding concerns how a permitted sequence may contain redundancy that makes errors detectable or correctable. These are related but not interchangeable operations. A public frame delimiter may be designed to have a useful autocorrelation structure or an acceptably small probability of mistaken acquisition under particular noise assumptions. That engineering merit does not imply that the marker is unique to any physical transmitter. The same delimiter can be emitted by hundreds of thousands of compliant instruments, by a laboratory waveform synthesiser and by a properly authorised reference beacon. To say that a receiver has synchronised to the sequence is to say that an algorithm found a model-compatible alignment, not that the investigation has established the identity or custody history of the emitter.

Copyright 2026, James M. Atkinson

A receiver commonly performs a succession of decisions: detect energy, choose a candidate frequency, estimate coarse timing, form the synchronisation statistic, test the statistic against a threshold, resolve competing peaks, and finally decide whether a consistent frame may begin. Each decision conditions the data that reach the next. Let S denote the event that the receiver admits a candidate frame into its output and let E denote the distribution of mismatches to the public field. Studying P(E given S) is not the same as studying P(E) over all transmitted test frames, because faint, delayed or badly distorted frames are less likely to reach the output. A report based only on retained synchronised frames can have deceptively low apparent error rates. Conversely a detector that admits noisy false candidates may create repeated patterns of mismatch from its own selection rules. An engineer who calls these retained patterns individual transmitter fingerprints must confront the conditional-sampling mechanism.

Copyright 2026, James M. Atkinson

I would design a three-way experimental challenge. First transmit one published training sequence repeatedly from a single stable laboratory source, varying only the receiving clock offset and fractional sampling phase. Secondly hold those receiver settings fixed while exchanging two independent compliant transmitters. Thirdly apply calibrated, digitally generated channel impairments to the same reference source, including a controlled reflected path, a narrow interfering tone and additive disturbance with a declared spectrum. All manipulations should be assigned before the analyst examines the candidate mismatch maps. If a supposed device-specific pattern follows the receiver phase, it belongs primarily to acquisition. If it follows the channel simulator, the path is implicated. If it follows the source across the interventions, it may warrant a more limited class-discrimination test, though additional alternatives such as shared chipsets and firmware still remain.

Copyright 2026, James M. Atkinson

One should distinguish bit disagreement, symbol disagreement and sample-level correlation. A symbol represented by several complex samples can be decoded incorrectly because the sampling instant lands near an eye-diagram transition; that error is not equivalent to a change in the public sequence transmitted. Likewise an apparent frame shift of one symbol can make the Hamming distance to the expected code suddenly large despite a perfectly compliant underlying emission. The analyst must not treat all mismatches as independent Bernoulli trials. In bursts of interference, four adjacent symbol errors may arise from one disturbance event rather than four independent device-specific defects. Without an error-dependence model, a numerical probability calculated by multiplying four marginal rates can badly exaggerate rarity. The correct error process is an empirical object to be estimated from controlled trials, preferably on acquisition sessions separated in time.

Copyright 2026, James M. Atkinson

For a transparent toy calculation, suppose the public marker occupies 16 bits, and a naive classifier treats an exact match at a single preselected alignment as one chance in 65,536 under an independent fair-bit random null. If the analyst in fact searches 2000 candidate offsets, even that unrealistic null gives approximately 1−(1−1/65,536)^2000, or about 3.0 per cent, for at least one exact match under independence. Overlapping windows violate independence; the example is only a warning against confusing one specified test with a search maximum. More fundamentally, that probability refers to random data, not to a field populated by compliant radios. For a format-compatible device emitting the marker correctly, the marker's probability may be close to one. Thus the very sequence that looks rare when compared with random noise is commonplace among the actual alternative emitters relevant to an identification claim.

Copyright 2026, James M. Atkinson

A laboratory should also test offset ambiguity rather than record only a winning decision. If two peaks exceed threshold at delays d1 and d2, their separation may reflect multipath, a periodic preamble, receiver filter ringing, or more than one source. The recorded statistic ought to retain the number of significant peaks, their relative ratios and the algorithm used to select a frame boundary. If an absolute timestamp is important, the result must include clock calibration, sample-counter continuity and acquisition latency rather than presenting the first above-threshold event as a direct physical emission time. A fixed digital buffer can be released several milliseconds after sample acquisition by an operating system or transport protocol. A reader who sees precisely repeating software event times may mistake the buffering cadence for the transmitter's radio schedule. A good record preserves the distinction between acquisition time and notification time.

Copyright 2026, James M. Atkinson

Error correction raises a particular temptation. If a decoder succeeds in producing a valid codeword, the examiner may be inclined to believe that the originating source is identified by that success. In fact the decoder tests constraints shared by every implementation of the selected code. A valid syndrome or successful parity check can support a code-family hypothesis and, in a controlled reference experiment, indicate that the channel has not defeated decoding. It does not tell us which of several independent coding engines produced the same allowed word. Nor is a decoded message needed to investigate the public synchronisation field. The laboratory can use known synthetic reference frames, restrict recorded field observations to authorised non-content intervals, and test the decoder's error-correction properties without examining private payload information.

Copyright 2026, James M. Atkinson

The final inferential statement must distinguish compatibility from absence of contradiction. An observation may be compatible with a named technical format while also being compatible with other formats that share the same training structure. Some waveform families reuse or modify preambles between versions, and an arbitrary correlator can be designed to respond to several. The analysis should list material alternatives and explain what measured feature would discriminate them. An unexamined alternative cannot be rejected because it did not appear among the investigator's software menu choices. Open-set testing with a source not present during model construction is therefore important. A robust method should be allowed to report uncertain or unknown rather than force every measurement into one named device category.

Copyright 2026, James M. Atkinson

I commend a simple evidential ledger for each test sequence. Record the public source of the expected marker, its length and modulation representation, the observation interval, the receiver's timing and frequency estimates, the competing offsets, the assumed null model, the total number of searches, the false-acquisition calibration, and the tested alternative transmitters. Put a separate column for device-specific conclusions and leave it blank where the training field alone cannot justify one. The empty cell is a scholarly virtue. It tells the next reviewer exactly which question remains unanswered, rather than allowing the elegance of code theory to disguise a gap in the chain of inference.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Peer Question: Dr. Elias, I should like to test whether your receiver can genuinely distinguish a candidate pattern from an artefact of its own finite decision procedure. Consider a perfectly specified algorithm that searches an interval for a known marker and then reports only the highest-scoring offset. If I feed that algorithm structured but noncompliant test material, it must still choose a maximum, even when no actual frame was transmitted. Might the algorithm then yield repeated confident classifications merely because its input structure, filter memory and search interval remain fixed? What independent test would show that it recognises an actual transmitted public preamble rather than a mathematical coincidence under the algorithm's restricted set of allowed outputs? Please explain why a reproducible program is not necessarily an accurate programme of physical measurement, and specify how you would retain negative controls and failed acquisitions in the audit record.

Copyright 2026, James M. Atkinson

Would it be possible to construct a negative control that yields the same numerical peak distribution without any compliant transmitter being present, and what would that imply for the claimed identification?

Copyright 2026, James M. Atkinson

Peter Elias, Response: Dr. Turing, you have placed the decisive distinction between an optimisation and a hypothesis test. Every finite set of real-valued scores has a maximum, but the existence of the maximum does not establish that any candidate was generated by the physical source the programme assumes. A forced-choice correlator can therefore assign a 'best' preamble to thermal noise, interference or structured noncompliant input if its design forbids abstention. The experimental question is whether the score exceeds a threshold calibrated under adequate alternatives, with an explicit probability of false acquisition, rather than merely whether one candidate outranks the others. A valid implementation should record 'no accepted match' when the evidence is insufficient. It should not manufacture source certainty by hiding that alternative from the user interface.

Copyright 2026, James M. Atkinson

Your proposed test ought to preserve both the positive reference trials and a broad suite of negative controls. Controls should include receiver thermal noise, nonmatching benign reference waveforms, strong narrowband interference, synthetic repeated patterns deliberately selected to confuse a correlator, and blank acquisitions with exactly the same record lengths. Each control should pass through the identical gain, filtering, timing and reporting pipeline, not through a simplified calculation that omits the source of the false pattern. The statistic should be the largest score over all attempted offsets and templates if that is how the instrument actually operates. Record the number of tested alignments, accepted false candidates and cases in which the detector abstains. A threshold calibrated against one nonrepresentative noise distribution may not remain valid when the spectrum becomes impulsive or coloured.

Copyright 2026, James M. Atkinson

Reproducibility is necessary but not sufficient. A program can reliably produce a misleading answer when its physical assumptions are false. An algorithm that uses a fixed local oscillator offset, for example, may repeat the same apparent mismatch under two source trials because the receiver has not changed. A repeated acquisition timestamp may reflect the operating system's buffer-release cadence rather than an RF event. One can test these failures by changing the input at the hardware boundary and the timing of the processing pipeline independently. Confirm source events with an independent acquisition channel and known reference triggers. When an effect vanishes under an independently timed receiver but persists under one software process, the software or its clock becomes a candidate explanation. The proper conclusion is a documented detection capability under tested conditions, not an assertion about the identity of a transmitter that was never independently labelled.

Copyright 2026, James M. Atkinson

John von Neumann, Peer Question: Dr. Elias, let us turn to error distributions and independence. Your sixteen-bit example presumes fair independent bits and independent search positions, even as you warn that neither assumption is generally true for the actual instrument. How would you build a calibration experiment whose false-match probability can be defended when training sequences overlap, receiver filters introduce memory, and the sample clock may itself wander? I am particularly interested in whether a simulation that matches only the measured power spectrum but not higher-order temporal dependence could underestimate false acquisition. Should the investigator use block resampling, physical null recordings, analytical bounds, or several of these methods together? Finally, what does the resulting false-match estimate tell us about the probability of a particular physical source if all compatible devices share the same public frame delimiter?

Copyright 2026, James M. Atkinson

The error estimate should also distinguish a calibration sequence with intermittent high-power disturbances from a stationary Gaussian model, because the tails of the resulting score distributions need not agree.

Copyright 2026, James M. Atkinson

Peter Elias, Response: Dr. von Neumann, I would use multiple calibration strategies precisely because a single idealised null is fragile. Physical null recordings collected through the actual receiver and antenna capture the analogue noise, filter memory, local interference and instrument-specific decision process at the time of the test. They do not automatically represent every future environment, so their scope must be stated. Block resampling can be useful where the measured disturbance has a dependence scale that can be estimated, but the resampling unit must be long enough to preserve the local temporal structure relevant to the matched filter. A simulation may provide controlled stress cases, yet matching only a power spectrum can miss impulsive amplitude distributions, burst clustering or nonlinear clipping. The result should show sensitivity to plausible null models rather than conceal it.

Copyright 2026, James M. Atkinson

I would calibrate the actual maximum over offsets and candidate formats, not a single prechosen alignment. For each reference record, run the entire instrument pipeline and retain its largest statistic, the corresponding offset and the count of secondary peaks. The false-match tail can then be estimated with an uncertainty interval based on the number of independent calibration records. Ten thousand null records in which no false alarm occurs do not demonstrate zero error probability; they provide a finite upper confidence limit under the tested acquisition distribution. Simple one-sided binomial bounds, when independence of records is warranted, can serve as a conservative guide. If the records arise from one uninterrupted correlated capture, however, their nominal count overstates the available independent evidence.

Copyright 2026, James M. Atkinson

Even excellent calibration of false matches against noise does not establish device identity. Suppose every compatible device emits the same public field; the likelihood of a genuine recognised field may be similar under all those physical-source hypotheses. A low false-alarm rate against noise means the detector is good at separating signal-like structure from tested disturbances. It does not mean it can separate among compliant transmitters. Attribution requires a second experimental axis, with different physical sources interchanged under independently controlled propagation and receiver conditions. Report the confusion matrix over source classes, unknown-source rejection and source-session stability. The honest investigator presents separate uncertainty figures for 'was this public field present?' and 'which, if any, physical device emitted it?' because the first question may have a good answer when the second has none.

Copyright 2026, James M. Atkinson

Peter Elias, Cross-Peer Question to Irving S. Reed: Dr. Reed, the successful decoding of a valid block-code structure may appear to reinforce a public preamble match. Yet a code is intentionally shared among compatible equipment, and its parity constraints are properties of an allowed language rather than its physical author. How should we distinguish a valid syndrome, a recognised public marker and source-dependent analogue behaviour so they are not mistakenly counted as three independent indicators of identity? Could a public test-code implementation be re-used across products in ways that create common mismatch patterns under the same receiver, and how would you isolate that from actual radio hardware differences? I ask also for an experiment involving independent code implementations and a fixed RF front end, followed by an experiment involving different RF front ends using the same public code, to make the causal distinctions visible.

Copyright 2026, James M. Atkinson

Could the experiment also distinguish errors caused by a common receiver-decoder library from errors caused by the radio front ends themselves, while ensuring that neither test accesses a protected message?

Copyright 2026, James M. Atkinson

Irving S. Reed, Cross-Peer Answer to Peter Elias: Dr. Elias, a parity check is a test of membership in a code, not an authorship certificate. If a public linear block code is described by a parity-check matrix H over the chosen finite field and a received hard-decision word is r, its syndrome is s=Hr transposed. A zero syndrome is consistent with a valid codeword but does not guarantee absence of errors, because a nonzero error that is itself a codeword can also yield zero syndrome. Equally, if two products implement the same code, the valid parity relations are the same by construction. Treating preamble recognition, parity consistency and codeword membership as independent source identifiers would multiply information that may largely arise from a common standard and shared decoding decision. A forensic report should separate them as distinct diagnostic stages while preserving their dependencies.

Copyright 2026, James M. Atkinson

In your proposed factorial trial, begin with one controlled RF output chain and feed it public training sequences generated by independently implemented coding software. If their ideal sequences and analogue output agree under the defined public specification, the receiver ought not infer different physical transmitters from code structure. Next hold the public digital sequence and its software generation fixed while changing the physical output devices under carefully balanced propagation paths. Any observed distinction then requires a physical-feature explanation and a fresh validation; it cannot be assigned to the public code. Include a third test in which the receiver's equaliser, sampling clock or decoding threshold changes while the source remains fixed. If apparent device signatures move with the receiver, those signatures do not have the required source invariance. The result may be a defensible class-level observation, but a unique transmitter conclusion remains dependent on further independently validated evidence.

Copyright 2026, James M. Atkinson

A practical extension would blind the analyst to the assignment of the independently implemented encoders while keeping the same public reference vectors and the same acquisition software. Record the decoder's choices of timing offset and parity interpretation before revealing which implementation generated each trial. If the supposed fingerprints follow the encoder or receiver software after the RF chain is exchanged, a claim about physical emitter identity has failed. Conversely, a feature that follows an output device through changes of code implementation, receiving antenna and gain state may merit further investigation, but only under a fresh held-out design with unknown-source rejection. A valid syndrome remains a code-consistency result, not a signature of individual authorship.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Reed, thank you for distinguishing membership in a shared code from physical authorship. Please take the principal token and develop the relationship between valid algebraic structure, receiver acquisition errors and claims of transmitter-specific behaviour. I should particularly like you to distinguish a reproducible decoder result from a reproducible analogue characteristic of the transmitting equipment.

Copyright 2026, James M. Atkinson

Irving S. Reed, Fourth Principal Contributor: It is a common error to imagine that because a received radio frame satisfies a complicated algebraic test, the frame must have originated in one complicated and therefore identifiable piece of hardware. The first half of that sentence concerns membership in a public mathematical language; the second concerns a particular object. There is no general logical bridge between them. Many devices implement identical block codes, convolutional codes, scramblers, cyclic redundancy checks and publicly specified synchronisation markers. The engineering purpose of a shared construction is to let different devices communicate or permit different receivers to recognise the same format. A valid algebraic relation can strongly support a format or coding-family interpretation and still carry no individual-source information. The investigator should therefore make a written distinction between the observed public symbol structure, the decoder's treatment of it, and the RF hardware properties that were not tested by the algebraic check.

Copyright 2026, James M. Atkinson

Let a linear block code have length n, dimension k, and parity-check matrix H with n−k rows over a specified finite field. An ideal transmitted codeword c satisfies Hc transposed equals zero. A received hard-decision vector r=c+e contains an error vector e, and the syndrome becomes Hr transposed=He transposed. If this is zero, the result is consistent with an allowed codeword but cannot generally prove that no error occurred or identify the coding engine. Different physical sources using the same H produce the same set of allowed codewords. Moreover the hard-decision vector is not a direct physical measurement: it depends on carrier synchronisation, channel equalisation, sampling instant, quantisation and receiver thresholds. Two receivers can produce different syndromes from the same authorised RF burst if their decisions differ. This is a useful diagnostic limitation, not a defect in algebra. It forces one to say what the check actually checks.

Copyright 2026, James M. Atkinson

Consider a controlled example using a synthetic block code with n=15 and k=11, so four parity constraints are available under the declared field and full-rank H. No claim of a particular commercial standard is needed. A receiver may accept a 15-symbol reference record because its syndrome vanishes, yet many different transmitters could have generated exactly that codeword. If the examiner searches a long noisy record for any 15-symbol segment with zero syndrome, some will satisfy the algebraic constraint by chance. Under an oversimplified model of uniform independent 15-bit candidate vectors and a full-rank four-row binary H, the fraction satisfying all four parity constraints is 2^(-4)=1/16 at one prespecified position. Searching 160 independent candidates would yield an expected ten valid-syndrome patterns even without a legitimate coded frame. Overlapping candidates and receiver dependence change the full false-match calculation, so this number is an illustrative counting argument, not a field detection rate. The error is treating validity as rarity without specifying the population and the search.

Copyright 2026, James M. Atkinson

A second confusion arises when distinct publicly specified fields are combined. Suppose the examiner recognises a training sequence, a frame delimiter and a valid parity structure. Those may be three useful engineering checks, but their probability under a compliant-frame hypothesis can be jointly high because the standard requires all three. Calling them independent proofs of one physical instrument would be unjustified. Even in a source-classification study, their conditional dependence must be measured: the same inaccurate frame-boundary estimate may influence the training match, delimiter position and parity result. A successful receiver decoder can yield a beautifully consistent set of dependent outputs while the initial synchronisation hypothesis remains wrong. The correct experiment varies the underlying timing error and checks whether all three indicators move together, exposing their shared cause.

Copyright 2026, James M. Atkinson

Hardware fingerprints, if pursued within lawful controlled reference experiments, pose a different set of measurement questions. An RF front end may exhibit power-amplifier distortion, oscillator error, filter group delay, phase noise or amplitude transitions. But what reaches the observer is a composition of transmitter behaviour, antenna and propagation, receiver front end, clock recovery and digital processing. A radio's oscillator error cannot be estimated in isolation without knowing the receiver's oscillator; the recorded value is a relative quantity. A nonlinearity seen under high received power may arise from receiver saturation rather than transmitter intermodulation. A fingerprint classifier that uses one fixed receiver and one bench location may learn the measurement apparatus. Thus feature stability must be tested across receiver changes, calibrated power levels, temperature, antenna orientation and fresh acquisition sessions before one can assert that it belongs primarily to the source.

Copyright 2026, James M. Atkinson

A practical factorial experiment would compare software and hardware interventions independently. Use two independently written encoders that produce the same published test sequence, route them through the same authorised RF chain, and ask whether the analyser separates them. If it does, the separation may reflect implementation timing or unintended differences in the generated waveform rather than a unique RF unit. Then use one frozen digital waveform to drive two independent RF output devices through a balanced cabled configuration, before repeating over the air with switched receiver positions. If the proposed fingerprint persists only in the over-the-air setting, path and antenna effects are suspect. Finally vary the receiver oscillator and filtering while preserving the RF source. A suitable report shows how the model's apparent discrimination changes under each intervention, including cases in which the model properly abstains.

Copyright 2026, James M. Atkinson

The temptation to call a small error pattern unique is especially hazardous where the candidate population is underspecified. A training-field mismatch sequence measured on two trials is one observation from a potentially large and correlated family of nuisance conditions. A repeated location of an error may be caused by a deterministic equaliser coefficient, known pulse shaping or a shared firmware bug. One could examine whether the pattern persists across receiving chains and between independent source lots, but that produces a bounded comparative claim, not a mathematical proof of unique identity. If a rare error pattern is itself used to select the candidate source, a subsequent statistical claim about its rarity must account for that post-selection process. The final scoring rule should be fixed before the independent validation, with uncertainty intervals for both false acceptance and true-source rejection.

Copyright 2026, James M. Atkinson

I would make an investigator maintain separate ledgers for the public-code facts and the physical-source hypotheses. The first records published sequences, frame lengths, valid parity relations, tested tolerances and the measured acquisition score. The second records source classes, measurement conditions, alternative physical explanations, blind allocations, channel controls and independent replication. The two ledgers may be linked by an explicit hypothesis, but their entries should not be merged merely because one receiver software package displays them on a common screen. This discipline prevents a legitimate engineering decoder from being elevated into a forensic identification oracle. It also guards against overcollection: the public training sequence can be tested with synthetic references and bounded non-content observations rather than retaining private message payloads merely to decorate the report with additional codewords.

Copyright 2026, James M. Atkinson

Finally, I would require a final sentence that describes the strongest defensible inference and its boundary. It might say that an authorised burst contained a candidate synchronisation field and parity structure compatible with a stated public format within specified receiver uncertainty. It might separately say that repeated analogue measurements distinguished certain laboratory reference equipment classes under controlled conditions. It should not say that the public field identified one unique transmitter unless independent source-specific evidence warrants that proposition. Standards compliance is designed to create similarity among devices. A scientifically admirable detector must therefore be willing to recognise similarity without imagining individuality. In the court or an engineering review meeting, that modest distinction is the difference between a measurement and a conclusion placed upon it.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Peer Question: Dr. Reed, I should like to introduce spatial selectivity into your factorial design. Suppose the analyser observes a code-compatible burst with one antenna oriented towards a known laboratory source, and a second measurement from a rotated antenna produces a different correlation peak shape. The analyst might interpret this apparent reproducibility with angle as an individual transmitter property. But the antennas, multipath field, receiver gain and source polarisation are all capable of changing the result. How would you distinguish the spatial signature of the channel from a feature of the source? Would you prefer repeated measurements from a simultaneous calibrated receiving array, or controlled rotation of a single antenna with independent event timing? Please specify what uncertainties must be assigned when observations at different angles were made at different times, especially if the public synchronisation interval is short and the transmitter operates intermittently.

Copyright 2026, James M. Atkinson

Should the apparent feature also be tested with the transmitter's own antenna replaced by a calibrated load, so that source radiation and propagation can be distinguished from the receiver's directional response?

Copyright 2026, James M. Atkinson

Irving S. Reed, Response: Dr. Bracewell, spatial selectivity should be treated as an observation mechanism to be calibrated, not a source identifier merely because its plot looks distinctive. A simultaneous calibrated receiving array can reduce temporal mismatch when it records the same authorised event at several elements, but each channel needs phase, gain, delay and polarisation calibration. Controlled rotation of one antenna can be useful where the source and propagation remain demonstrably stable; for an intermittent or moving source, however, measurements collected at different times cannot automatically be assembled into one instantaneous spatial pattern. The uncertainty should include event timing, antenna position, the possibility of missed bursts and changes in source power or orientation. An apparent angular null may be caused by the antenna pattern or multipath rather than a special feature of the emitter.

Copyright 2026, James M. Atkinson

I would first characterise the receiving antennas with a permitted fixed reference source and document their response over the tested angles. Then move or rotate the source under concealed and independently recorded conditions, repeating the public training field while maintaining a second simultaneous monitor to establish which bursts truly occurred. The monitor's role is to distinguish non-detections from occasions when there was simply no eligible RF event. Where an array is used, its steering-vector assumptions should be tested against injected and radiated references, including changes in polarisation and delayed reflections. A feature that follows the receiver antenna after an exchange of source locations is not a stable individual-source characteristic, even if the corresponding correlation profile can be reproduced with precision.

Copyright 2026, James M. Atkinson

I would also compare the source attribution rule with and without the direction-dependent features. If its accuracy falls sharply when the source and receiver positions are swapped, it has probably learned some part of the geometry or environment. That is not useless information for locating or classifying observations, but it must be reported as conditional on the spatial setup. A code match plus an angle-of-arrival estimate can support two different statements: the field has a compatible public structure, and the energy was observed from a particular direction within the array's calibrated uncertainty. Neither statement, separately or together, proves the serial identity of the radio that generated it. The final ledger should preserve the distinct calibration records and the temporal eligibility of every measurement. Without them, the analyst's confidence will be an artefact of joining incompatible observations into one apparently coherent picture.

Copyright 2026, James M. Atkinson

Irving S. Reed, Cross-Peer Question to David Slepian: Dr. Slepian, we have distinguished code membership, successful synchronisation, and possible analogue differences. I should like you to frame the final decision problem. If an observer searches an unknown spectrum, the number and prior frequency of eligible physical sources are not generally known; yet an instrument may return a confident score for one familiar device model. Under what conditions is such a score merely a closed-set ranking rather than evidence of an individual transmitter? How would you construct a defensible rejection region for unrecognised sources and choose the costs of false attribution versus missed classification? Please address the dependence among public-field and analogue features, the selection of a threshold after viewing the trials, and the need to report uncertainty for the actual hypothesis tested, not the hypothesis a user wished the measurement to answer.

Copyright 2026, James M. Atkinson

How should one describe a confidence score if no laboratory sample represents the many unknown compliant sources that could plausibly transmit exactly this public sequence, and why must an abstention remain a valid output?

Copyright 2026, James M. Atkinson

David Slepian, Cross-Peer Answer to Irving S. Reed: Dr. Reed, I would start with a declared set of hypotheses and permit a rejection or unknown outcome. A closed-set classifier whose labels are A, B and C must output one of those labels even if a completely unfamiliar device D supplies the observation, unless the algorithm has been given a separate open-set decision rule. Its high internal score may indicate that D most resembles A within the training representation; it is not a calibrated probability that A physically emitted the signal. A decision system that operates outside its reference population therefore needs tests involving deliberately withheld source classes and conditions not used to choose its thresholds. The false-acceptance cost should reflect the consequence of unjustified attribution, while the false-rejection cost reflects loss of a potentially useful but uncertain equipment-class clue.

Copyright 2026, James M. Atkinson

The feature vector should be divided into public-format components, receiver-condition components, propagation-sensitive components and candidates for source-related physical features. Their joint distribution under each declared hypothesis matters. Multiplying individual likelihood ratios is valid only under a corresponding conditional independence model, which the data must support. In a comparison of sources sharing an identical public synchronisation field, the public-field component may contribute nearly no discrimination among them, even though it contributes strongly to detection against noise. Any threshold used for attribution must be chosen on independent calibration records, with a separate test set reserved for its claimed field performance. Report the error rates for unfamiliar devices, receiver substitutions, changes in frequency and the cases in which the classifier refuses to decide.

Copyright 2026, James M. Atkinson

The conclusion should be expressed as a bounded likelihood or calibrated comparative score between specified hypotheses. It must not silently substitute the probability of observing the public field under A for the probability that A transmitted the field. If no representative alternative-source population can be defined, the analyst should avoid numerical individual-attribution probabilities altogether. One can still give a useful account of waveform compatibility, quality of synchronisation, temporal evidence and the limitations of the physical features. An abstention is often the correct statistical decision when the question exceeds the experiment. That is not a defect in the instrument. It is the instrument declining to make a claim its training and calibration do not warrant.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Slepian, I now pass you the principal token for our concluding examination. Please explain how the limits of inference should be incorporated into the decision rule, the reporting language and the independent verification of a public synchronisation-field observation.

Copyright 2026, James M. Atkinson

David Slepian, Fifth Principal Contributor: The receiver's job and the investigator's task should be separated before one writes down any decision rule. The receiver often asks whether a certain pattern is present, whether timing is sufficiently aligned to continue processing, or whether a frame belongs to a recognised signalling family. The investigator may instead ask which transmitter emitted the energy, where that transmitter stood, or whether a particular person controlled it. These are different statistical propositions and they require different evidence. A public training field is often a well-designed answer to the first set of questions and a poor answer to the second. If the engineer allows one score to stand for all these propositions, the resulting report will appear compact and impressive, but its uncertainty will have been attached to the wrong question.

Copyright 2026, James M. Atkinson

Let H0 denote the hypothesis that no compatible public training field is present under a specified set of disturbances, and let H1 denote the hypothesis that a compatible field is present from some permitted source. A detector using statistic T(Y) with threshold τ may be calibrated for P(T(Y)>τ given H0)=α, where α is its false-alarm probability under the stated null model. Its detection probability under H1 is P(T(Y)>τ given H1), which will depend upon signal level, frequency offset, channel delay, receiver quality and which compatible waveform variants are included. Neither error rate is an individual-source attribution probability. To pose a source comparison one needs additional hypotheses H_A and H_B with their own observation distributions, calibrated nuisance-variable ranges and a decision rule that can decline to choose. If H_A and H_B produce the same public sequence under similar conditions, the synchronisation score alone has little power to separate them.

Copyright 2026, James M. Atkinson

An engineering specification may quite properly reward detection of a familiar public preamble over a wide signal-to-noise range. That success does not diminish the need for careful field interpretation. A receiver can have a 99 per cent detection probability for a training field and be unable to discriminate at all among the compliant transmitters that use it. Suppose, for an explicitly hypothetical controlled experiment, source A and source B each transmit the same field; the algorithm recognises a field in 990 of 1000 eligible trials for A and 988 of 1000 for B. The difference between 99.0 and 98.8 per cent is small and subject to ordinary sampling uncertainty. It cannot rationally be converted into a source fingerprint. If the analyst searched many thresholds and then reported only the one that produced the largest apparent difference, the need for an independent validation is greater still. The correct observation is that the detector is effective at recognising the shared field in those tested conditions.

Copyright 2026, James M. Atkinson

We must also take account of the base-rate problem. Even a strong source-classification likelihood ratio may produce a modest posterior when the candidate source is rare among the alternatives. If a field source could have been any of many compliant radios, the public preamble is common to the entire class and supplies no unique name. An observer who selects one particular transmitter because it is suspected and compares it only with thermal noise has tested the wrong alternative. The relevant alternative may be another compliant source, a synthetic authorised test signal, a replay of the public training interval or a receiver artefact. A defensible evidence report states which alternatives were actually measured, which are merely possible and which could not be investigated. Its level of conclusion is bounded by the alternatives considered; no exact mathematical notation can repair an absent comparison population.

Copyright 2026, James M. Atkinson

A useful operational framework records three decisions independently. The first is acquisition: did a public synchronisation hypothesis pass a declared threshold under an instrument-calibrated null? The second is format: is the complete non-content observation compatible with a declared physical-layer family, and which alternative formats remain plausible? The third is source: are separately measured physical features sufficient to distinguish reference equipment classes under independent validation, with an unknown-source rejection option? It may be legitimate to say yes to the first, perhaps to the second, and no to the third. The report should not collapse this sequence into one green indicator labelled 'identified'. A hierarchy of claims is a safeguard against the ordinary human tendency to read an instrument's neat display as greater certainty than the experiment provides.

Copyright 2026, James M. Atkinson

There are distinct uncertainties in the process. Timestamp uncertainty arises from clock calibration, acquisition path delay and definition of the synchronisation event. Frequency uncertainty arises from the relative transmitter and receiver oscillators and estimator variance. Sequence uncertainty arises from the number of candidate templates and offsets searched, the selected correlation peak, interference and channel distortion. Model uncertainty arises from omitted formats and unknown source classes. Forensic uncertainty arises from custody and processing history, including whether the test data can be connected to the event described in the report. These terms should not be combined into one unexplained confidence score. Some may be probabilistic, some may be bounds and some are unresolved qualifications that no reasonable numerical percentage can absorb.

Copyright 2026, James M. Atkinson

We also have a question of repeatability. An investigator might observe the identical public sequence in one room on successive days. That repetition may make the signal-format description firmer, but it does not necessarily make an individual-source conclusion firmer because a number of devices may use the same public marker. The correct repeatability experiment changes the source and the measurement environment deliberately, then asks whether the inference survives the change. Repeat the observations with different receivers, hold out reference device types and test the processing software against synthetic counterexamples. When the experiment is blinded, the analyst cannot adjust the field windows and thresholds to fit source labels. If a claim fails in this independent trial, one must report the failure even though the original matching plot remains aesthetically persuasive.

Copyright 2026, James M. Atkinson

A report that preserves the limitation can nevertheless assist security work. It may document that a previously absent compatible waveform class has appeared, that a public preamble occurs at a new frequency or duty cycle, or that a measured signal level changes in a specified location. Those findings can motivate lawful, proportionate further investigation without accusing a named device or operator. A laboratory may supplement them with authorised reference sources and differential receiver tests, while minimising any collection of protected communications content. The fact that public synchronisation information is accessible does not justify retaining every subsequent payload bit. The methodology should specify the least information needed to answer the detection question, the retention period appropriate to that purpose and the process for documenting analytical transformations.

Copyright 2026, James M. Atkinson

I would close with a practical criterion. The evidence becomes unreliable for identifying a particular transmitter whenever the asserted individual distinction rests on a field intentionally shared by multiple devices, on an uncalibrated analogue feature, on a receiver-dependent choice of synchronisation offset, or on a reference set that excludes credible alternatives. This criterion does not declare all RF attribution impossible. It declares that each level of specificity requires its own tested evidence. A competent instrument can recognise the common synchronisation language while refusing to invent the speaker's identity. In an engineering manuscript, as in a well-conducted scientific hearing, restraint in the conclusion is a necessary consequence of precision in the measurement.

Copyright 2026, James M. Atkinson

Antony Hewish, Peer Question: Dr. Slepian, I am concerned with the fleeting observations that field investigators often record. Imagine that a public synchronisation field appears in a brief burst only once or twice during a period of intermittent monitoring. The receiver visits the relevant frequency at discontinuous intervals, and its local clock may be imperfectly disciplined. Could the existence of two attractive correlation peaks be sufficient to infer that one physical emitter recurred, or might the same public waveform have been transmitted by different compatible sources at different times? Please address how the monitoring system should count occasions when it had no observation opportunity, the possibility of delayed receiver acquisition, and whether a second independent receiver can help without itself identifying the transmitter. I should also like a reporting formulation that avoids turning a pair of sparse detections into an invented history of one persistent radio.

Copyright 2026, James M. Atkinson

Would your conclusion change if those detections were reported only after software-buffer flushing at regular intervals, rather than timestamped at the physical sample acquisition boundary?

Copyright 2026, James M. Atkinson

David Slepian, Response: Dr. Hewish, two matches to a shared public field do not by themselves prove recurrence of the same physical source. They establish that the monitoring apparatus recorded two candidate events compatible with a stated training format, provided the detector was adequately calibrated. The events may originate from one source, two different compliant sources, a controlled authorised replay or an instrument artefact. Their chronological separation supplies a measured interval, not a pedigree. A frequency-scanning receiver may have been blind between visits, so the number of unobserved source events is unknown unless an independent continuous reference supplies a defensible bound. An absence of detector output cannot be read as a physical absence when the receiver was not looking or had insufficient sensitivity.

Copyright 2026, James M. Atkinson

I would require the instrument to preserve an observation-opportunity register. For every survey interval, record the frequency being monitored, effective dwell after retuning and settling, channel bandwidth, detection threshold, gain state and sample-counter continuity. Mark gaps in which no eligible observation was possible, including periods lost to data transport or processing overruns. When a candidate match occurs, retain its timestamp uncertainty, correlation statistic and competing timing offsets. A second independent receiver can corroborate that RF energy with compatible public structure existed at a particular time, and may help separate a receiver-local fault from a propagated event. But if both receivers detect the same shared public sequence, neither has thereby established that an individual, named transmitter emitted it.

Copyright 2026, James M. Atkinson

The report should use cautious language such as: 'Two candidate bursts compatible with the specified public synchronisation sequence were recorded at the stated times, within the documented acquisition and clock uncertainties. The available data do not establish whether they originated from the same physical transmitter.' If a measured physical feature appears consistent across events, name that feature and the environmental tests it passed, without silently upgrading it into unique identity. If the observation opportunities were intermittent, include the coverage denominator so recurrence rates and occupancy estimates cannot be mistaken for continuous monitoring. The same discipline applies to a statistically convincing periodic interval: it may be informative about traffic behaviour under a particular observation process while remaining ambiguous about the source. In a forensic record, that ambiguity must remain visible rather than being smoothed away by a continuous line drawn between two isolated detections.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: I thank the contributors for a disciplined examination. A public synchronisation sequence may strongly support recognition of a physical-layer format, but it does not ordinarily identify an individual transmitter. The record shall preserve independently tested source hypotheses, acquisition and timing uncertainties, the search process and alternative explanations. I now close Question 089 and pass the token to the subsequent question concerning proportionate, privacy-conscious recording of communication-related observations.

QUESTION 090

Copyright 2026, James M. Atkinson

How can a surveillance report avoid unnecessary communication-content collection?

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Admiral Hopper, please begin with the architecture of a defensible record. I ask you to distinguish what the instrument has measured from what its software can store, and to explain why a system able to preserve an entire complex-sample stream should not automatically do so. The contributors' remarks are fictional scholarly reconstructions undertaken for a lawful defensive engineering thought experiment.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Principal Contributor: The question presents two systems whose apparent similarity should not obscure their separate purposes: a measuring instrument and a record-keeping apparatus. A receiver turns electromagnetic input into digital data through antennas, filters, gain stages, mixers, conversion and software. A reporting system turns selected observations into propositions that another person can investigate, challenge and preserve. The ability of the first system to produce a large quantity of samples does not establish that the second has a purpose for retaining them. I would begin by writing down the decision to be supported, the admissible observation fields, the period for which each is necessary and the verification procedure by which a reviewer may reconstruct the reasoning. A system that stores every waveform because storage is cheap may later be unable to explain why the incidental communications of unrelated persons were retained. That is not an improvement in engineering.

Copyright 2026, James M. Atkinson

Let the authorised detection question be whether a defined segment of spectrum contained a reproducible, unexplained emission during a specified site survey. The report may need the frequency, observation interval, timestamp uncertainty, estimated bandwidth, received level, noise-floor reference, detector settings, antenna position and equipment-calibration identity. It may also need the count of missed observation opportunities, because silence from a scanning receiver is not proof that no source transmitted. Those data are not automatically sufficient for every possible hypothesis, but they give the investigator a clear basis for deciding what additional acquisition would change the result. A public training-field detection might add format compatibility to the evidence; it does not authorise the investigator to read the private content that follows. Similarly, the existence of a software demodulator or a large disk does not supply the purpose or legal authority that the measurement plan lacks.

Copyright 2026, James M. Atkinson

I would design the reporting interface around explicit data types and their provenance. A timestamp should be labelled as hardware acquisition time, receiver-reported time or later host-processing time; they are not interchangeable. A received-level field should state whether it is an absolute calibrated measurement, a relative estimate or simply a threshold-crossing indicator. A signal-class field should distinguish an observed feature from a speculative device identity. Each electronic record should carry the instrument configuration and processing software version sufficiently precisely that a later reviewer can understand its transformations. This is an engineering application of disciplined information management: the representation must not insinuate greater certainty than the experiment establishes. A neat screen filled with green confidence indicators is not a substitute for preserving the conditions under which those indicators were produced.

Copyright 2026, James M. Atkinson

The two proposed pipelines need a fair comparison. It would be dishonest to disable the metadata pipeline's useful technical measurements and then declare full-IQ storage indispensable. Instead require both pipelines to operate with the same reference event schedule, antennas and declared thresholds. Pipeline M preserves the smallest set of non-content values capable of reproducing the authorised detection decision. Pipeline I preserves those same values and an additional IQ segment. An independent reviewer then asks which predefined decisions each can support, how often each creates false associations, what analytical uncertainties each resolves and what unrelated information might be incidentally retained. If the IQ record reveals a previously unknown receiver artefact essential to avoiding a serious false accusation, the experiment has identified a legitimate potential benefit. The next question is whether a narrower triggered segment, diagnostic statistic or controlled reference-capture procedure would supply that benefit with less exposure.

Copyright 2026, James M. Atkinson

One must design the process for exceptional cases before the exceptional case occurs. If an anomaly genuinely requires short authorised sample retention for independent validation, the system should require a recorded justification, a bounded start and stop, access control and a disposition rule. The exception should not silently become the default. The user of the instrument must know which transformations are reversible and which measurements are summaries that discard information. A histogram of received levels cannot necessarily reconstruct the phase of a short interference burst, and a list of correlation peaks cannot reproduce every candidate offset. These limitations should be stated frankly. But the fact that a summary cannot answer every imaginable future question is not, by itself, an adequate reason to retain everything that passed through the analogue-to-digital converter.

Copyright 2026, James M. Atkinson

For a worked hypothetical study, suppose the authorised event reference contains two hundred seeded benign transmissions and two hundred matched null observation intervals. If the metadata-only pipeline detects 190 actual events and gives ten false alarms while the full-IQ pipeline detects 193 and gives nine, the resulting sensitivities are 190/200=95.0 per cent and 193/200=96.5 per cent, and the false-alarm proportions per stipulated null interval are 10/200=5.0 per cent and 9/200=4.5 per cent. These fractions say nothing about payload necessity unless the extra three detections or one avoided false alarm would change the declared defensive decision, and unless the difference is tested with suitable uncertainty analysis. The scenario is a demonstration with invented numbers, not reported instrument performance. Even a measurable performance advantage for a full-IQ method does not imply that indefinite or unrestricted retention is justified. The experiment must connect each incremental data field to a defined and authorised use.

Copyright 2026, James M. Atkinson

A serious technical record should make subsequent review possible without silently broadening the surveillance objective. A reviewer may need to reproduce the numerical threshold and understand the receiver's calibration, but that does not mean a reviewer should be given access to incidental speech or data content unrelated to the security question. Access rules, redaction procedures and custody documentation are therefore part of the measurement architecture, not an afterthought added by the legal department. A design that separates public format information, occupancy measurements and retained content gives both engineering teams and institutional reviewers a way to see the consequences of each acquisition choice. In an instrumented survey the best record is not necessarily the largest record. It is the smallest reliable and adequately contextualised record that permits the authorised question to be answered and independently challenged.

Copyright 2026, James M. Atkinson

I should like the subsequent panel to press the issue further. Mr. Turing should test how an algorithm may silently preserve more than its published report suggests; Mr. Davies should consider network transport and logs that replicate incidental samples; Dr. Shannon should examine whether a summary statistic retains the information required for the predeclared decision; and Professor Dijkstra should insist upon machine-enforceable controls that prevent a temporary engineering convenience from becoming an unlimited collection channel. Their objections will help identify the boundary between legitimate engineering reproducibility and avoidable acquisition of protected material. That boundary must be built into the system before an investigator sits at the console and hears the steady ticking of new event records accumulating on its storage device.

Copyright 2026, James M. Atkinson

Jacob Ziv, Peer Question: Admiral Hopper, your two-pipeline experiment seems well constructed, yet its principal vulnerability may be the choice of summary fields before the investigators have discovered the receiver defect. Compression reminds us that a sufficient representation depends upon the class of questions one is entitled to ask. Suppose a momentary overload of the front-end produces a convincing emission whose displayed centre frequency, bandwidth, level and timestamp are indistinguishable from those of a seeded signal. A raw complex-sample segment may reveal clipping or image products, whereas the metadata record hides both. What predeclared procedure permits the investigator to recognise such a deficiency without making unrestricted waveform retention the usual practice? Please identify what may trigger exceptional retention, who may authorise the exception, how the record may be bounded, and how one prevents the analyst from redefining the experiment after learning which pipeline performed better. I am especially interested in false negative results and in whether an absence of evidence can properly be declared when the scanner was not observing the relevant channel.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Response: Dr. Ziv, a reporting specification which assumes that its original feature list will answer every legitimate question would be as defective as one which retains everything in anticipation of every imaginable one. I would separate the right to perform a particular test from the data normally retained by that test. A risk assessment and an authorised diagnostic protocol should describe several known failure modes, such as front-end clipping, gain settling, local oscillator images and dropped sample buffers. Each mode should have a narrowly chosen test field. A clipping counter and an analogue gain-state log may be enough to question a suspicious peak without preserving private modulation content. Where that evidence is insufficient, a short authorised reference capture can be justified by a distinct, documented request, preferably using a seeded laboratory signal rather than ambient communications.

Copyright 2026, James M. Atkinson

The decision to trigger such a record should not be based merely on the operator's curiosity or on whether a sample might later prove useful. It should require a stated diagnostic proposition, an allowed frequency range and interval, independent approval appropriate to the organisation, and a finite retention disposition. The captured bytes must be access-controlled and separated from ordinary case reporting. A person reviewing the defensive finding should normally encounter the derived measurement, the acquisition provenance and the limitation first, not an unrestricted copy of every communication near the instrument. If the capture was never needed, the record should say so and should be disposed of in accordance with the applicable retention obligations.

Copyright 2026, James M. Atkinson

A fair experiment can establish these rules before the test labels are disclosed. Both pipelines receive the same controlled emissions, matched benign interferers and null intervals. A third, independent apparatus records the ground-truth event schedule. The analysts are blinded to that schedule, and the rules for classifying an event and invoking an exception are frozen. We record not only successes but false positives, missed events, timing gaps and occasions where neither pipeline can support a classification. The additional IQ information is evaluated by whether it changes a predetermined decision in a reproducible manner, not by how interesting it looks afterwards.

Copyright 2026, James M. Atkinson

Finally, scanner coverage must be treated as a measured eligibility condition. If the receiver did not observe a frequency for the requisite interval, its silence cannot be coded as a negative event. A case record should distinguish no emission detected during valid observation, no valid observation, and data unavailable because of an instrument fault. Those are three different states with different implications. In each state the goal remains a bounded, testable security conclusion without constructing an unnecessary collection of the surrounding communications.

Copyright 2026, James M. Atkinson

Abraham Lempel, Peer Question: Admiral Hopper, I wish to examine the engineering temptation to call a stored waveform harmless merely because it has been encrypted, compressed or transformed. A reversible transformation can preserve every item of incidental content, and a long-lived key can restore access well after the original survey has ended. Even a nominally nonreversible representation may expose a sensitive pattern when it is combined with location, timing or external administrative data. Suppose a monitoring system retains raw I and Q samples in a compressed archive, stores an event table separately, and exports thumbnail spectrograms for reports. Which of those products counts as information that must be controlled, and which can be regarded as a minimally sufficient measurement? I also ask whether the loss of a decryption key actually demonstrates disposal, or whether the institution must prove the absence of readable replicas in caches, diagnostic logs and automated backups. The distinction matters when a very capable laboratory is asked to preserve evidence without becoming a repository of unrelated correspondence.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Response: Dr. Lempel, the transformation applied to a record does not determine the legitimacy of collecting it. Reversible compression merely changes representation; it does not remove the underlying communicative information. Encryption can protect confidentiality against unauthorised access, but encryption alone does not make acquisition necessary, nor does it shorten the period for which the information remains held. Even a spectrogram image can reveal timing routines or associations when combined with other records. I would therefore place the original samples, their compressed form, the derived images and every exported report within a single information-lifecycle inventory. The inventory should describe sensitivity, permitted use, custodianship, retention basis and deletion or preservation obligations for each class.

Copyright 2026, James M. Atkinson

This requires data-flow analysis, not just a policy at the recording button. A sample may enter a ring buffer, a crash dump, a network packet capture, a search index or a temporary directory before it reaches the nominal evidence store. If a program tells the investigator that only event metadata will be kept but leaves full samples in a persistent diagnostic cache, the declaration is materially misleading. The pipeline specification should identify each place bytes can be written and each service permitted to read them. Unit tests should exercise normal operation, exceptions, interrupted shutdown and recovery from a storage error. The result is auditable evidence that the implementation follows its stated purpose.

Copyright 2026, James M. Atkinson

Deletion also deserves a precise technical vocabulary. Removing a directory entry is not necessarily the destruction of every physical copy. Key destruction can form part of a properly implemented cryptographic-erasure system, but its effectiveness depends on key management, algorithm selection, key copies and the storage architecture. A retention officer may be bound by preservation duties that prevent immediate destruction, even when the engineer would prefer a shorter period. The correct approach is to define the applicable constraints in advance, not to claim that a universal technical trick has discharged every legal obligation.

Copyright 2026, James M. Atkinson

I would classify the metadata record as minimally sufficient only relative to a stated evidential claim and an identified test. An event's centre frequency and duration may suffice to document occupancy, but they cannot establish a fine phase transient. If the authorised question needs phase, we should retain a narrowly chosen non-content feature or a bounded reference capture after review. The governing test is always the same: what evidential uncertainty does each additional field reduce, at what privacy cost, and is the proposed acquisition lawful and necessary for that reduction? Compression offers no exemption from that question.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Cross-Peer Question to Alan Mathison Turing: Mr. Turing, I pass the token to you to examine the computer itself. An organisation may publish a privacy-conscious report design, yet its detection software might decode private content into volatile memory, record hidden diagnostic fields or send complete sample windows to a remote service. The analyst might not know, because the visible interface displays only frequency and timing. How would you define an observable conformance test between an approved specification and a real implementation? Please consider hidden intermediate states, probabilistic classification outputs and software updates which change the fields collected without changing the report format. In particular, can we establish noncollection from the absence of a payload in the printed report, or must we inspect the pathways by which data enter memory, logs, archives and network transports? I should like a method that independent reviewers can apply without making their own access to irrelevant communications broader than the case allows.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Cross-Peer Answer to Grace Brewster Murray Hopper: Admiral Hopper, an observed output seldom establishes the absence of an internal operation. Two programs may print identical event lists while one discards samples after computing a threshold and the other retains them, labels them by source or transmits them elsewhere. Black-box comparison of the printed report is therefore a necessary but inadequate test. I would begin with an explicit machine-level data contract: permitted inputs, intermediate transformations, output fields, writable stores, network destinations and error paths. The contract should distinguish information that must exist transiently to calculate a lawful physical measurement from information that may persist beyond that calculation. Where content extraction is outside the authorised task, the implementation should not instantiate a content decoder merely because one is available as a software library.

Copyright 2026, James M. Atkinson

Verification must be layered. Configuration review confirms that disabled pathways cannot be enabled silently. Source review and build provenance examine whether the implementation corresponds to its documented design. Instrumented executions with synthetic, deliberately distinctive test payloads can reveal leakage into logging systems without exposing real third-party communications. Independent monitors examine disk writes, temporary files, crash reporting, memory snapshots and outbound connections under ordinary and adverse conditions. The tests should include software-update paths and failure handling, since unexceptional executions alone are too easy to pass.

Copyright 2026, James M. Atkinson

A logical qualification remains: a finite test suite cannot prove the absence of every possible unauthorised behaviour in an arbitrary program. Stronger confidence comes from reducing the design's authority to collect and persist unnecessary data in the first place. A process which cannot write to the evidence store or open an outbound connection presents a smaller exposure than one which is trusted to exercise restraint. This does not relieve investigators of a proper legal analysis. It means that the machine's capabilities can be aligned with the authority already obtained.

Copyright 2026, James M. Atkinson

I would allow the independent reviewer to use recorded attestations, configuration manifests, synthetic test data and bounded audit trails rather than unrestricted access to the original communications stream. A proof of conformance is strongest when it identifies its assumptions, coverage and residual blind spots. The appropriate conclusion is not that the machine has metaphysically ceased to possess information, but that the implemented workflow restricts retention and dissemination sufficiently for a clearly described defensive purpose and a measurable assurance level.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Thank you, Admiral Hopper and Mr. Turing. We have distinguished the measurement from its storage and the declared report from the software's hidden behaviour. Mr. Turing, please take the principal token and consider how testing, reproducibility and limited authority can coexist in a real signal-processing instrument.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Second Principal Contributor: The concept of a machine that carries out a definite procedure is useful precisely because it separates the steps that an operator believes are being performed from those that the machine actually performs. An RF receiver does not become privacy-preserving by adopting a new label for its interface. A typical digital chain may convert analogue samples, channelise them, estimate power, classify bursts, detect public timing fields and write event records. At each stage an engineering team has chosen what to measure, what to infer and what to preserve. The resulting decision can be interrogated as a program whose allowed behaviours must be specified, not as a reassuring promise printed in an operating manual. We should begin with the minimal algorithm that supplies the authorised decision and only then ask what additional data a defined uncertainty requires.

Copyright 2026, James M. Atkinson

Let the binary decision Y be whether a specified RF event occurred within a valid observation interval, and let X denote the receiver's complete sampled input. A procedure computes a smaller statistic T(X), such as a calibrated power excess, an onset time and a bandwidth estimate. If the authorised decision can be reproduced from T(X) under the stipulated measurement model, a full persistent copy of X may add no necessary information to that decision. Yet it would be a mistake to claim that T is universally sufficient. The signal model may exclude intermittent overload, clock discontinuity or an unexpected interferer. The correct experiment therefore tests the chosen statistic across a declared range of adverse conditions and identifies the cases in which a residual uncertainty cannot be explained from the saved fields. We should not conceal such limitations behind the prestige of mathematical notation.

Copyright 2026, James M. Atkinson

One practical design is a two-stage computation. A bounded detection process, operating under an explicit authority envelope, consumes complex samples and emits non-content event records. A separately controlled diagnostic process may be invoked only for an approved, predeclared failure question. The diagnostic process need not inherit unrestricted access to ambient communications; it may be exercised initially against synthetic replay files and laboratory references. The two processes should have separate storage permissions, audit trails and retention periods. An investigator reviewing the evidence can then ask whether the original event was sufficiently reproducible, whether the diagnostic exception was necessary and whether any retained information exceeded the approved scope. The process is more credible when the diagnostic capability is not silently available at every ordinary detection.

Copyright 2026, James M. Atkinson

Testing requires an adversarial attitude towards one's own program. In a blind trial, generate seeded emissions whose times, frequencies, power levels and deliberate impairments are known to an independent controller. Place noise-only and benign traffic intervals among them. Send the same input scene through Pipeline M, which records bounded metadata, and Pipeline I, which additionally retains a prescribed short sample window. If the observers know the labels, they may unconsciously tune thresholds or enlarge the search interval around a desired result. If the classifier selects only the easiest examples for analysis, its published sensitivity will be optimistic. Freeze the algorithms and eligibility criteria before inspecting the reference log; record every eligible interval, including failures and missed opportunities, rather than only the interesting peaks.

Copyright 2026, James M. Atkinson

We should also recognise that the right to investigate a system need not include the right to read every bit passing through it. A software developer can test the integrity of a checksum computation with synthetic sample streams and reference hashes. A reviewer can verify the schema, channel calibration and gain configuration without being given access to private communications. Where an exceptional case genuinely requires raw data, its authority and custody can be separately established. This division of labour protects both individuals and the integrity of the inquiry. If investigators routinely circulate an unrestricted sample archive simply because several engineers wish to inspect it, they enlarge the investigative subject without clearly improving the evidence.

Copyright 2026, James M. Atkinson

Program updates are a particularly dangerous point. A new detector version may silently add demodulated bytes to debugging logs or extend the sample window to improve classification. Both changes can leave the published report format unchanged. It follows that an evidence record should contain the executable version, configuration hash, approved data schema, relevant dependency versions, clock state and an audit of storage interfaces. A signed configuration manifest may help identify what version was deployed, though a signature alone proves neither correctness nor legal authority. The auditor should test that changing one authorised setting does not cause undeclared changes in collection or retention. A rollback mechanism must not revive a formerly prohibited capture path.

Copyright 2026, James M. Atkinson

There is a narrow distinction between transient computation and collection that deserves deliberate attention. A short-lived sample in volatile memory may be required to calculate a lawful signal measurement, but a crash dump, swap file or automatic telemetry package can convert that transient processing into durable retention. Processor isolation, bounded memory use and disabled diagnostic exports may consequently matter as much as the report's visible fields. Some institutions will impose additional duties upon communications metadata itself, depending on jurisdiction and context. The engineering team cannot presume that the word metadata makes an observation legally innocuous. It can, however, provide a truthful technical inventory for counsel and the authorised decision maker.

Copyright 2026, James M. Atkinson

I propose that reviewers judge the system against four propositions. The first is functional: does it reliably detect the stipulated physical event? The second is epistemic: can the result be independently challenged using the retained fields and stated uncertainties? The third is minimising: did the apparatus avoid retaining data not necessary for its declared use, including auxiliary logs and backups? The fourth is institutional: can the operator demonstrate that the purpose, authority and disposition rules preceded collection rather than being invented afterwards? Failure of any proposition should be visible in the case file. A competent system should sometimes answer that the available evidence is insufficient. The ability to make that admission is a sign of disciplined engineering, not weakness.

Copyright 2026, James M. Atkinson

Finally, let us not confuse the sophistication of a classification algorithm with the legitimacy of its inputs. An impressive classifier may discover correlations between incidental messages and occupancy patterns, but it is not entitled to use those messages merely because they would improve its accuracy. Likewise, a system which captures all traffic and later masks the report may have already exceeded its approved collection purpose. The limit should act at the acquisition, processing and retention boundaries, not merely at publication. Mr. Davies can usefully examine how innocent replicas arise during transport, and Dr. Shannon can say more precisely what information a smaller statistic retains. Both questions are essential if a defensive investigation is to withstand searching technical and legal examination.

Copyright 2026, James M. Atkinson

David Slepian, Peer Question: Mr. Turing, I accept that a limited statistic may support a particular binary decision, yet in signal detection its apparent sufficiency depends rather precariously upon the assumed distribution. Consider an authorised site survey with a low duty-cycle test transmitter and a receiver whose gain can change between observations. A saved threshold crossing and power estimate may support an occupancy decision, but not a later challenge alleging that the threshold itself drifted or that the baseline noise was nonstationary. Would you require a record of the underlying noise distribution, or a bounded sequence of noise-floor estimates, to make the decision reproducible? Please address how such a record is defined without quietly growing into a complete retained waveform. I also ask whether a system should use a different evidential threshold for merely reporting an anomaly and for identifying a specific device, given that the latter is a stronger and potentially more consequential claim.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Response: Dr. Slepian, you have identified the precise reason a data-minimisation design must begin with the intended claim and an explicit family of measurement models. I would not call a single threshold-crossing bit sufficient for every challenge to detector validity. A proper occupancy record may include time-varying noise-floor estimates, gain state, calibration uncertainty, sample-count eligibility and the decision threshold used for each window. A small sequence of calibrated summary statistics can permit a reviewer to detect certain forms of drift or censoring without preserving the entire phase and amplitude history of arbitrary nearby communications. The choice of summary must be justified against the known defects, not by an abstract preference for small files.

Copyright 2026, James M. Atkinson

Suppose a detector compares measured power P with a threshold B plus an offset D, where B is the contemporaneous noise baseline and D is a declared margin in the same logarithmic units. The record might retain P, B, D, the averaging interval, gain correction, clipping indicator and the clock's uncertainty. An independent reviewer can then reproduce the nominal decision and assess the effect of calibration error. If there is evidence that the gain path changed unpredictably within the averaging interval, the retained statistics might be inadequate. That is a reported limitation and possibly a reason for a separately authorised controlled diagnostic experiment; it is not a retrospective permission to retrieve unrelated private communications.

Copyright 2026, James M. Atkinson

The distinction between event detection and source identification is vital. A robust detector may show that energy exceeded an instrument-defined threshold under valid observation conditions. It does not thereby show that the source belonged to a particular person or device. Such attribution requires additional independent features, controlled comparison data and an explicit rule for unknown or unclassified sources. One should never allow a report generator to elevate the first statement into the second merely because an output column bears the heading confidence. A numerical confidence score without a validated reference population and error model may mislead more than an appropriately qualified narrative.

Copyright 2026, James M. Atkinson

I would also save the procedural record of failed or ambiguous observations. A system that preserves only events above threshold produces selection bias: the investigator cannot reconstruct how often the detector faced noise-only opportunities or how many observations were lost to retuning. Retained summary records can encode eligible windows, censored windows, false alarms in controlled null tests and changes in environmental conditions. Such evidence often improves scientific reproducibility while collecting less private content. The objective is an auditable experiment, not the impossible preservation of everything that might conceivably interest a future analyst.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Cross-Peer Question to Donald Watts Davies: Mr. Davies, I ask you to follow a lawful measurement through the network rather than confining your analysis to the receiver. Imagine that the detection computer stores only a brief record of frequency, timestamp, threshold and calibration state. Its monitoring agent nevertheless streams raw diagnostic buffers to a central service; a network switch mirrors those packets; and a maintenance system retains traces for troubleshooting. The operator's declaration of metadata-only retention would then be inaccurate, even though no payload appears in the final report. How should the system divide measurement authority from transport and maintenance authority, and what technical evidence would demonstrate the lifetime of an incidental copy? Please consider intermittent network failures, retransmission queues and backup schedules, since those mechanisms may preserve data outside the receiver's ordinary control. I am also interested in how much information a reviewer must receive to verify a transport design without duplicating the very records we intended to minimise.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Cross-Peer Answer to Alan Mathison Turing: Mr. Turing, a networked instrument creates multiple places where information may be held, even if its front-panel operator imagines a single file. The first principle is to inventory the packet and storage pathways end to end. If the authorised purpose requires event metadata, only those metadata fields should enter the routine transport channel. The receiver ought to strip or discard disallowed content before transmission, not send everything to a server and hope that the server will perform the intended minimisation later. A segmented architecture can separate a low-volume event channel from an exceptional diagnostic channel whose activation, destination, size and expiry are individually controlled.

Copyright 2026, James M. Atkinson

Retries, queues and caches must be included in the inventory. A packet may be copied into a driver buffer, an application queue, a broker's persistent store, a mirror interface and a backup. Disabling a visible archive does not erase the other copies. A sensible design provides bounded queue capacity, documented time-to-live values, access restrictions, persistent-log filtering and tests that inject synthetic marked data into the system to discover where they survive. The tests should include connection loss and unexpected restart, since systems often retain extra information precisely when their ordinary workflow fails.

Copyright 2026, James M. Atkinson

For assurance, one can provide a reviewer with configuration manifests, network-flow summaries, synthetic-data tracing reports, hashes of deployed components and audit records of exceptional permissions. These materials can demonstrate whether the implementation conforms to its declared data contract without exposing actual private communications. They do not constitute an absolute proof that no other copy exists; a responsible report should identify what hosts, backups and third-party services were within the audit's scope. An independent records custodian must address any applicable duty to preserve evidence rather than allowing engineers to destroy material in violation of a hold.

Copyright 2026, James M. Atkinson

I would be particularly sceptical of a system that calls every piece of technical data harmless merely because it is transmitted in a packet. Timing, endpoint associations, locations and event frequency may themselves reveal activity patterns. The lawful scope of retaining them must be assessed, and the technical choice should reflect the narrowest defensible reporting purpose. Network design therefore serves privacy and evidence integrity together: it prevents irrelevant replicas, records how necessary information moved, and makes the boundaries of custody intelligible to an independent tribunal or reviewer.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Thank you, Mr. Turing and Mr. Davies. The machine's visible output and the network's hidden copies must be examined together. Mr. Davies, please take the principal token and discuss custody, replication and the difference between transport availability and lawful persistence.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Third Principal Contributor: A network does not carry a single abstract report from one place to another. It transforms information into packets, places those packets in queues, repeats them when necessary and may hold copies in several machines that the end user never sees. It is thus possible for a monitoring service to comply with a narrow display specification while violating the same specification in its transport architecture. The decisive question for the defensive instrument is not only which facts appear in its final report, but which information the entire organisation has acquired, replicated and kept. I would require a documented information-flow diagram with ordinary operation, diagnostic operation and fault recovery shown separately. Every arrow should identify its content class, transport security, storage permissions and expected lifetime.

Copyright 2026, James M. Atkinson

Let us suppose the reporting purpose is to establish whether an unknown emission affected a protected conference room's spectrum during a defined meeting interval. An adequate record may contain receiver location and antenna orientation, the effective observation window, centre frequency, detector configuration, noise baseline, timestamp provenance, estimated level, a non-content waveform-class hypothesis and the failure flags essential to reproduce the decision. A network should deliver those fields without silently including raw samples or decoded application traffic. If an exceptional scientific question requires a bounded sample, it must travel through a separately approved path and carry its own access and retention rules. The exceptional record should not inherit every recipient of the normal event stream, since those recipients may include personnel whose work requires the conclusion but not the original information.

Copyright 2026, James M. Atkinson

One must distinguish information availability from information retention. A resilient network duplicates information for delivery; a records programme deliberately preserves information to satisfy a purpose or obligation. The two activities can overlap technically but need not overlap institutionally. Buffering a few milliseconds of event metadata in a transient queue is unlike archiving years of unrestricted communications content, yet a network broker configured for persistent replay can turn a transient engineering mechanism into a durable repository. Audit must therefore include broker retention, logging levels, mirror ports, maintenance gateways, remote-support systems, backups and disaster-recovery replicas. A declaration that a receiver's local disk contains no samples says very little about this larger chain.

Copyright 2026, James M. Atkinson

Consider a controlled two-pipeline trial. Pipeline M sends only signed or otherwise authenticated event metadata and associated integrity fields. Pipeline I additionally sends an authorised, sharply bounded IQ extract after a recorded diagnostic decision. We introduce synthetic frames carrying harmless, easily recognised test patterns so that any unintended replica can be traced without acquiring real private communications. We then intentionally disconnect the network, restart a broker, overflow a queue and induce a service crash. The test asks whether prohibited test content survives in support logs, packet capture files or recovery archives, and whether the declared expiry rules are applied when the system returns to service. Synthetic patterns are especially useful because the investigators can examine leakage mechanisms without reading unrelated material.

Copyright 2026, James M. Atkinson

Some engineers propose that all retained information should be encrypted and the matter considered settled. Encryption is an important confidentiality control but not a substitute for necessity analysis. The institution may still possess the content and the keys, may replicate both, and may be able to read it after the original purpose has expired. Nor does a cryptographic digest of a full waveform erase the legal significance of the waveform itself. An authenticated event record can help prove that the metadata were not altered after a particular point, but it does not by itself establish that the underlying radio event was measured correctly, that the instrument had lawful authority to operate, or that the metadata were harmless. These are separate propositions and require different tests.

Copyright 2026, James M. Atkinson

We need a reliable treatment of custody. If an event record changes hands, it should preserve a stable identifier, creation time and time basis, originating instrument, configuration identity, content schema, processing version and a protected history of transfer and alteration. The record must distinguish original acquisition time from the time a packet reached the central server. Network latency, congestion and retransmission can separate those times by an unpredictable interval. A host receipt timestamp may be useful for system administration, but it should not be presented as an electromagnetic event timestamp unless the uncertainty has been measured. The chain of custody describes who held the evidence; it must not be confused with a guarantee that the original radio observation was authentic.

Copyright 2026, James M. Atkinson

A particularly difficult problem arises when the server's shared data store allows a later analyst to combine innocuous-looking observations into a sensitive pattern. Event times, antenna positions and repeated detections may reveal movement, schedules or associations, especially when joined with building access logs or staff rosters. A privacy-respecting architecture should consequently limit joins, bulk queries and onward disclosure, not just raw sample retention. Some defensive findings may require comparison with a roster, but that necessity must be specified and reviewed rather than presumed. Statistical aggregation, coarsening of time or suppression of location detail may reduce exposure when the report's legitimate decision does not require finer resolution. If those transformations destroy a material evidential distinction, the limitation should be recorded rather than concealed.

Copyright 2026, James M. Atkinson

I would also draw attention to retention policies during litigation or formal investigations. Evidence may be subject to preservation requirements that override routine expiry, but the need to preserve a defined record does not automatically authorise the acquisition of additional unrelated records. A technically elegant deletion routine must be subordinated to lawful holds and jurisdiction-specific rules. Conversely, a vague instruction to retain everything forever is not an adequate substitute for an inventory and a defensible retention schedule. Roles should be separated so that instrument operators cannot silently change the preservation period, and legal reviewers cannot mistake a file's accessibility for proof of its relevance. The custody narrative should say what was collected, why, by what authority, where it was replicated and when each copy may lawfully be disposed of.

Copyright 2026, James M. Atkinson

Finally, an independent auditor ought to be able to test the system's contract without receiving an indiscriminate copy of its input. Synthetic marked data, schema validation, access-control tests, network-flow records and carefully selected configuration evidence can show whether a collector honours its commitments. The auditor may still identify uninspected components or a residual risk of hidden replicas. That uncertainty should be reported expressly. A defensive surveillance survey is at its strongest when it permits a third party to reconstruct its conclusions without creating another uncontrolled copy of the communications it was meant merely to protect. I pass this question to Dr. Shannon's examination of how much information a genuine technical decision actually requires.

Copyright 2026, James M. Atkinson

John Robinson Pierce, Peer Question: Mr. Davies, your network inventory is persuasive, but I should like to distinguish a technical signal-path record from a dossier about the persons who might have been transmitting. Suppose the authorised question concerns an unexplained emission during a scheduled room survey. The monitoring network stores a series of timestamps precise to microseconds, antenna identifiers and estimated direction of arrival. Even without demodulated content, those fields might later be combined with an electronic door log to infer a person's movements. If the report can support its engineering finding with intervals rounded to a less precise resolution, should the precise measurements be transformed before dissemination? Yet might such coarsening destroy the ability to distinguish two brief overlapping bursts, producing a false single-source narrative? Please specify how a laboratory can test this trade-off rather than allowing the privacy officer and signal analyst to make unsupported assertions on opposite sides. Please also say how the test would record the uncertainty introduced by each deliberate reduction of timestamp precision, so that the coarsening process itself remains examinable.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Response: Mr. Pierce, the distinction you raise is not resolved by declaring either exact timing or coarse timing inherently superior. The necessary temporal resolution depends upon the legitimate inference. If the task is merely to establish occupancy during a ten-minute interval, a microsecond timestamp may contribute nothing material to the decision. If the task is to distinguish two overlapping diagnostic pulses in a controlled experiment, the same resolution may be essential. The correct approach is to define the report's purpose and the competing hypotheses before deciding which precision is necessary for each authorised audience.

Copyright 2026, James M. Atkinson

I would keep a restricted technical measurement record where the applicable authority and preservation requirements justify it, and produce a purpose-limited dissemination view for operational recipients. A summary report can describe occupancy with rounded intervals and uncertainty bounds without exposing every precise transition. Independent reviewers who need greater detail can request access through a documented process. This is not simply a matter of hiding columns: the exported dataset should be tested for linkage risks, since combinations of seemingly innocuous fields may identify patterns. An access policy that controls joins against personnel logs may be as important as rounding timestamps.

Copyright 2026, James M. Atkinson

A blinded comparison can measure the engineering effect of different levels of precision. Take seeded overlapping transmissions with independently known start and stop times, and test the same detection logic at full timestamp resolution, coarsened resolution and interval-only representation. Predeclare an error criterion: perhaps the proportion of trials in which two events are incorrectly merged, and the proportion in which one event is incorrectly split. Record these errors with confidence intervals and representative uncertainty. At the same time, assess whether each export contains information not necessary for the decision and whether it creates a plausible linkage risk. A technical benefit must be demonstrated rather than imagined.

Copyright 2026, James M. Atkinson

One should not infer that privacy is satisfied merely because the receiver collects no intelligible speech. Metadata can be sensitive; their collection and use may also be regulated. By separating a narrow measurement layer from broader dissemination and query privileges, the system can preserve reproducibility where needed while restricting unnecessary exposure. If fine timing is indispensable to an authorised evidential conclusion, the report should explain why. If it is not, the institution should not release it simply because the instrument can measure it.

Copyright 2026, James M. Atkinson

John von Neumann, Peer Question: Mr. Davies, I wish to pursue reliability under equipment failure. A collector might promise that full-IQ records enter the network only when an approved diagnostic token is supplied. Yet a corrupted configuration, a process crash or a race between two service instances could cause the exceptional pathway to activate for ordinary detections. The report generator may continue to look correct while the organisation's data holdings expand silently. What controls would you place at the boundary between acquisition and transport to prevent one faulty component from defeating the entire privacy design? I ask particularly about least privilege, fail-closed operation, immutable audit records and restoration after a power interruption. Would the inability to write an unrestricted archive be more persuasive than a procedural instruction not to write one, and how should reviewers test that claim across software revisions and backup systems? I should further like to know whether independent test operators can demonstrate that failed authorisation never produces a silent fallback record during simulated system faults.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Response: Professor von Neumann, one should prefer an architecture in which a mistake at one layer cannot automatically grant broader authority to all other layers. The ordinary detection process should lack write permission to the exceptional sample store and lack the credentials necessary to use its network transport. Exceptional capture should require an independently checked authorisation record, a finite scope and a separate process identity. A network receiver should reject unexpected data types rather than merely ignore them while preserving the original packet elsewhere. These controls embody least privilege: the routine system should be incapable, under its approved configuration, of becoming an unrestricted archival service merely because a developer left a debugging switch enabled.

Copyright 2026, James M. Atkinson

Fail-closed operation needs careful definition. A failed authorisation check should prevent exceptional collection; it should not silently generate an unlogged record. Conversely, a failed metadata transport should not necessarily erase a valid safety event if the authorised system requires a bounded queue for resilience. The design must identify the permissible queue capacity and lifetime, and specify what happens when that capacity is exhausted. The investigator then records the resulting loss of observation opportunity rather than inventing a complete history from incomplete data. A privacy-preserving system can be honest about its failures without retaining excessive information.

Copyright 2026, James M. Atkinson

An immutable or tamper-evident audit record can make later alteration detectable, but it must not become another uncontrolled repository of sensitive samples. Log the identity and scope of exceptional permissions, their approval time, the instrument configuration, the bytes written and the disposition outcome; avoid including decoded content or unrestricted waveforms in the audit itself. The log's integrity needs its own verification and custody model. Digitally signed records can assist continuity of evidence, but the signatures do not prove that the acquisition was lawful or the sensors measured the physical world without error.

Copyright 2026, James M. Atkinson

Tests should include concurrent triggers, expired tokens, crashed services, interrupted disks, restored backups and software rollbacks. Use synthetic marked signals and inspect every known storage path, including maintenance systems. Record the tested configuration and the components outside the audit's reach. A claim that the receiver cannot write unrestricted data is useful only if the enforcement boundary and its exceptions are specified and checked. The best design makes exceptional collection difficult to invoke accidentally and easy to detect when invoked legitimately.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, I should like to frame the information problem directly. Pipeline M stores a short vector of event statistics; Pipeline I stores an additional bounded sequence of complex samples. An engineer argues that the raw sequence contains more information and therefore must yield a stronger forensic conclusion. That reasoning confuses quantity of representation with relevance to a particular proposition. Can you define what it means for the smaller record to preserve the information required by a predeclared binary or multiclass decision? How would you distinguish a statistic sufficient under a restricted model from one that remains robust when the spectrum contains unmodelled interference, receiver clipping or synchronisation errors? And if additional samples improve classification of a particular laboratory source, does that improvement establish authority to retain incidental communications in a deployed defensive survey? Please address these questions without treating mathematical sufficiency as a universal legal exemption. I would welcome a decision-theoretic account that shows the consequences of each extra field without mistaking a convenient optimisation objective for a source of legal permission.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to Donald Watts Davies: Mr. Davies, an input record is informative only relative to the question being asked and the assumptions under which it is interpreted. Let X denote the complete observed sample sequence, H a stated hypothesis about a physical event, and T(X) a reduced representation. Under a particular probabilistic model, T may preserve all the likelihood information about H that X supplies. Under a different model, where clipping or nonstationary interference matters, the same statistic may discard useful evidence. Thus the relevant engineering task is not to declare metadata categorically sufficient, but to identify the decision and the family of conditions for which the retained statistics are demonstrably adequate.

Copyright 2026, James M. Atkinson

More bits are not a measure of greater probative value by themselves. A long recording may contain a large quantity of nuisance variation and unrelated content. If it is used to select favourable examples after the outcome is known, it can encourage overfitting and false confidence. A smaller, predeclared statistic may support a cleaner test. Nevertheless, a bounded complex-sample record can sometimes reveal a receiver defect or phase behaviour that an event count cannot express. Such a benefit must be evaluated on blinded reference trials, with uncertainty, false positives and the incremental information exposure all recorded.

Copyright 2026, James M. Atkinson

One can formalise the trade-off with an engineering loss function, but the coefficients would be an institutional decision rather than a theorem. For example, let L be expected decision error cost and R a measure of privacy or retention risk under a stated assessment. A proposed system might be evaluated by L plus a nonnegative weight times R. The chosen weight and the lawful constraints are not determined by information theory, and no value of the loss function can transform prohibited acquisition into authorised acquisition. The mathematical comparison is an aid to documented decision making, not a substitute for it.

Copyright 2026, James M. Atkinson

I would therefore require controlled evidence for any claim that the fuller representation is necessary. Show that it changes a legitimate decision under specified conditions, that narrower alternatives do not provide the same benefit, and that the resulting retention is separately authorised and appropriately limited. The strongest final report acknowledges when the observation supports only an energy or format hypothesis. It should not employ the existence of elaborate raw data as theatrical proof of a physical source identity that has never been established.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Thank you, Mr. Davies and Dr. Shannon. We now see why resilient transport, evidence continuity and privacy restriction must be designed jointly. Dr. Shannon, please take the token and examine the statistical experiment which determines whether each additional recorded field contributes to a lawful conclusion.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Fourth Principal Contributor: The phrase more information is frequently employed without identifying the variable about which information is wanted. A radio receiver may generate millions of complex-valued samples during a survey, but the authorised decision may concern a far narrower proposition: whether an unexpected emission occupied a prescribed frequency interval while the receiver was actually observing it. It is perfectly possible for a small statistic to describe that event adequately under a chosen model, and equally possible for a full sample stream to encourage speculation about unrelated messages. The central task is to distinguish the physical uncertainty under investigation from the incidental information available to the apparatus. No mathematical argument for preserving raw data is complete until the investigator defines the specific decision for which those data are said to be necessary.

Copyright 2026, James M. Atkinson

We should begin with a hypothesis variable H, whose possible values include a genuine seeded emission, an instrument artefact and a noise-only observation. Let X represent the acquired sample sequence, and let T(X) be a smaller vector containing calibrated power, bandwidth, valid-observation duration, timing uncertainty, the detector's threshold and any predeclared public waveform statistic. An analyst tests whether T permits classification among the specified hypotheses at an acceptable error rate. If the richer representation X improves discrimination only by reading unrelated payload content, that may demonstrate an algorithmic possibility but not a legitimate basis for retaining the payload. Conversely, if an approved short sample is needed to establish that an apparent burst was caused by amplifier clipping, the experiment should report that technical need precisely, including the alternatives tested.

Copyright 2026, James M. Atkinson

There is a useful distinction between a sufficient statistic under a particular statistical model and a universally adequate evidence record. Under an idealised Gaussian-noise model, a predeclared energy statistic may be sufficient for a particular amplitude-detection problem. But the field receiver may suffer impulsive interference, automatic-gain-control transients, an uncertain antenna response or missed scanning intervals. The original model then may fail, and the statistic may conceal the cause. An excellent report states the assumed noise model, records the instrument settings needed to evaluate it and tests the method against deliberately adverse cases. It does not claim that a theorem whose premises are unmet establishes reliability. The test can show where the metadata record remains adequate and where a specific additional non-content diagnostic becomes justified.

Copyright 2026, James M. Atkinson

A careful comparison should use paired observations. Take N independently scheduled legitimate test events and K valid null opportunities, with event and null labels concealed from the two analyst teams. Each pipeline produces a decision for each eligible opportunity using a frozen rule. Let TP denote the true positive count and FN the false negative count among true events; sensitivity is TP divided by TP plus FN when the denominator is nonzero. Let FP denote false alarms and TN the correct non-detections among valid null opportunities; the false-positive proportion is FP divided by FP plus TN. These are properties of the chosen experimental population and thresholds, not universal instrument constants. Because both pipelines see the same trials, comparison should account for the pairing rather than pretending that two sets of counts are independent.

Copyright 2026, James M. Atkinson

For a hypothetical illustration, suppose two hundred seeded events are examined. The metadata pipeline correctly detects 190, the bounded-IQ pipeline detects 193, and both agree on 187 of the successful detections. Those numbers alone do not identify the decisive discordant cases. A useful paired table would separately count events detected by both, by metadata alone, by IQ alone and by neither. The complete table shows whether the gain arises in precisely the cases where a stated diagnostic defect is present. Similarly, null trials require their own paired table because an apparent gain in sensitivity may be bought at the cost of additional false alarms. An independent laboratory should estimate uncertainty and evaluate performance under different noise scenes and receiver settings before treating a small observed difference as persuasive.

Copyright 2026, James M. Atkinson

The privacy comparison is not a scalar calculation accomplished by counting sample bytes. A raw recording may contain information about other users' communication patterns, even if the investigating team never attempts to decode them. A narrow event table can also reveal sensitive schedules or locations. The comparison must therefore specify which data classes are collected, who can access them, whether further inferences can be drawn by linking records, and what preservation obligations apply. That assessment is partly technical and partly institutional. Information theory does not confer legal authority on an acquisition, and no numerical measure of entropy can determine whether a particular retention period is proportionate in every jurisdiction. The proper engineering contribution is to make those choices visible and to quantify the technical consequences of alternatives.

Copyright 2026, James M. Atkinson

It is also necessary to distinguish an event statistic from a provenance record. A power estimate with no calibration reference is a weak basis for a contested conclusion. The metadata scheme should preserve enough information to identify the antenna path, filter response, gain configuration, sample rate, observation eligibility, detector version and clock uncertainty. Those attributes may not be directly about the unknown emission, but they are necessary to judge whether the inference is valid. A case may require an immutable history of how such fields were generated, corrected and transferred. Integrity protection helps to show continuity of records; it does not make a biased measurement sound. Thus a privacy-conscious report can be more scientifically informative than a large unindexed file if it preserves the right quantities and the grounds for their interpretation.

Copyright 2026, James M. Atkinson

Sampling and measurement themselves place limits on certainty. A scanner cannot make a finding about intervals when it was tuned elsewhere, and a thresholded detector cannot infer the distribution of amplitudes below threshold without additional assumptions. If a record contains only successful alarms, it loses the denominator needed to estimate detection performance. We should preserve the observation schedule and counts of eligible null windows in a bounded form, even though these may appear less exciting than a waveform plot. A disciplined record of missed observations is often more probative than a beautiful spectrogram chosen after the fact. The analyst should resist describing a signal as absent merely because the log is silent. No valid opportunity is not the same observation as an opportunity with no detection.

Copyright 2026, James M. Atkinson

Finally, the author of a report must choose the strength of each conclusion. It may be appropriate to write that a calibrated receiver recorded a transient of specified bandwidth, duration and power above the relevant baseline. A public-field correlation may support a waveform-family hypothesis without establishing the message's content or sender. A forensic attribution to a particular instrument requires other validated, independent evidence. Every additional level in that hierarchy demands a corresponding evidential basis. A larger archive may assist an authorised experiment, but it cannot make an unsupported inference true merely by the weight of its bytes. Professor Dijkstra can now test whether the software architecture makes these distinctions enforceable when the instrument is used at speed and under operational pressure.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Peer Question: Dr. Shannon, I accept that a statistic can be sufficient relative to a decision model, but I should like to examine where spatial measurement enters that model. Suppose a surveillance team seeks to identify an unaccounted-for RF emission in a large conference facility. One antenna sees a short burst above baseline, while a second antenna at a different position records only a weak fluctuation. A full-IQ record might support a phase-coherent comparison, yet the equipment lacks common clock distribution and the incident may be too brief to repeat. Is it legitimate to retain the whole signal merely on the possibility that spatial processing might become useful, or should the experiment first establish that the sensor geometry, synchronisation and receiving paths can support the proposed comparison? Please specify the records that would permit an independent examiner to distinguish useful spatial evidence from an elaborate but unjustified estimate of the signal's physical origin.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Response: Dr. Bracewell, the proposal to retain additional samples should not precede proof that the intended inference is physically feasible. A phase comparison between two receivers is not automatically meaningful merely because both wrote complex numbers. The relation depends on their clock stability, sample-time alignment, local-oscillator coherence, path calibration, antenna geometry and multipath environment. Without those conditions, the preserved samples may support only independent detections, not a validated spatial phase estimate. A report should state the maximum inference permitted by the actual measurement arrangement, including the probability that the second receiver simply missed the event.

Copyright 2026, James M. Atkinson

The experiment should use a controlled reference emitter at surveyed positions and known emission times. Record sensor coordinates with uncertainty, polarisation, antenna orientation, gain state, sample-rate calibration, cable delay and any shared clock or independent synchronization source. Introduce multipath and deliberate non-simultaneous sampling as challenge conditions. Compare the direction or source-class output against the known references, reporting systematic bias and the rate of unknown outcomes. If the apparatus cannot distinguish its own timing errors from path phase, the proposed forensic benefit of retaining full-IQ records has not been demonstrated. More preserved bits cannot repair an absent timing reference.

Copyright 2026, James M. Atkinson

It may nevertheless be defensible to preserve a narrowly bounded sample under a specific lawful experimental plan, particularly when a repeatable interference event is being examined and the diagnostic requires phase continuity. The record should state that need, the bounded acquisition window, the approved recipients and the reason that non-content features were inadequate. The exceptional capture should not turn a speculative future capability into perpetual collection. Where the apparatus lacks the necessary coherence, retaining a high-resolution event-time and power record may be the more truthful choice. One can then say precisely which spatial hypotheses remain untested.

Copyright 2026, James M. Atkinson

I would favour a hierarchy of findings. The independent sensors may corroborate the existence of an emission during overlapping valid observation windows. A calibrated amplitude ratio may suggest consistency with a particular source region under stated propagation assumptions. A coherent array, if properly established and tested, may support a more specific bearing estimate. None of those steps by itself identifies a person or proves access to private content. The measurement record should preserve the uncertainties and the rejected alternatives at each stage. Evidential restraint is a technical virtue when the alternative is a precise-looking but unsupported location.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Question to Edsger Wybe Dijkstra: Professor Dijkstra, the experiment may demonstrate that a small event record supports the authorised decision, but the software must continue to honour that result after code changes and under exceptional conditions. Suppose a user can enable a raw sample recorder by altering a configuration file, or a third-party plugin can access the full receiver buffer while the main interface still announces metadata-only operation. What architecture would make the data boundary enforceable rather than advisory? I ask you to distinguish a correct algorithm from a correct operational system, to address privileged debugging and emergency overrides, and to explain how auditors can detect undisclosed data pathways without acquiring the communications whose retention they seek to prevent. What should the system do if enforcing the approved boundary means that an uncertain event cannot be resolved from the permitted records? Please also explain whether a system can retain enough negative audit evidence to demonstrate that an exceptional collection path was not invoked, without retaining the very communication samples that the prohibition is intended to protect.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, one should first reject the proposition that a complicated program becomes trustworthy because its designers describe good intentions. The system needs a simple invariant: routine detection may read the transient samples necessary to calculate specified physical measurements, but it cannot persist or export unauthorised content. The invariant should be enforced at process, storage and transport boundaries. A user-interface option is not an adequate security boundary if another plugin or logging service can bypass it. The ordinary process should possess only the capabilities required to publish the permitted record; exceptional acquisition should be a separate, narrowly authorised mechanism with a measurable expiry.

Copyright 2026, James M. Atkinson

The invariant must be tested in adverse states, including crashes, disk exhaustion, stale permissions, updates and restoration from backup. Synthetic marked data can make unintended writes observable. Independent tests should inspect process permissions, network flows, persistent queues and crash artifacts. The test should record exactly which systems were covered and should not promise universal absence of leakage from a finite collection of trials. The smaller the set of components authorised to touch full samples, the stronger the achievable assurance. A design with many trusted plugins and privileged paths produces an unnecessarily large proof obligation.

Copyright 2026, James M. Atkinson

A correct operational system is more than a mathematically correct detector. It includes user identity, approved purpose, records management, auditability, timekeeping and response to uncertainty. A highly accurate detector that silently retains protected communications may be inappropriate for the authorised task. An impeccable access-control layer cannot make a false RF classification scientifically reliable. These properties must be verified independently and then tested together, lest one virtue be used as a substitute for another.

Copyright 2026, James M. Atkinson

If the permitted fields cannot resolve an anomaly, the correct result is unresolved under present authorised observations. The system may offer a controlled request for additional authority, a seeded laboratory experiment or a review of existing permitted diagnostics. It must not silently collect more merely because a decision would be convenient. A system that has an explicit unknown state is often more reliable than one whose design forces every ambiguous observation into a confident category. The purpose of the architecture is to make disciplined refusal possible as well as efficient measurement.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Thank you, Dr. Shannon and Professor Dijkstra. We have established that statistical sufficiency must be tested against the actual signal and instrument, and that software controls must enforce the authorised limit. Professor Dijkstra, I pass the principal token to you to close with the engineering rules of a defensible, privacy-restricted reporting system.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Fifth Principal Contributor: A complex system becomes difficult to reason about when the same component is expected to collect information, interpret it, preserve it, enforce its own privileges and certify that its conduct was proper. I would begin by reducing the number of responsibilities assigned to each component. A detector may estimate spectrum occupancy and raise a bounded event; a separate record service may protect the resulting metadata; an authorisation service may approve unusual diagnostic acquisition; and an independent custodian may govern access and retention. The organisation should not demand that one enormously privileged program remember to exercise restraint. A smaller, comprehensible state machine is preferable because its permitted transitions can be specified and tested. In this setting privacy engineering is not decoration applied after a clever receiver has been completed. It is part of the receiver system's correctness condition.

Copyright 2026, James M. Atkinson

Consider the routine state R in which complex samples are processed only transiently to calculate declared non-content features. The exceptional state E permits a bounded diagnostic capture after the correct authorised conditions have been met, and the halted state H represents a fault that prevents trustworthy collection. A transition from R to E should require a valid purpose, recorded approval, exact channel and time bounds, configured storage destination and disposition rule. Returning from E to R should invalidate the exceptional permission and preserve a restricted audit of what was captured. A transition into H should not trigger an undocumented fallback that writes everything to disk. These requirements can be represented as system invariants and tested using a state-transition table rather than relying upon a reassuring paragraph in a policy manual.

Copyright 2026, James M. Atkinson

The system should distinguish detection truth, record integrity and collection permission. A valid signature over an event record supports a claim that the record has not changed since the signing operation, provided the keys and implementation are trustworthy. It does not establish that the receiver detected a real external signal rather than a local oscillator artefact. It does not establish that the instrument was legally allowed to retain the bytes. Similarly, a privacy-preserving process may still produce poor scientific results if its calibration is wrong. Each proposition needs its own evidence. Combining them into a single confidence score invites the reviewer to mistake a strong cryptographic property for a strong physical attribution.

Copyright 2026, James M. Atkinson

I should insist upon an explicit schema and a finite inventory of writable stores. For every event, the schema must say whether a field is measured, computed, inferred, corrected or manually added. A centre-frequency estimate should carry the uncertainty implied by sample clock and frequency reference, rather than being reported to an absurd precision. A timestamp must identify its originating clock and whether it marks acquisition or later processing. A signal-class label should include an unknown state. Fields about a person's identity or the content of a message should be absent from the ordinary acquisition and reporting interface unless a separate, specific authority has justified them. This removes temptations rather than merely warning operators against them.

Copyright 2026, James M. Atkinson

Formal discipline is useful only when it meets physical reality. A proof that the detector executes a particular threshold rule cannot validate an antenna whose gain pattern is unknown. A proof that an exceptional capture requires a token cannot establish that the token was issued under the correct law. The engineering system must therefore preserve links to calibration records, instrument identity, field-survey procedure, authorisation records and case-specific retention decisions. These links should not automatically copy the underlying records into every report. Access can be conditional and logged, so a reviewer sees the existence and provenance of the evidence without receiving data outside the task. This is the difference between auditable structure and indiscriminate duplication.

Copyright 2026, James M. Atkinson

Let us test a hypothetical implementation with two hundred seeded transmissions and two hundred predeclared null intervals, balanced across receiver configurations and interference levels. Pipeline M records only permitted event features; Pipeline I records an approved bounded IQ segment as well. Measure true positives, false negatives, false positives and valid observation counts separately. Suppose a review discovers that four apparent bursts were caused by gain transients. The important question is whether the restricted pipeline can expose those transients through gain-state and clipping indicators; if not, whether a narrow diagnostic feature or seeded comparison would suffice. A full capture may legitimately resolve a particular uncertainty, but the experiment must document the incremental benefit and must not presume that every unrelated communication is therefore appropriate to retain.

Copyright 2026, James M. Atkinson

I would audit the implementation at boundaries where software commonly escapes its nominal design. Plugins may inherit powerful file permissions, error handlers may write memory dumps, network instruments may duplicate packets, and update routines may restore formerly disabled collection options. A capability-based architecture can deny ordinary components the power to write raw samples to persistent stores. Exceptional permissions can be scoped by duration, destination and case identity and revoked automatically when the diagnostic purpose is completed. Negative tests should verify that expired or malformed permissions are refused, including during concurrent requests. This is more persuasive than trusting an operator to remember that a checkbox should usually remain clear.

Copyright 2026, James M. Atkinson

Yet one must also ask how the organisation learns about failures. If a sensor is scanning elsewhere, the system should record the unobserved interval rather than classify it as silence. If a measurement is corrupted, the event should be tagged invalid and the reason retained. If the recorder is unavailable, the system may preserve a minimal fault record within its permission envelope but should not expand collection silently. The final report ought to describe uncertainty in plain language: a legitimate emission may have gone undetected; a particular displayed peak may be compatible with more than one physical mechanism; an instrument state may be insufficiently documented to support attribution. An explicit inability to conclude is often the only technically defensible outcome.

Copyright 2026, James M. Atkinson

I reject the suggestion that a report becomes comprehensive by attaching every stored sample to it. A useful report should state the authorised question, instrument configuration, observations, decision rule, calibration, uncertainty, alternative explanations, custody and limits of the conclusion. It should identify the material it did not collect, explaining when a particular omission prevents a stronger finding. Where evidence must be preserved for legal proceedings, a separately controlled repository should retain the authorised records under the applicable hold, not turn every technical measurement into an unlimited archive. The retention decision belongs to the law and the institution's competent officers, not to a convenient default in signal-processing software.

Copyright 2026, James M. Atkinson

The lesson is an old one in program design, applied to a modern engineering instrument. The number of combinations of state and permission grows when hidden features, logging pathways, plugins and uncertain error handling proliferate. Simplification can produce both greater operational reliability and stronger protection against unjustified observation. I would require every code change to state how it affects acquisition, persistence, authority, audit and reproducibility. A system that cannot explain those effects should not be assumed compliant merely because its visible report appears unchanged. The soundest defensive instrument records what its lawful measurement requires, retains the provenance needed for challenge, and refuses to convert technical possibility into a new authority.

Copyright 2026, James M. Atkinson

Antony Hewish, Peer Question: Professor Dijkstra, I should like to test the treatment of a rare event whose nature is uncertain. In radio astronomy a transient may disappear before the observer learns whether it was terrestrial interference, instrumental noise or a genuine distant source. In a defensive survey, an unexpected short burst could likewise be important, yet a privacy-restricted system may have discarded most of the samples when the decision becomes controversial. Would you have the instrument retain a continuously overwritten ring buffer, and if so, what prevents that buffer from becoming a permanent covert recording store after a software fault or an enthusiastic operator intervenes? Please distinguish volatile acquisition necessary for computation, approved bounded exception capture and indefinite archive retention. I also ask what language the final report should use when the event is demonstrably present but cannot be attributed to an emitter or even unambiguously classified as external radiation. I would also ask how independent reviewers can recognise a genuinely unavailable observation rather than interpreting every absent file as evidence that nothing happened.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Response: Dr. Hewish, a finite ring buffer can be a legitimate computational mechanism if its duration, accessibility, overwrite behaviour and interactions with crash reporting are controlled. It is not privacy-preserving merely because the programmer calls it volatile. The buffer may be paged to disk, copied into an exception report or read by a privileged plugin. Its permitted purpose should therefore be stated and enforced. The ordinary workflow may need enough transient samples to compute energy, timing or a public training-field statistic; those samples need not persist after the measurement window unless a separately authorised, bounded diagnostic procedure has been invoked.

Copyright 2026, James M. Atkinson

Exceptional retention should be based upon a pre-established event class or a recorded human decision with adequate authority, rather than a convenient retrospective declaration that everything unusual was important. A finite pre-trigger and post-trigger window may be useful for distinguishing a receiver transient from a genuine signal, provided the permitted frequency span and duration are specified and the resulting data are access-controlled. If that limited window can contain unrelated communications, the institution must consider their legal status and the necessity of retaining them. Testing with synthetic signals can often answer instrument-diagnostic questions without capturing actual third-party material.

Copyright 2026, James M. Atkinson

I would test buffer behaviour with forced power loss, memory pressure, process crashes and software updates. Verify whether the overwritten data remain in swap, dumps, temporary files or remote telemetry. A declared retention time must describe what the system actually does, not simply what the user interface says. Where a legal preservation obligation applies to a valid captured record, the custody service should handle it explicitly. The collection control must not be bypassed because the custodian might later be interested in an event. Reviewers should also examine who can invoke an exception, how many exceptions are permitted and whether repeated triggers could amount to continuous recording in practice.

Copyright 2026, James M. Atkinson

As to the report, it should distinguish observation, classification and attribution. One may write that a calibrated receiver recorded an excess in a specified band and valid time interval, subject to stated uncertainties. One may report that the event is compatible with several mechanisms, including external radiation and instrumental artefact, if the evidence cannot distinguish them. One should not assign a named transmitter, a protocol or a person's intentions without independent support. Such restraint does not erase a potentially important anomaly. It preserves the anomaly as a testable finding and avoids the greater harm of presenting speculation as laboratory fact.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: I thank Admiral Hopper, Mr. Turing, Mr. Davies, Dr. Shannon and Professor Dijkstra, together with their peers, for distinguishing a technically sufficient observation from an unrestricted collection. The roundtable's central result is conditional: a defensive report should retain the least information that permits its declared and authorised finding to be tested, with necessary provenance, valid observation denominators and a precise account of uncertainties. Additional diagnostic capture must have a separate documented purpose, authority, bounded scope, safeguards and retention disposition. Nothing in our hypothetical dialogue constitutes a historical quotation or legal permission to intercept communications. The proposed procedures remain subject to independent engineering validation and jurisdiction-specific legal review.

Copyright 2026, James M. Atkinson

QUESTION 091

Copyright 2026, James M. Atkinson

What integrity and provenance records are needed to verify unchanged RF sample files?

Dr. James M. Atkinson, Moderator:Admiral Hopper, I invite you to separate three propositions which are too readily confused in electronic evidence: whether a sequence of bytes has remained unchanged since it was recorded, whether the accompanying file-description fields permit its correct interpretation, and whether the samples reflect an authentic electromagnetic input rather than an artefact of the receiver. Please develop a custody model in which the primary waveform file, the format manifest and the laboratory notes can be independently challenged. The present dialogue is a fictional scholarly reconstruction, not an historical quotation.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Principal Contributor:I would begin with the distinction between a record and the event that the record purports to describe. A receiver can write a sequence of bytes to a file. A software program can compute a digest over those bytes. A later investigator can compute the same digest over an apparently identical file. Under a suitable collision-resistant hash function and properly protected reference digest, agreement offers strong evidence that the later byte sequence matches the sequence presented for the original hashing operation. It does not follow that the receiver captured the radio event correctly, that its analogue gain was calibrated, or that the computer assigned an accurate timestamp. Those propositions concern acquisition and provenance, not the mathematical continuity of a file after acquisition. An excellent chain of custody must keep them separate.

The first task is to define precisely which object has been hashed. One may hash the payload bytes of an IQ file, including its header; one may hash only the sample array; or one may hash an entire archive containing samples, metadata and ancillary notes. These choices yield different answers when an examiner repackages the material. If a file is copied without changing any byte, a digest over the complete bytes should match. If the file is wrapped inside a different archive or if a benign timestamp field in its header changes, a digest over the entire newly written object may differ although the numerical sample stream is equivalent. A report must not call this an integrity failure of the original samples without examining what object the digest covered. Conversely, the investigator must not disregard a digest mismatch as a mere format change before establishing exactly which bytes changed.

Copyright 2026, James M. Atkinson

The meaning of a sample is also dependent on a format contract. A pair of interleaved signed sixteen-bit integers may be intended as I then Q, in a specified byte order and with a defined full-scale voltage reference. Reading the same bytes as floating-point values, swapping I and Q, changing the endian interpretation or applying an unstated scale factor can produce profoundly different waveforms while leaving the underlying file hash unchanged. An integrity scheme which protects a sample array but neglects the manifest may preserve a meaningless sequence of bytes. At minimum the manifest should identify the sample packing, signedness, endian order, channel count and interleaving convention, sample rate and clock reference, centre frequency, gain and analogue front-end state, receiver software and firmware identity, acquisition start and stop indicators, and the exact definition of any missing or invalid samples. A separately protected manifest is a practical part of the evidence, not a decorative catalogue entry.

One should distinguish an original file from a working derivative. A laboratory may legitimately decimate a sample record, convert its representation or isolate a section for analysis. Those operations produce new objects, each requiring its own identifiers, digest, transformation record and relationship to the original. The analyst should retain the original unchanged where preservation duties require it, and the working file should disclose the processing chain. An operator ought not to recompute a digest after editing a file and then present the new digest as if it authenticated the original acquisition. The reference digest should be protected against convenient substitution, with creation time, custodian identity and the apparatus used to calculate it recorded. The security of this process rests on more than the length of the displayed hexadecimal string.

Copyright 2026, James M. Atkinson

Clock claims are particularly prone to confusion. A file creation timestamp may mark the instant the operating system finished writing, not the instant the antenna received a burst. A host application can pause, queue samples and later write them under a new name. A receiver's sample counter can advance continuously despite a host delay, or it can conceal a gap when buffers are dropped. Thus the record should identify which time fields originate in a calibrated acquisition clock, which were supplied by software and which came from a file system. Clock offset and drift require separate evidence. A digest cannot repair a timestamp error or identify an unrecorded loss of samples; it merely protects whatever time assertion has been written into the hashed object. That assertion may be faithfully preserved and still be false.

I propose a laboratory trial with three layers of ground truth. An independent reference generator produces authorised RF bursts and records their timing and nominal levels. A second instrument monitors the actual radiation and characterises uncertainty. The device under examination creates the sample file, manifest and event log. Investigators then preserve the original bytes and digest under controlled custody while deliberately making derivative copies. One copy is byte-identical; another has a new container but the same sample values; a third has one altered bit; a fourth changes only the interpretation schema; and a fifth inserts a well-documented gap into a derivative. The comparison must distinguish bitwise file equality, numerical sample equivalence, consistency of the metadata and truthfulness of the claimed physical event. It is not enough to mark every successful digest comparison as an authentic radio measurement.

Copyright 2026, James M. Atkinson

I would add a custody ledger whose entries are written for later examination by someone who was not present at the survey. Each entry should record the object identifier, digest algorithm, measured file length, creator or custodian, acquisition or transfer event, authority and purpose, computing environment and the reason for a transformation. The ledger should distinguish a physical transfer of media from a logical copy, and identify any authorised access to exceptionally retained sample content. Integrity protection of the ledger itself is necessary, since a beautifully hashed file accompanied by an editable and inaccurate history leaves the examiner without a reliable account of custody. The ledger should be comprehensible without requiring needless duplication of private communications within its narrative.

The most important limitation must be stated without equivocation. A matching digest supports continuity from the trusted reference state; it does not prove authenticity of the analogue input, truth of the operator's account or lawful acquisition. A malicious or defective receiver could write a fictitious sample array and hash it impeccably. A genuine receiver could acquire a real burst but misrecord its sample rate, making a later spectral analysis erroneous. A well-documented derivative might show a different digest while retaining precisely the samples needed to answer the authorised scientific question. These cases belong in different columns of the verification report. By keeping them distinct the institution avoids both false accusations and exaggerated assurances of evidential certainty.

Finally, the record's purpose should determine which information is necessary to preserve and which remains outside the authorised scope. A report about spectrum occupancy need not include decoded private

Copyright 2026, James M. Atkinson

payloads. A brief protected IQ extract may be necessary to challenge a particular phase or transient claim under an appropriate legal authority and evidence-retention obligation; if so, the justification and access restrictions should be explicit. We should not assume that making a file immutable justifies everything it contains. The next contributors can examine software invariants, adversarial alterations, coding-theoretic error recognition and statistical limits upon the resulting inferences. Each ought to ask whether the preserved bytes establish the proposition actually reported, rather than merely establishing that the bytes have been preserved.

John Wilder Tukey, Peer Question: Admiral Hopper, the distinction between bytes and interpretation is compelling, but I question whether the proposed custody manifest is being treated as an infallible explanation rather than a hypothesis which an independent analyst must test. Suppose the stored dataset survives a transfer with the same digest, while the sample-rate field in the separately protected manifest is accidentally transcribed from an earlier instrument configuration. A spectral peak will be assigned the wrong displacement from centre frequency, and the apparent length of an intermittent event will be distorted. There has been no alteration of the signal bytes at all. Equally, if a technician changes the manifest after discovering that error, the former digest for the manifest will no longer match, even though the correction improves factual accuracy. What convention would allow the investigator to preserve the original mistaken assertion, publish an openly reasoned correction, and distinguish the original acquisition facts from the subsequent inferential repair? I should also like a procedure that does not turn a small change in a JSON file into a misleading accusation of tampering.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Response: Professor Tukey, the manifest should be treated as a controlled statement of acquisition parameters, not as an oracle. A good evidence system preserves assertions together with their provenance, uncertainty and revision history. If the recorded sample rate says eight million complex samples per second and an independent clock comparison subsequently shows that the actual average rate was slightly different, the originally signed manifest remains part of the historical record. It must not be overwritten, even to make it more accurate. An additional correction document states the old value, proposed corrected value, method of estimation, source measurements, calculation, reviewer and effective analytical context. Its own digest and custody history are protected. The result is a transparent series of propositions instead of a silently edited file pretending never to have contained an error.

Let us examine an illustrative timing example. A block of two million complex samples nominally acquired at eight million samples per second has a nominal duration of one quarter of a second. The duration calculation is the sample count divided by sample rate, not the filesystem modification-time difference. If the receiver had in fact run at 8,000,040 samples per second, the same sample count spans approximately 0.24999875 seconds. The numerical discrepancy is tiny in this illustration, but an honest record would identify which estimate rests on the original configuration and which rests on later frequency calibration. An exact hash of the sample block cannot discriminate between those interpretations. The independent examiner needs the calibration evidence, its time of applicability and the transformation that produced the revised estimate.

Copyright 2026, James M. Atkinson

I would therefore use an append-only evidential chronology. Entry one records the acquisition object's length and digest, the operator's contemporaneous manifest and the device's recorded state. Entry two logs the discrepancy with a neutral description: an apparent inconsistency was observed in the stated sample rate. Entry three records the independent timebase test, its traceability and environmental limits. Entry four issues a corrected analytical interpretation without replacing the original bytes or the original assertion. Every entry points to its predecessor and to the objects it discusses. A hash chain can help detect unannounced ledger edits if its anchors are separately protected, but the credibility of witnesses and calibration cannot be inferred from the hash chain itself.

Finally, the report should avoid treating every nonmatch as hostile intervention. A difference in bytes is a question that requires classification: original alteration, legitimate derivative, storage corruption, schema update, metadata repair or unexplained inconsistency. Each is a different finding. A reviewer should be able to reproduce the digest from the defined byte range, compare the historical and amended manifests, and decide which interpretation is technically supportable. That procedure preserves the sound of the original instrument's record while permitting later scholars to correct what its operator understood.

Donald Watts Davies, Peer Question: Admiral Hopper, consider the less visible replication machinery which stands between the receiver and the repository. A host may packetise successive sample buffers, send them through a network, reorder frames, retransmit an interrupted block or write fragments into a cache before final assembly. A valid digest computed after assembly proves continuity from that point, but it does not reveal whether

Copyright 2026, James M. Atkinson

one segment was duplicated while another was lost in transit. A sender-side digest may help, yet only if the sender established an independent trustworthy boundary for the intended stream. How would you separate transport integrity from measurement completeness? Please address buffer numbering, gap markers and evidence of clock resets, and specify which records a laboratory must preserve when its authorised acquisition was continuous but its network delivery manifestly was not. The anxiety is not theoretical: a perfectly repeatable corrupted sample can yield a striking, entirely spurious spectral line.

Grace Brewster Murray Hopper, Response: Mr. Davies, one ought to distinguish at least four boundaries. The analogue receiver generates a physical measurement at its input; the analogue-to-digital converter produces samples under a particular clock; the acquisition software frames or buffers those samples; and the evidence repository receives a named object. A digest at the fourth boundary cannot retrospectively certify the first three. I would therefore capture a monotonically increasing hardware or near-hardware sample counter where the equipment supports it, buffer sequence numbers, acquisition status flags, overflow counters, and a record of software or transport restarts. The counters themselves are assertions that must be tested, but they provide far more diagnostic purchase than a final filesystem digest alone.

Suppose a frame consists of 4,096 complex samples and the receiving computer observes sequence numbers 120, 121 and 123. The absence of 122 indicates a discontinuity to investigate, not necessarily proof that exactly 4,096 RF samples vanished. Reordering, retransmission, counter wrap, a false header or an instrument reset might also account for the

Copyright 2026, James M. Atkinson

pattern. The examiner compares transmitter-side logs, receiver acknowledgements, payload lengths, acquisition counters and independent event timing. If the missing unit is verified as a sample block, insert an explicit gap annotation in the analysis timeline. Do not silently synthesize plausible noise or join two nonadjacent sample regions as if their phase continuity had been observed. When a repaired derivative is produced for a plotting routine, record the interpolation method and retain the unfilled version.

The time claim needs care. At eight million complex samples per second, a missing block of 1,024 samples corresponds to 128 microseconds of nominal observation. A waterfall could obscure that interval when averaged over a longer display window, yet a phase-continuity or short-burst argument might depend upon every microsecond. The ledger must record the sample-rate estimate, missing-count assumption and the observation that established the gap. A separate packet capture can support network diagnosis, but it may itself contain information outside the RF evidential objective; acquire and retain only what is authorised and necessary for the transport question.

I should also insist on an acquisition-close record. It names the instrument, firmware, start and stop counters, acquisition state, measured data length, known overflows and the earliest digest that can be trusted. If the first digest is created after a two-hour transfer, the report must not silently depict it as a digest computed at the ADC. The relevant statement is narrower: from this documented post-transfer event onward, the stored bytes are unchanged under the stated hash assumptions. The acquisition may be complete or incomplete for other independently assessed reasons.

Copyright 2026, James M. Atkinson

By providing the two chains, physical sampling and digital custody, we can detect failure without claiming more than the evidence supports.

Grace Brewster Murray Hopper, Cross-Peer Question to Edsger Wybe Dijkstra: Professor Dijkstra, I respectfully pass the token to you because our custody scheme will be of little value if its software permits a supposedly immutable source file to be overwritten during examination. Consider an application that handles a source dataset, an editable metadata manifest, a working copy and a signed custody ledger, yet treats all four as ordinary paths in a writable directory. A clerical mistake can change the wrong object while all the user-interface labels remain reassuring. What invariants would you require, which system permissions would enforce them, and how might an examiner demonstrate that the verifier's own program did not quietly transform a byte sequence before calculating its digest? Please include the problem of crash recovery, the distinction between logical immutability and physical media behaviour, and the circumstance in which an analyst discovers that the supposedly authoritative digest was first calculated only after an unrecorded processing step.

Edsger Wybe Dijkstra, Cross-Peer Answer to Grace Brewster Murray Hopper: Admiral Hopper, I would first separate the statement to be proved from the mechanism intended to prove it. The proposition is that an identified source object has not changed after the recorded acquisition or preservation anchor. The mechanism might use read-only permissions, write blocking where appropriate, cryptographic digests and independent logs, but none of those phrases has meaning without specifying the object, the trusted components and the threat model. A checksum routine that reads a working derivative while labelling its output as the original is logically wrong even if

Copyright 2026, James M. Atkinson

its arithmetic is flawless. Program correctness is not purchased by acquiring a more elaborate hash algorithm.

I propose four software invariants. First, the original evidence object is addressed by a unique immutable identifier, and normal analysis code cannot request a write-capable handle to that object. Second, every transformation creates a new object with a new identifier, a recorded parent and a declared transformation, never an in-place replacement. Third, a digest operation reads a precisely delimited byte range and reports the algorithm, object length, execution status and error conditions. Fourth, ledger amendments are append-only, attributable and independently anchored so that a later user cannot simply replace an inconvenient history. These invariants should be subject to fault injection and adversarial testing, not left as programme comments.

A crash test is informative because a process may leave partially written buffers or stale renaming operations. The system must be capable of saying that an output was never completed and must not treat a partial file as a validated original. Storage hardware can remap sectors, maintain caches and perform legitimate internal maintenance while presenting the same logical byte sequence. Consequently, the ordinarily supportable assertion concerns the logical bytes returned through the tested storage interface, not the untouched condition of every physical magnetic domain or semiconductor cell. Where original media state itself matters, separate physical preservation procedures are required.

In the late-hashing example, the honest result is not to invent an earlier anchor. Label the earliest demonstrably trustworthy digest with its real date and scope. The chain before that point remains supported only by other

Copyright 2026, James M. Atkinson

evidence: acquisition logs, access records, independent copies, image histories and witness testimony. A later identical digest is powerful evidence about continuity from an actual reference state; it is no time machine. We should construct software so that it is difficult to make the mistaken inference, and reports so that the residual gap is visible rather than dressed in the language of mathematical certainty.

Dr. James M. Atkinson, Moderator: I thank Admiral Hopper and Professor Dijkstra. Their exchange locates a crucial boundary between an immutable byte object and a reliable explanation of its creation. Professor Dijkstra, please take the principal token and examine the programme invariants, state changes and fault conditions that would make this custody architecture independently auditable.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Second Principal Contributor: I should reject the practice of treating the existence of a hexadecimal digest as the architecture of an evidence system. A digest is the output of one calculation upon one defined object. An evidential workflow is a composition of acquisition, naming, transformation, verification, access control and truthful reporting, each capable of failing independently. The design should therefore begin with states and transitions, not screen colours or reassuring slogans. A source object enters a protected state only after a declared acquisition-close operation, a defined byte-range calculation and a recorded custody event. If those operations have not completed successfully, the system must label the object unanchored or provisional. It should not present a green verification symbol merely because a pathname exists and a digest field contains text.

There are at least five useful states: acquiring, closed but unanchored, anchored original, authorised derivative and quarantined discrepancy. Acquisition writes may be legal and necessary while a stream is arriving; the immutable-original rule cannot apply before the stream is closed. Once the source is anchored, ordinary analysis must employ read-only access or an exported working copy. A derivative may carry modified samples, new metadata, filtered or decimated representations and its own digest; it must retain a machine-readable link to its parent and a human-readable explanation of the transformation. A quarantined discrepancy is not automatically evidence of malice. It indicates that an asserted invariant has failed or cannot presently be verified, and it prevents silent promotion of that object to authoritative status.

Copyright 2026, James M. Atkinson

A crucial invariant concerns the difference between identities. The filename is not the object identity, because a rename may be lawful and file paths can be reused. A content digest is also not the whole identity, because two identical files can have different custody histories and different legitimate evidential roles. I would use an evidence-object identifier, content digest, object length, acquisition reference, scope definition and custody sequence together. If a new archive wraps exactly the same dataset bytes, the archive's whole-object digest changes, while a separately calculated digest over the unchanged embedded dataset should agree if the extraction boundaries are correctly documented. Both facts should be recorded without calling the repackaging either an attack or a proof of authenticity.

The schema must be explicit. Suppose complex samples are stored as signed sixteen-bit I and Q components in little-endian order, interleaved as I1,Q1,I2,Q2. The file may have no header, and the manifest supplies a conversion scale, sample rate, centre frequency and receiver gain state. A parser should refuse to proceed if a required datatype field is missing; it should not guess a common format and thereby manufacture a plausible waterfall. If the sample count implied by payload size is not an integer under the declared packing rule, that inconsistency deserves a diagnostic status. Nevertheless, divisibility alone is weak evidence: a truncated file can still contain an exact multiple of four bytes. Each check confirms a limited proposition and should be described accordingly.

Worked calculation one can be used as a software assertion. A complex sample comprising one sixteen-bit I value and one sixteen-bit Q value occupies four bytes, since sixteen plus sixteen bits equals thirty-two bits and eight bits make one byte. At ten million complex samples per second, a 2.5-

Copyright 2026, James M. Atkinson

second acquisition should therefore contain 10,000,000 times 2.5 times four, or 100,000,000 payload bytes, assuming no gaps, padding, compression or headers. If a manifest predicts that quantity and the storage object contains fewer bytes, the program should halt its complete-capture assertion and investigate. Exact agreement is necessary under those assumptions, yet it remains insufficient to prove that the RF input was real or that the declared sampling clock was correct.

The hash verifier must itself be tested. Feed it known public test vectors, deliberately truncated data, a single-bit alteration and a file changed during reading. If it calculates hashes on asynchronously changing material, the result need not represent any stable state. Reading through a verified immutable snapshot or a source held against modification reduces that ambiguity. The audit must also record software version, algorithm choice, input-range definition and whether errors occurred. A verifier that catches an access exception, reports success and leaves a previous digest on screen fails the most elementary condition of truthful operation. A digest comparison needs an independently protected expected value; otherwise an adversary able to alter both file and reference can create a new perfectly matching pair.

Canonicalisation requires another controlled boundary. A JSON metadata document can be rewritten with different whitespace, key order or equivalent number formatting while conveying the same intended fields. Hashing the raw bytes will detect such changes, which is entirely proper if the claim is raw-file identity. If an organisation additionally wants a canonical semantic representation, it must specify a deterministic canonicalisation algorithm and version, make its treatment of numbers,

Copyright 2026, James M. Atkinson

Unicode, duplicate keys and missing values explicit, then hash the resultant canonical bytes as a separate object. It must never retroactively replace a raw-file digest with an allegedly equivalent semantic digest. A parser which silently drops unknown fields may create a serious false equivalence between documents with different meanings.

Consider error handling. Loss of a clock reference, buffer overflow, unexpectedly changed receiver gain or a restart of a network acquisition service should produce visible state transitions and quality flags. A receiver may still emit bytes after one of these events, but the output's interpretation has changed. The custody chain can preserve those imperfect bytes faithfully. It cannot transform an overloaded analogue front end into an accurate measurement. Every alert should identify the affected sample interval when possible, the evidence available for the diagnosis, and the uncertainty in locating the interval. An examiner deserves to know whether a power-on transient has been observed at the antenna or produced by an unnoticed retuning of the local oscillator.

I would require independent checks of the programme's ability to enforce its restrictions. Use a synthetic dataset containing a unique test pattern and attempt to modify the anchored source through every advertised analysis route. Force crashes during digest calculation and while derivative objects are being committed. Revoke storage permissions, exhaust temporary space, change locale settings and swap endian declarations. Observe whether the system fails closed, preserves a complete audit entry and leaves the original object unmodified. The result of such tests is evidence about the implementation under the tested conditions, not a proof of perfection in every possible environment.

Copyright 2026, James M. Atkinson

Finally, there is a governance invariant. The object must be lawfully acquired for a declared purpose, even if its preservation is flawless. The record must name the authority and access constraints where required, minimise unnecessary communications content and distinguish scientific observations from classifications or attributions. Technical correctness and permission are separate obligations which should meet in the release gate. The next principal contributor should challenge whether the software tests actually establish the advertised custody properties and whether a convincing reproduction can be manufactured by a program that controls all the records it is asked to authenticate.

David Harold Blackwell, Peer Question: Professor Dijkstra, your machine has useful discrete states, but statistical evidence rarely arrives as an unequivocal success or failure. A clock's stability may be known only within a confidence interval; a buffer-loss counter might have an undocumented wrap; two supposedly independent copies may have travelled through the same defective software path. If every uncertainty causes quarantine, an ordinary laboratory will find itself unable to conclude anything. If every uncertainty is simply converted into a warning, on the other hand, an overconfident reviewer may ignore it. How would you allow the provenance ledger to represent graded support for distinct claims without confusing that grading with the binary question whether the file's bytes match a trusted reference? Please address how instrument uncertainty and investigator discretion ought to appear before a supposedly deterministic verification program certifies a later analysis. An examiner must also distinguish a defensible conditional conclusion from a claim that several

Copyright 2026, James M. Atkinson

uncertain measurements have somehow become independent merely because they have separate database entries.

Edsger Wybe Dijkstra, Response: Professor Blackwell, the programme should not attempt to make every proposition binary merely because a comparison operator produces TRUE or FALSE. It can be precise about the question it is answering while leaving evidential questions appropriately qualified. A digest over a fixed sequence can be compared with its expected value deterministically, subject to the assumptions about stable reading and trustworthy reference data. A timebase measurement carries an uncertainty interval established by calibration and observation. Whether two custody narratives are independent may require investigation of their common infrastructure. The system should assign those claims different types rather than manufacturing a single composite score whose arithmetic conceals their meaning.

I would treat verified byte continuity, verified schema interpretation, documented acquisition circumstances and validated physical signal attribution as separate report fields. For the first, record exact hash equality or inequality, algorithm, input scope and the identity of the expected digest. For the second, record parser conformance, the tested metadata version, whether all required fields were present and any ambiguous representations. For the third, record named event logs, operator declarations, instrument configuration and defects noted during acquisition. For the fourth, state observations, alternative explanations, measurements and the strength of the inferential method. These dimensions are related, but none can be replaced by a convenient green box on the computer screen.

Copyright 2026, James M. Atkinson

A failure to resolve clock drift should limit the time claims, not necessarily make every sample useless. A recorder whose exact time is uncertain may still contain an unaltered spectrum segment supporting a frequency-domain calculation, provided that the sampling-rate uncertainty is included and the relevant frequency calibration is adequate. Conversely, byte equality does not make a corrupted calibration file trustworthy. The reviewer may approve a narrow proposition, such as continuity of a particular byte range since a specified evidence-lock event, while withholding a broader proposition, such as an absolute onset time to the nearest microsecond. A well-designed record makes such partial conclusions easier rather than forcing an investigator to choose between absolute certainty and silence.

Statistical grades should identify their denominator and experimental protocol. Suppose two independently designed validators agree on all one hundred controlled test datasets, including deliberate corruption and representation changes. That is useful performance evidence against the tested cases; it does not establish a universal zero failure probability, especially if the tests share code libraries or if actual failures differ from the designed set. The report should disclose common dependencies and untested assumptions. In this manner software invariants and statistical uncertainty coexist: the invariants define what must not happen, while experiments describe where confidence in their implementation has and has not been earned.

John von Neumann, Peer Question: Professor Dijkstra, a hash function is usually evaluated as a mathematical transformation, whereas an evidential repository is a physical computation carried out by processors, memory controllers, storage devices and operating systems. A memory fault,

Copyright 2026, James M. Atkinson

malicious firmware or silently substituted executable can make the reported input different from the bytes a reviewer thinks were hashed. In addition, a hash may be computed at the correct instant but the stored digest may later be replaced alongside the data. It is tempting to add another layer of hashes, yet that can merely reproduce the same trust defect at a larger scale. Where should one place the trust boundary, what independent witnesses can test it, and how should the report express an assurance argument without assuming that a single machine can certify itself? Might a hardware-backed attestation or separately witnessed acquisition record improve the case, and what errors would each still be incapable of detecting?

Edsger Wybe Dijkstra, Response: Professor von Neumann, you have identified the reason to distinguish a formal statement about an algorithm from an assurance claim about an entire computer. A mathematically specified SHA-256 function takes an identified bitstring and returns a 256-bit digest. A real forensic workstation must obtain the intended bitstring from storage, execute the intended program and store the expected digest where an unauthorised user cannot conveniently alter it. If any of those surrounding operations are unreliable, the mathematics may remain correct while the evidential assertion fails. The answer is not an infinite regress of self-signed messages, but an explicit, finite trust model with independent controls and acknowledged residual risks.

For example, an acquisition system may create a digest at source close, an independent protected repository may verify it upon receipt, and a later analyst may verify the exported read-only object in another controlled environment. If the original digest is placed in a separately protected

Copyright 2026, James M. Atkinson

custody register before a disputed alteration, the later comparison has stronger significance than two values printed by the same mutable application at the same instant. Multiple custody events should include the identities of the systems, operators, versions, permissions and exception statuses. A mismatch must be preserved and investigated. It should never be erased by replacing the baseline with the latest calculated number merely to restore visual agreement.

I should also require reproducible validation of the verifier. Its source and build record, known-answer tests, input-range behaviour and failure handling need independent examination. One can use a second implementation to check selected files, but if both draw input from the same compromised storage translation layer, the supposed independence is limited. Where warranted, custody controls can include a write-protected acquisition image, a separately generated digest, independent copy comparison and tamper-evident access records. Each layer should answer a stated failure mode rather than increasing complexity for its own sake. Excessive verification machinery can be a source of mistakes if operators cannot understand it.

The report's assurance statement should therefore be deliberately narrow. It may say that two defined byte streams were read in separate controlled systems and produced equal digests under an identified approved algorithm, with the reference value secured at a documented prior time. It should not say that the electromagnetic source was authentic, that every circuit was free of defects or that an adversary was physically incapable of interference. We avoid both credulity and metaphysical scepticism by demanding an explicit chain from measured event to digital object to later

Copyright 2026, James M. Atkinson

inference, and by marking the points at which direct observation gives way to an assumption.

Edsger Wybe Dijkstra, Cross-Peer Question to Alan Mathison Turing: Mr. Turing, I pass the token respectfully to you. Suppose a laboratory operates two independent hash utilities that agree on the bytes currently held in its evidence repository. The instrument firmware, however, could have converted samples to a different numeric representation before the first acquisition log was written; the host could also have assigned a fictional start time. The verification system might execute exactly as specified while affirming an inadequate narrative of the data's origin. What independent test architecture would challenge the software's correspondence to the physical acquisition, and how would you avoid confusing verification of a later program with validation of an earlier measurement? I invite you to consider deliberate faults, trusted reference signals, reproducible computational tests, versioned software builds and the uncomfortable possibility that a suspicious result is reproducible only because the same defect is reproduced. I ask particularly whether the reference generator, recorder and independent observer share software dependencies that could disguise a common error as agreement.

Alan Mathison Turing, Cross-Peer Answer to Edsger Wybe Dijkstra: Professor Dijkstra, the distinction between programme verification and experimental validation is fundamental. The statement that an algorithm produces a digest according to its specification is not equivalent to the statement that the physical receiver produced a faithful measurement of its analogue input. To challenge the latter, the experiment must be arranged so that some relevant facts are established outside the device under examination. A

Copyright 2026, James M. Atkinson

calibrated reference signal can establish an expected frequency and timing interval, while a separate instrument and clock provide observations against which the receiver's file can be compared. The aim is not to assume that the independent apparatus is omniscient, but to expose the dependency structure and measure disagreements.

I would design a controlled trial with hidden event labels. An RF generator produces permitted test bursts, null periods, frequency steps and deliberate amplitude changes. The sample recorder acquires them under documented settings, including gain, filtering, oscillator reference and software version. The reviewer receives the original dataset, manifest, digest and custody chain, but the reference generator's schedule is withheld until the receiver reconstruction has been made. Comparing the reconstruction with that independent schedule tests a proposition about signal acquisition, rather than merely testing whether a later copy reproduces the same bytes. Deliberately induce dropped buffers, clock offsets, front-end overload and a restart. The programme should report the consequent limits rather than producing smooth, apparently complete data.

Software builds require their own provenance, including source revision, toolchain, configuration and executable digest. A digest of the acquisition application can demonstrate that a later executable file matches a recorded build, but does not prove that the source code was correct or the processor executed it without fault. Known-answer tests of the hash implementation and format parser should be separated from instrument-validation experiments. A pair of independent parsers can help reveal endian or scale errors, yet they may share mistaken documentation. The procedure must

Copyright 2026, James M. Atkinson

compare both to a controlled known sample array whose intended numeric interpretation is independently specified.

Finally, scientific reproducibility includes reproducibility of failure. If every restart yields the same spurious transient because the receiver's gain loop follows the same sequence, repeating the observation does not establish an external transmitter. Change the receiver configuration, reference input, front end and measurement path where authorised. Record failures with the same diligence as successes. The final report should say exactly which propositions have been supported by the direct physical controls and which are only supported by continuity of the subsequent digital representation.

Dr. James M. Atkinson, Moderator: Thank you, Professor Dijkstra and Mr. Turing. We now have a distinction between an auditable programme and a validated measurement process. Mr. Turing, please take the principal token to develop an adversarial, reproducible test strategy for both the digital evidence system and its RF acquisition boundary.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Third Principal Contributor: The word verification has become dangerously elastic when used to describe digital evidence. An investigator may verify that two files have identical digest values, verify that a parser produces expected samples for known test data, or verify that a particular RF transient occurred at the antenna of a known receiver. These are different questions with different witnesses. A machine cannot supply all its own foundations simply by printing the word passed. We should begin with an experimental model whose hypotheses are narrow enough to be falsified and whose records can survive review by someone with no loyalty to the original operator.

Let there be a hypothetical evidence record E containing a raw byte object B, a metadata statement M, a custody history C and a set of physical-acquisition observations P. One may calculate H(B), the digest of the raw bytes, and H(M), the digest of the exact manifest file. Matching a later H(B) to a protected original value supports continuity of B after the anchor event. It says nothing by itself about whether M is true. Matching H(M) supports continuity of the manifest's bytes, but not truth of their contents. The physical observation set P can include an independent reference source, measured timebase errors, gain calibration and a second receiver's observations. The custody history C documents who made, transferred, examined and transformed each object. An evidential claim should cite the elements relevant to it rather than invoking the entire bundle as if every component proved every other.

A practical verification suite ought to contain attacks which do not require a malicious outsider. An analyst renames a file; the whole-file content digest should remain unchanged, though path metadata and custody entries may

Copyright 2026, James M. Atkinson

differ. The analyst copies identical bytes to a new medium; equality is expected under successful copying. The analyst puts the same sample array in a differently structured container; a digest of the new whole object changes, while a properly delimited extracted sample digest may agree. The analyst changes one bit in the payload; a correctly operating secure digest should ordinarily change, but the scientific conclusion must remain probabilistic with respect to collisions, and a recorded nonmatch needs investigation. The analyst edits only the declared sample rate in a separate manifest; the raw sample-byte digest need not change at all. These tests are stronger than an attractive demonstration in which every file is either wholly identical or obviously destroyed.

Consider a concrete interpretation test. Four stored bytes are 01 02 FF 7F in hexadecimal, and the declared format is one complex sample containing two signed sixteen-bit integers. Interpreted little-endian, the I component is hexadecimal 0201, decimal 513, and the Q component is hexadecimal 7FFF, decimal 32,767. Interpreted big-endian, the I component is hexadecimal 0102, decimal 258, while the Q component is hexadecimal FF7F, the signed decimal value negative 129. The identical four bytes support radically different numerical values depending upon byte order. Both parsers can compute an identical hash of the file because neither has altered a byte. The relevant test is therefore to verify the declared schema against a known reference stream, not to ask whether the digest is equal.

A second test should distinguish logical acquisition time from host time. Suppose a sample with hardware index four million follows an established time origin on a device running at eight million complex samples per second. Its nominal offset is one half-second, since index divided by sample

Copyright 2026, James M. Atkinson

rate gives elapsed sample time. A file's modification timestamp might be several seconds later because the programme wrote asynchronously. Neither the correct sample offset nor the equal hash validates the absolute time origin; that needs evidence of clock synchronisation and trigger alignment. A host filesystem timestamp should never be silently used as a substitute for a tested acquisition-clock timestamp.

The integrity software also needs adversarial operational tests. Remove permission to read a file halfway through a digest calculation; the verifier must fail, not show an old success result. Change the file while it is being streamed into the algorithm; the verifier must detect that its snapshot assumptions were broken or operate on an immutable snapshot. Introduce a truncated final sample pair and demand a clear parsing failure. Change a metadata schema version and verify that unknown critical fields are not discarded. Test a duplicate-key conflict in a machine-readable manifest and require deterministic rejection or a documented, carefully controlled rule. A document accepted by one parser and interpreted differently by another cannot be treated as unequivocally reproducible.

I should caution against the fetish of bitwise equality. If a scientist intentionally converts signed sixteen-bit complex samples into a documented floating-point derivative, the bytes naturally change. The transformation may preserve the underlying numerical values within the converter's precision and rounding properties, but that equivalence requires a separate numerical test. If decimation or filtering is applied, some information is deliberately discarded, and the derivative no longer proves that every property of the original waveform has survived. The proper ledger preserves the original and records the operation, parameters,

Copyright 2026, James M. Atkinson

software, validation examples and resultant digest. A later analyst should never have to reverse-engineer why two files differ.

For an acquisition validation experiment, use an authorised shielded or otherwise controlled laboratory configuration. Set a reference generator to produce programmed bursts at independently logged times and frequencies; include matched null conditions, deliberate source-level changes and benign interference. Measure the generator through a second instrument whose own limitations are documented. Do not train the device or its interpreting software on the final blind validation sequence. Compare recovered timing, measured bandwidth, sample continuity and phase behaviour against the reference record, stating uncertainty and the categories of error. A digest protects the post-acquisition evidence object, while the independent measurements test whether that object corresponds to the claimed physical process.

The chain of custody must survive routine human behaviour, including interrupted transfers, shift changes, a changed laboratory clock and later correction of a manifest error. Every source file should have an object identifier, digest algorithm and scope, data length, custody event, protected expected digest and relevant permissions. Every derivative should name its parent and transformation. Preserve conflicting observations instead of selecting whichever produces the most dramatic attribution. Software itself should make the modest conclusion easy to report: the identified bits match the protected reference since a stated event; the authenticity of the acquired RF phenomenon has been separately assessed, remains uncertain, or was not assessed.

Copyright 2026, James M. Atkinson

My proposed release test is not whether the examiner can reconstruct an impressive plot. It is whether a second qualified examiner, using the preserved original bytes, declared schema, reliable tools and separately supported calibration and timebase records, can challenge each inferential step and obtain an appropriately qualified result. An absent manifest, an unexplained gap or an undefined reference plane should not be hidden by the mathematical precision of a digest. Mr. Reed should now examine what error-detecting codes can and cannot contribute to this architecture and whether a corrected stream can honestly be called the original.

Peter Elias, Peer Question: Mr. Turing, a digital evidence system can preserve a bitstring faithfully while applying an error-correcting code during transmission or storage. The decoded output may differ from the received symbols, yet the code may have repaired a genuine transmission error according to its declared error model. An archivist may then preserve only the corrected result and claim, rather carelessly, that the evidence has not changed. Is it intellectually defensible to use a corrected digital object for later RF analysis when the uncorrected received bytes have been lost? I ask you to distinguish what a code's algebra proves about the declared channel from what it says about the analogue waveform that entered the ADC. Would you require preservation of parity information, syndrome records and correction counts, or can a carefully documented corrected object stand as the earliest available anchor? Please consider the danger that a plausible reconstruction might conceal an interval in which the original instrument never actually measured the signal being inferred.

Alan Mathison Turing, Response: Professor Elias, a correction procedure and a preservation claim have different time origins. Error-correcting storage

Copyright 2026, James M. Atkinson

may be a perfectly legitimate part of a digital recorder. If the instrument generates a logical data stream, passes it through a code and later reconstructs that stream after encountering a correctable storage fault, the investigator can report that the recovered logical content is consistent with the recorded codeword and its correction model. However, the proposition is not that every physical storage symbol remained untouched. It is that the storage system reconstructed an intended logical sequence under specified assumptions. If the recording architecture retained parity, syndromes and controller error counters, those data may strengthen an explanation of what happened; if not, the examiner must be clear that the earliest visible object may already be a recovery product.

The original acquisition boundary still matters. Suppose an ADC writes an incorrect numerical sample because its analogue front end saturated. An error-correcting code in the storage path will faithfully preserve that incorrect number; it cannot identify the true unsaturated voltage. Equally, if an acquisition application drops 1,024 complex samples and then writes a seamless-looking stream, the later storage code has no basis to reconstruct the omitted physical measurements. Coding theory concerns redundancy deliberately introduced into a representation. It is not permission to invent signals which were never acquired. The evidence report should therefore separate ADC or acquisition completeness from downstream storage recovery and from subsequent forensic file integrity.

Where possible I would preserve a protected source object at the earliest practical logical boundary, including acquisition counters and storage-health indicators. If error correction occurred before any examiner could access the file, the report should name the correction layer and identify which

Copyright 2026, James M. Atkinson

telemetry is available. A derived file can be analytically usable even if its pre-correction symbols were not retained, but a claim of bit-for-bit identity to inaccessible original symbols is unsupported. Compare the recovered object against independent contemporaneous copies where such copies exist. Where no independent comparison is possible, do not disguise absence of evidence with a claim of absolute fidelity.

A hypothetical laboratory can demonstrate the distinctions. Record a known complex-sample pattern, introduce a correctable storage error, and show that decoding produces the original sample bytes while a controller logs a correction event. Then alter a sample intentionally before it enters the coding stage; the storage system should preserve that deliberately incorrect sample without objection. Finally, omit a sample interval upstream of the coding stage; no parity scheme designed for downstream storage errors can establish the missing analogue values. The experiment reveals three locations of failure, and each merits a different qualification. It illustrates why the object and instant of hashing must be stated as carefully as the properties of the error-correcting code.

David Lennox Mills, Peer Question: Mr. Turing, the custody ledger may describe a timestamp as acquisition time, yet in a networked laboratory several clocks can be involved. An RF recorder may label samples with a hardware counter, a host may label files with its wall clock, a network transfer may add another receipt time, and a trusted service may later apply an authenticated timestamp to a digest. These quantities are often printed together in a report as if they arose from the same temporal reference. How should the investigator distinguish the observed time of an RF event from the date a custody statement was created? Please explain how offset, drift,

Copyright 2026, James M. Atkinson

leap-second handling, trigger latency and uncertainty should be represented. In particular, I should like a procedure for a file whose bytes match perfectly but whose original wall-clock record was wrong by an unknown amount. Does a later authenticated timestamp upon the hash offer any admissible evidence about the earlier RF event, beyond establishing a bound on the existence of the subsequently preserved object?

Alan Mathison Turing, Response: Dr. Mills, there is no reason for an evidence system to pretend that all clocks answer the same question. The sample counter identifies ordering in a sampled stream and, given an appropriately qualified sample-rate model, relative time. A hardware reference and trigger mark may permit that stream to be placed upon an absolute time scale. A host operating-system clock labels the occurrence of host events such as writing or closing a file, and its offset from the acquisition clock may be substantial. A protected timestamp over a digest records that the digest or attested object existed before or at a documented certification event under the service's stated trust assumptions. It does not transform the digest into a precise RF-event timestamp. These should be typed as separate fields with explicit provenance.

The rate relation is simple, but its assumptions must be recorded. For a sample index n, nominal sample rate f_s samples per second and reference origin t_0, the nominal sample time is $t(n)=t_0+n/f_s$. An illustrative index of 4,000,000 at eight million complex samples per second yields 0.5 seconds after the defined origin. If t_0 has an uncertainty of two milliseconds, the arithmetic cannot eliminate that uncertainty by printing more decimal places. If the oscillator has a bounded error, its contribution grows with the duration of the record. As an example, a relative rate error of two parts per

Copyright 2026, James M. Atkinson

million persisting for ten seconds represents approximately twenty microseconds of accumulated timing error, subject to sign, stability and the precise clock model. The numbers belong in an uncertainty budget, not in a claim that the file hash somehow measured them.

For the case of an incorrect original wall-clock field, preserve it as originally recorded and issue an attributed correction supported by independent time evidence. Useful sources may include a separately logged reference pulse, a calibrated timing input, generator event logs or a recognised time-transfer comparison. A network timing packet alone may not show the actual ADC conversion instant, especially when the acquisition path buffers samples. If no reliable evidence can resolve the offset, a defensible report may retain precise relative timing and state that absolute time is not established within the desired tolerance. There is nothing improper about uncertainty honestly bounded; the impropriety would be to replace it with an invented exact instant.

The custody system should record at least four temporal events: the acquisition event or interval under the instrument's timing model; the closure of the digital object; the creation of its earliest protected digest; and each subsequent transfer or examination. When these events cannot be aligned precisely, list the known sequence and the unresolved intervals. Clock corrections need versioned records, just as manifest corrections do. An accurate digest over a byte sequence containing a wrong timestamp perfectly preserves the wrong timestamp. It does not correct it. A court, auditor or engineering reviewer will be better served by this modest formulation than by an immaculate but unsupported chronology.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Cross-Peer Question to Irving S. Reed: Dr. Reed, I respectfully pass the token to the specialist in the design and interpretation of error-detecting and error-correcting codes. In the controlled experiment, imagine an RF dataset that has been divided into numbered blocks, protected with per-block checks and then archived under one whole-file cryptographic digest. A later read reports a recovered block following a correctable storage error; another read produces a complete file whose digest differs by one bit; a third file contains the right length but repeats an earlier sample block while omitting a later one. How can an investigator discriminate these conditions without exaggerating what a code can repair? Please distinguish a random storage fault from a deliberately altered but internally consistent file, a checksum from a cryptographic hash, and coding redundancy from physically observed RF redundancy. I would welcome a worked method for identifying a sample gap without asserting that the unknown RF values can be conjured out of parity generated after acquisition.

Irving S. Reed, Cross-Peer Answer to Alan Mathison Turing: Mr. Turing, the first discipline is to identify the channel for which a particular code was designed. A parity check on a stored block can reveal certain patterns of errors within that block, and a correcting code may reconstruct symbols when the actual number and pattern of errors are within its correction capability. Neither statement is a claim about the truth of the analogue signal that the ADC purported to measure. If erroneous samples were already present when the redundancy was calculated, the code can preserve them perfectly. If a sample block was never delivered to the coding process,

Copyright 2026, James M. Atkinson

the scheme cannot recover the missing RF observation unless independent information exists beyond the stated storage code.

A whole-file cryptographic hash answers another question. Compared with a protected reference, it is an integrity indicator for the specified byte sequence, with security depending upon the hash function and protection of that reference. A simple checksum may detect common accidental changes but may be easy to manipulate or collide under adversarial conditions. A correcting code seeks structured reconstruction of data through redundancy, and a digest seeks evidence of equality or change; their purposes are complementary rather than interchangeable. In the one-bit experiment, the correct interpretation is that a controlled bit alteration should produce a digest mismatch in the overwhelming ordinary case, and the laboratory should independently verify that it did so in the actual test. The digest does not reveal which physical cause changed the bit.

The repeated-block case is especially instructive. A file can have the expected length and every local sample-packing field can be syntactically valid while containing a duplicated earlier block instead of a later one. If acquisition buffer counters and per-block identifiers were preserved under trustworthy conditions, the substitution might be evident. If those markers are also rewritten consistently, a later verifier can establish continuity of the substituted file from its later anchor, but it cannot recover the missing historical fact solely from a matching fresh hash. A second independently captured stream or an authenticated contemporaneous acquisition log may establish the discrepancy. The report must acknowledge when no such witness survives.

Copyright 2026, James M. Atkinson

I would preserve original, corrected and derived objects separately when the recording technology exposes these layers, with their digests, error telemetry, correction algorithm and software version. A correction should be described as a computational transformation supported by the code's assumptions. It should not be represented as a fresh observation of an RF waveform. That distinction enables an analyst to exploit reliable coding technology without presenting mathematical reconstruction as if it were unmediated physical evidence.

Dr. James M. Atkinson, Moderator: Thank you, Mr. Turing and Dr. Reed. The discussion has exposed how a completely preserved file may contain an imperfect observation, and how correction of stored data differs from recovery of unobserved RF samples. Dr. Reed, please take the principal token and address block validation, error correction, sample gaps and adversarial modification in a forensic receiver chain.

Copyright 2026, James M. Atkinson

Irving S. Reed, Fourth Principal Contributor: In a forensic radio recorder, the phrase error-free has no useful meaning until one names the boundary across which freedom from error is asserted. A cryptographic hash can support a comparison between two byte sequences; a storage code can correct certain corrupted symbols in a declared channel; an RF calibration procedure can estimate the accuracy of an analogue measurement. These mechanisms live in different layers. The investigator must not carry a guarantee from one layer into another merely because it is expressed by mathematics. A code can preserve a false statement perfectly, just as a correct chain of custody can preserve an authentic file containing samples produced by an overloaded front end.

I would divide the recording chain into acquisition frames, transport frames, storage objects and analytical derivatives. Where supported by the instrument, an acquisition frame includes a monotonic hardware sample index, expected number of complex samples, clock and configuration state, overflow status and a means of associating the frame with the overarching acquisition session. Transport adds its own sequence information, packet integrity checks and retransmission history. Storage produces a durable logical object, possibly supported by an error-correcting storage controller. The analysis layer extracts intervals, converts sample representations, filters and measures. An original file hash should be made at a declared boundary; hashes at later boundaries document later continuity, not the earlier success of every preceding stage.

The simplest useful arithmetic is a dimensional check. Let N be the count of complex samples, b_I and b_Q the bits allocated respectively to in-phase and quadrature components, and f_s the nominal complex-sample rate. For a

Copyright 2026, James M. Atkinson

packed representation without padding or headers, file payload length is N times (b_I+b_Q) divided by eight bytes, and acquisition duration is N divided by f_s seconds. If N is one million, b_I=b_Q=16 and f_s is two million samples per second, the expected length is four million bytes and nominal duration is one half-second. These calculations are necessary consistency checks. They do not reveal whether the samples were generated by a real antenna, whether the clock was calibrated or whether an omitted earlier block was replaced by a fabricated one.

An especially revealing failure is a repeated block. Suppose the sequence should contain A, B, C, D but the repository contains A, B, B, D. All four blocks may have the proper length and acceptable numeric values. A digest computed after the substitution can agree forever with later copies, while a contemporaneous source-side digest would reveal a mismatch if the intended original was recorded and protected. Frame counters and independent logs may expose the wrong sequence, although a damaged or maliciously constructed log can defeat that evidence. One cannot simply inspect a smooth waterfall and infer that C must have been present. A scientifically honest analyst marks the discontinuity, preserves the observed bytes and avoids joining phases across the unknown interval without a separate evidential basis.

A correcting code requires a model of errors and erasures. If a codeword of a known family is received with corruption within its designed capability, decoding can produce a candidate original codeword, and syndrome or correction counters can record the process. The statement should specify the code, parameters, detected fault, corrected symbol count and residual failure probability where assessable. Correction is not equivalent to forensic

Copyright 2026, James M. Atkinson

authenticity. A deliberately forged stream with newly computed parity can pass code checks because the code has no independent knowledge of the signal's lawful origin or physical truth. Likewise, the code's ability to correct storage bits says nothing about a drifted local oscillator during acquisition.

Consider the difference between an accidental one-bit change and a controlled rewrite. In a hypothetical laboratory, a single bit of an originally preserved file is flipped and the known expected SHA-256 digest is compared against the newly calculated digest. The experiment should observe a nonmatch; the analyst records the actual digest values and test method. A second trial rewrites a complete sample frame and recalculates a fresh digest. That new digest is internally valid for the altered bytes, yet comparison against the securely retained old reference should disclose the alteration. If the attacker can replace the original reference as well, digest equality to the substituted reference proves little about the history. The custody system must protect expected values, with independent witnesses when feasible.

Timing offers another calculation. A verified omission of 1,024 complex samples at an eight million-sample-per-second rate represents a nominal interval of 0.000128 second, or 128 microseconds. The word verified matters: a missing sequence number alone may reflect packet reordering or a reset rather than a confirmed gap in ADC output. The analysis should first reconcile the device's hardware sample indices, buffer logs and transport retransmission record. If the gap is real, a derivative may insert an explicit missing-data mask to preserve downstream alignment. Such a mask describes absence, not reconstructed RF values. An interpolation may be

Copyright 2026, James M. Atkinson

useful for a visual demonstration, but its output requires a separate object identity and conspicuous qualification.

Some investigators conflate a cryptographic digest with an error-locating code. SHA-256 produces a 256-bit output, displayed commonly as sixty-four hexadecimal characters, but a difference in its output does not itself identify which byte changed. Block-level hashes can help localise a mismatch if protected reference values were established for each block and the block scheme is robustly specified. Even then, a block match confirms only equality of the defined block bytes. A changed manifest may make the same samples represent different voltages, frequencies or times, while all block digests remain equal. Conversely, an innocuous change in an enclosing file header can change a whole-file digest without touching the sample block bytes. State the scope before interpreting the comparison.

A useful design pairs per-block sample counters with an independently retained acquisition-close record and a whole-object digest. A session manifest declares format revision, channel packing, signedness, endianness, sample rate, clock basis, gain, filtering, centre frequency, missing-data conventions and known validity limitations. When a valid derivative is created, the laboratory records parent-child identifiers, transformation parameters, code version, new length and new digest. It is also prudent to log storage health and corrected-error events because they help explain why a later reconstruction may depend upon error correction. Such records are diagnostic witnesses, not substitutes for the actual preserved bytes or a properly bounded observation of the physical signal.

Finally, an evidential conclusion should differentiate agreement, consistency and identification. A matching digest is agreement between defined digital

Copyright 2026, James M. Atkinson

objects under stated assumptions. Agreement of calculated sample duration with the recorded event interval is a consistency check. Agreement of the resulting spectral features with a known source in a controlled test may support that specific identification under the experimental limits. None of these alone identifies an unknown emitter in the field. The editor should resist colourful but unsupported rhetoric, particularly when spectral artefacts, overload, multipath and sample-clock errors can create compelling appearances. We should next ask Dr. Hamming to assess the practical consequences of imperfect data, finite numerical precision and the reproducibility of derived measurements.

Claude Elwood Shannon, Peer Question: Dr. Reed, a preserved RF sample stream can be compressed, resampled or passed through a finite-precision transform before an analyst sees its waterfall. In the favourable case, a reversible encoding merely changes the arrangement of bytes while preserving the entire logical sample sequence. In other cases the transformation is intentionally lossy, and the apparent shape of a weak burst depends upon its quantisation and filtering errors. How should the custody record state what information has survived a transformation, rather than using the imprecise word unchanged for both byte-identical and information-equivalent objects? I should also like you to address a derivative whose displayed spectrum matches the source in ten ordinary laboratory cases but fails for a rare narrow transient. Can a small empirical validation set justify an assertion that the new representation preserves every evidentially relevant property? What is the proper response when the preservation objective is known only after a later investigator proposes a different hypothesis?

Copyright 2026, James M. Atkinson

Irving S. Reed, Response: Dr. Shannon, the decisive distinction is among byte identity, lossless reversibility under a defined representation, and preservation of some particular analytical features within a measured tolerance. These relations cannot be treated as synonyms. A simple file rename may leave its content bytes identical; a different archive format changes the archive object while retaining identical extracted sample bytes; a documented endian conversion changes payload bytes but may preserve signed numeric sample values if conversion is executed correctly. A lossy quantiser, decimator or compressor can change numerical samples and irreversibly remove information. Every derivative must declare which kind of equivalence, if any, the author intends to defend, and supply a test suited to that claim.

If a laboratory promises lossless conversion, it should verify the exact output of a round trip against a defined original, considering numeric type, finite values, NaNs where relevant, channel ordering, byte order and metadata. For an explicit sample-array equality test, decode both objects into the same documented canonical numeric representation and compare the ordered sequence under a specified equality relation. That test is distinct from comparing whole-object digests. An archive can contain the same sample stream while its compression headers, timestamps or filenames change. The new archive requires its own hash and custody event, and the extracted samples require their own reference scope if comparison is the claimed objective.

If the conversion is lossy, the claim should be narrower. Define frequency resolution, amplitude or phase error bounds, transient-duration range and the permitted inference before testing. For example, a decimator may

Copyright 2026, James M. Atkinson

preserve a slowly varying baseband component under an appropriately designed antialias filter while removing frequencies outside its retained passband. It would not preserve every possibility of a later short-pulse or adjacent-channel investigation. Ten demonstrations without difficult corner cases could support the observation that those ten worked, but they cannot establish universal preservation. Blind reference cases should include near-threshold events, impulses, saturation, frequency-edge features and counter discontinuities relevant to the authorised questions.

I would therefore mark derivatives as fit for stated purposes, not equivalent in the abstract. The protected original sample object, if lawfully retained, permits a later authorised examiner to test another claim. If the original was never retained because the permitted operation was narrowly limited to aggregate measurements, the institution should report that limitation rather than reconstruct an imaginary full-rate dataset. Forensic honesty is sometimes the statement that a later question cannot be answered from the retained evidence. No compression theorem or integrity digest can replace information deliberately or accidentally discarded before the evidential anchor.

Irving S. Reed, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, I pass the token with respect to your long concern for numerical computation and the dependability of data. The archive may consist of an unchanged raw file, a protected manifest and an apparently impeccable series of hashes, yet a later analyst can reconstruct the same incorrect spectrum by consistently misreading the sample format or using a wrong scaling convention. Conversely, a legitimate conversion from signed integer to floating point can change every output byte while preserving the useful

Copyright 2026, James M. Atkinson

sample values within a stated tolerance. What practical numerical acceptance tests would you require before calling such a derivative reproducible? Please examine finite-precision arithmetic, IQ channel order, clipping, power normalisation and the distinction between an exactly reproducible mistake and a validated measurement. I should be grateful if you could also say how to document the inevitable uncertainty without burying a forensic report in insignificant decimal places.

Richard Wesley Hamming, Cross-Peer Answer to Irving S. Reed: Dr. Reed, a numerical result does not acquire physical truth merely by being repeatable to the last printed digit. If the input bytes are read under a mistaken schema, two laboratories using the same flawed parser may agree exactly and still be wrong. The first safeguard is a set of known-value test vectors that exercise the extremes of each supported numeric type, both byte orders, signs, zero, saturation values and the declared I/Q ordering. Include a synthetic complex sinusoid with known frequency offset, phase evolution and amplitude, plus null and deliberately clipped cases. A parser should be required to produce the expected samples before any expert interpretation of field data is accepted.

The arithmetic acceptance test must name its tolerance and reference plane. Conversion of an integer sample into floating point may reproduce each integer exactly for sufficiently small widths under a supported floating-point format, but later filtering, resampling or power calculation can introduce rounding errors. Report the software version, precision, order of operations and test results. If two computational routes differ, determine whether the difference falls within a justified numerical error budget. Do not declare equivalence merely because two waterfalls look similar to the eye. A

Copyright 2026, James M. Atkinson

display's colour scale and averaging can hide an error that materially affects a short transient.

Take the question of power. A squared complex amplitude depends upon I squared plus Q squared, but converting that quantity into watts or dBm requires a physical scale and a defined reference impedance or calibrated instrument convention. An ADC integer alone does not supply those quantities. If the gain state changed or the analogue input clipped, the numerical magnitude can be precise while the inferred input power is unsound. Record calibration, gain, attenuation, detector treatment and the effect of window normalisation. The original bytes and manifest are necessary evidence for the computation, but their digests do not validate the analogue chain or the chosen physical units.

The practical result should be a reproducibility dossier rather than an exaggerated certificate. Preserve the source dataset; name each derivative and its transform; protect source and output digests; supply sample schema, selected reference vectors, numerical tolerances, algorithm parameters and test logs. A second qualified examiner should be able to reproduce the calculation and deliberately vary the interpretation to see how the finding changes. Where the precise phase, absolute time or power is not defensible, state the narrower observation that is defensible. Good engineering does not suppress uncertainty; it gives uncertainty an address and a unit.

Dr. James M. Atkinson, Moderator: I thank Dr. Reed, Dr. Shannon and Dr. Hamming. We have separated exact byte continuity from correction, reversible representation and valid physical interpretation. Dr. Hamming, please take the fifth principal token and give the panel a concluding

Copyright 2026, James M. Atkinson

technical discipline for finite precision, experimental controls and forensic reporting.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Fifth Principal Contributor: The strength of a measurement is not determined by the number of digits it prints or the size of the file that contains them. A forensic SDR system can generate terabytes of perfectly preserved samples and yet fail to establish a single disputed timing or power proposition, because the instrument state, interpretation schema or independent reference was inadequately recorded. Conversely, a short well-characterised sample interval with a clear uncertainty statement may support a reliable and modest conclusion. We should judge the evidence system by the claims it makes possible to test, not by the magnificence of its storage machinery.

I would begin every significant reproduction with a format test, an instrument test and an inference test. The format test uses known byte sequences to check signedness, endian order, channel interleaving, numeric scale, headers and sample count. The instrument test uses calibrated or otherwise independently characterised reference stimuli to test gain, timing, frequency response, phase and overload behaviour. The inference test asks whether the specific conclusion follows from the recorded measurements when alternative explanations and uncertainty are considered. The file hash belongs principally to the continuity of the digital object. It must be present and protected, but it cannot substitute for the other tests.

A full-scale integer conversion offers a simple illustration. Suppose a file contains signed sixteen-bit I and Q samples. The declared digital range extends from negative 32,768 to positive 32,767 for each component, but those raw integers are not voltages until a scaling rule has been specified and validated. The physical range represented by full scale depends upon the converter, analogue gain, reference setting and any digital rescaling. If

Copyright 2026, James M. Atkinson

the analyst multiplies by the wrong scale factor, the reconstructed graph may look entirely plausible while its power labels are materially wrong. The error will be faithfully reproducible from an unchanged file. The reviewer must demand the instrument scale and the calculation, not merely inspect a matching hexadecimal digest.

Suppose a receiver writes 1.5 million complex samples per second, each sample represented by two thirty-two-bit floating-point components. Each complex sample then occupies eight bytes. A sixty-second uninterrupted payload should contain 1,500,000 times sixty times eight, or 720,000,000 bytes, equal to approximately 686.65 mebibytes when divided by 1,048,576. These are decimal and binary unit conventions that should not be confused. The byte count can help detect gross truncation, but a different packing rule, compression, gap annotation or header naturally changes the calculation. State the format assumptions whenever quoting expected size; a coincidentally correct length is not proof of correct content.

Error budgets should be constructed from independently identified mechanisms, with correlation considered rather than every uncertainty being combined mechanically. An acquisition time may have a trigger uncertainty, reference-clock offset, sample-clock drift, buffering uncertainty and subsequent software labelling error. A frequency estimate may depend on clock calibration, FFT-bin resolution, window leakage, front-end nonlinearities and estimator bias. A measured received level may depend on the antenna factor, cable loss, input attenuation, gain calibration, detector and reference impedance. Each input must be connected to the actual claim. It is misleading to present a single generic plus-or-minus figure which does

Copyright 2026, James M. Atkinson

not identify whether it is a tolerance, standard uncertainty, expanded uncertainty or merely a manufacturer's typical specification.

The distinction between a correct copy and a correct measurement can be tested with deliberately contrary examples. In one trial, copy a valid RF dataset byte-for-byte to another medium; a secure digest should match and a correctly implemented parser should recover the same numerical sequence. In another, alter a single bit; the comparison should detect that the content differs, while an independent analysis determines whether the physical interpretation changes significantly. In a third, retain every byte but swap the declared I and Q interpretation; the hash remains unchanged while certain phase and frequency-sign conclusions may reverse. In a fourth, preserve all bits from an overloaded receiver; the file remains authentic as a record of what the receiver output, but the nonlinear distortion can make inferred external signals unreliable. These counterexamples prevent the report from treating continuity as a synonym for truth.

A simple numerical clock test can sharpen the discussion. Let a sampling clock have a nominal rate of ten million complex samples per second and a relative systematic error of five parts per million. The magnitude of its rate error is approximately fifty samples per second, assuming the stated relative error applies to sampling frequency. Over a two-second interval the cumulative discrepancy would be approximately one hundred sample intervals under a constant-error model. The experiment must distinguish the sign and stability of the error and relate the sample count to an independent time reference. Nothing about the unchanged sample file

Copyright 2026, James M. Atkinson

resolves that calibration question. Repeating the same reconstruction under the same mistaken ten-million rate will reproduce the same mistake.

Consider also a deliberately bounded diagnostic extraction. Suppose an authorised experiment retains one half-second before a benign trigger and one second after it at five million complex samples per second with four bytes per sample. The payload is 1.5 times 5,000,000 times four, or 30,000,000 bytes, before container overhead. That calculation informs storage planning and the scope of retained data. It does not by itself determine the legal or ethical propriety of retaining the contents. The custody record should identify the actual authorised purpose, capture bounds, operator and resulting file length. If the result contains unrelated private material, that question requires a separate lawful minimisation decision, not a mathematical assurance about the hash.

I am equally concerned by overinterpretation of checksums. A SHA-256 digest is a fixed 256-bit result, typically written as sixty-four hexadecimal characters. It should be compared with an expected digest protected independently of the contested bytes. The probability of accidental equality under a naive random-output model is astronomically small, but neither that idealisation nor the format of the digest permits a conclusion of absolute impossibility, and the trustworthiness of the reference state remains decisive. We should employ a suitable contemporary approved hash algorithm, document the implementation and verify its known-answer tests. That is a strong continuity control, but its evidential claim begins at the first trustworthy anchor and goes no further backwards.

The weakest numerical practice is to give a precise answer to a poorly posed question. A waterfall reconstructed with the wrong window and scale may

Copyright 2026, James M. Atkinson

support an exact but irrelevant power estimate. A post-processing programme can silently interpolate missing samples and present a visually continuous line which was never measured. A device may report excellent frequency resolution while its front-end intermodulation products imitate real emissions. The forensic report should identify what was directly measured, what was calculated, what was inferred, what was corrected and what remains unknown. Where one cannot reconstruct a timing edge or absolute amplitude from the retained evidence, the right conclusion is that the proposed determination is not supportable from those records.

For independent reproducibility I would retain a compact set of carefully chosen known-answer cases and boundary cases with the programme and manifest. Include positive and negative signed integer extremes, two byte orders, interchanged I/Q channels, a known sinusoid, a clipped waveform, an intentional missing block, a metadata change with identical sample bytes, a legitimate container conversion and a one-bit payload change. A second examiner should verify both successful reconstructions and expected failures. Beyond the bits, disclose acquisition hardware, firmware, analogue configuration, calibration provenance, clock source, software versions and authorised purpose. These facts are neither decoration nor excuses; they define the claim's limits.

My conclusion is intentionally restrained. An unchanged RF sample file, established by a defined digest comparison and trustworthy custody reference, supports continuity of that digital representation since its documented anchor. It does not alone certify an honest operator, authentic antenna input, correct acquisition clock, calibrated analogue measurement, lawful collection or correct scientific inference. Those propositions require

Copyright 2026, James M. Atkinson

their own controls and independent witnesses. When the institution separates them, it gains a record that is genuinely testable, even when the final answer is uncertain. That is a far stronger forensic achievement than an apparently perfect graph accompanied by an overconfident certificate.

Dr. James M. Atkinson, Moderator: I thank Admiral Hopper, Professor Dijkstra, Mr. Turing, Dr. Reed, Dr. Hamming and the participating peers. This discussion is an explicitly fictional scholarly reconstruction and not a record of their actual speech. The defensible conclusion separates exact continuity of a defined byte object from correctness of a format interpretation, completeness of acquisition, calibration of the RF measurement and lawful provenance. A matching protected digest is powerful evidence within that limited scope, but every additional proposition must be supported by independent data and an identified uncertainty. The panel's worked calculations are hypothetical laboratory illustrations rather than observations of any unknown emitter. The author will retain the Stage B requirements for source-to-claim correspondence, historical suitability, independent technical examination, semantic distinctiveness and whole-volume production proof.

QUESTION 091. TECHNICAL SOURCE NOTES: NIST FIPS 180-4, Secure Hash Standard (https://csrc.nist.gov/pubs/fips/180-4/upd1/final); NIST SP 800-86, Guide to Integrating Forensic Techniques into Incident Response (https://csrc.nist.gov/pubs/sp/800/86/final); Signal Metadata Format (SigMF) specification, datatype and capture metadata (https://sigmf.org/sigmf-spec.pdf). These contemporary publications support technical background only and are not historic statements by the named participants. Individual source-to-claim verification and legal review remain for Stage B.

QUESTION 092

Copyright 2026, James M. Atkinson

Which configuration values are indispensable for reproducing a waterfall determination?

Dr. James M. Atkinson, Moderator: Professor Dijkstra, the panel has just examined preservation of RF sample files. I invite you now to address a distinct but related question: what must the examiner record so that an independent laboratory can reproduce a specific waterfall determination from the same lawful sample data? The display may resemble a meticulously coloured chart, yet its apparent peaks, durations and background noise are calculated through a succession of choices. Please distinguish the raw object, the measurement process, the processing recipe and the displayed image. This is fictional scholarly dialogue, not a historical statement by the participants.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Principal Contributor: I would begin by asking the investigator to specify the property to be reproduced. Recreating a similar-looking screen is not the same thing as reproducing an estimate of power spectral density, centre frequency, onset time or occupied bandwidth. A waterfall is a representation generated from samples by algorithms and display conventions. Its coloured rectangles are not physical quantities in themselves. If the claim is that a frequency interval exceeded a noise-relative detection threshold for a stated duration, then the reproduction protocol must define that threshold, its reference population, the valid observation intervals and the statistical estimator that produced it. Otherwise two implementations can agree pictorially while disagreeing in the measurement that matters.

The pipeline should be written as an explicit sequence of transformations. At the physical boundary, the reader needs to know antenna or reference input, front-end selection, gain and attenuation, frequency-conversion state, analogue and digital filtering, and clock conditions. At the digital boundary, the reader needs sample datatype, scaling and rate, I/Q ordering, missing-data treatment, tuning and decimation. At the analysis boundary, the reader needs the transform length, window coefficients, coherent and noise-power normalisations, frame placement, overlap, averaging, detector decision rule and any interpolation or rescaling. At the display boundary, the reader needs colour limits, logarithmic conversion, clipping and pixel aggregation. All four layers can influence a figure, yet only some determine the underlying scientific statistic.

For a first hypothetical calculation, take an uninterrupted complex sample stream at a nominal rate of eight million samples per second and a

Copyright 2026, James M. Atkinson

transform length of eight thousand samples. The unwindowed nominal spacing between adjacent discrete Fourier-transform frequency bins is one thousand hertz, calculated by dividing eight million by eight thousand. That number is a bin spacing, not automatically the minimum resolvable separation between two real emissions; effective resolution depends on the window and estimator, signal conditions and criterion of distinguishability. A report that simply labels the display as one-kilohertz resolution without identifying the window and measurement concept invites a false comparison with another laboratory.

A second calculation concerns frame cadence. If a transform uses 8,000 samples and a 50 per cent overlap, each successive frame begins 4,000 samples after the previous one, giving a nominal step of one half-millisecond at eight million samples per second. The window's support still spans one millisecond. The apparent time granularity of the waterfall is thus not the duration of an instantaneous event and cannot independently justify a half-millisecond onset precision. A different overlap can make the image denser without adding independent RF information. The examiner must record frame boundaries, time origin and how events crossing boundaries are handled.

Window choice requires equally careful language. A rectangular window, a Hann window and other tapers distribute leakage differently and have different equivalent noise bandwidths and amplitude responses. One cannot compare the raw heights of their spectral bins without stating the normalisation and the question being asked. A narrow sinusoidal component, an impulsive event and a diffuse noise process respond differently to changes in window shape, frame length and averaging. If the

Copyright 2026, James M. Atkinson

investigator changes a window while retaining the same data and observes a different colour patch, the change is not evidence that the external transmitter altered itself. It is an alteration of the estimator and representation. This may be the central issue in a disputed measurement.

Another difficulty is the measurement reference plane. Raw ADC counts are not automatically calibrated field strength or input power. The analysis needs the relevant gain state, attenuation, analogue bandwidth, any instrument-supplied calibration and the convention used to transform sample magnitude into engineering units. A logarithmic display must define whether it depicts power, amplitude or a density normalised per hertz. A difference of ten decibels in a graphic may emerge from a changed processing gain or reference convention, not from a real difference in the electromagnetic environment. If the measurement is relative to a local noise floor, the estimation of that floor and any exclusions must be reproducible.

Time coverage should also be explicit. A scanning receiver may observe one frequency interval while another is unobserved; an empty pixel in the display need not represent measured silence. Missing or invalid sample regions, buffer overflow flags, dropped frames and tuning transitions require masks or status records that prevent the software from converting absence of observation into a negative finding. If two analysts use different policies for filling gaps, one may display a visually smooth trace and another a conspicuous blank. Those displays cannot be compared meaningfully without the underlying time-coverage record. The report should mark observed, inferred, excluded and unobserved regions distinctly.

I propose an experiment in which independent investigators receive the same controlled and lawfully acquired sample file but different

Copyright 2026, James M. Atkinson

reconstruction manifests. The complete-manifest group receives every processing parameter and calibration reference. Other groups each lack one parameter chosen in advance, such as sample rate, window, overlap, detector or display scale. Their task is to reproduce a numerical finding, not to imitate a colour image. Record the distribution of their frequency estimates, detection decisions, timing boundaries and confidence statements; then reveal the omitted parameter and repeat. The important observation will be whether uncertainty or disagreement increases in a manner consistent with the parameter's scientific role. Any apparent agreement achieved by undocumented default settings should be identified as such.

The resulting evidential record should comprise an immutable original-data reference; a versioned machine-readable processing recipe; the tested analysis software and implementation; calibration and clock evidence; gap and validity records; the numeric results before display rendering; the plotting configuration; and a concise statement of alternative interpretations. Reproducibility is not achieved merely because someone can reopen a saved picture. It is achieved when a competent independent examiner can begin with the recorded, lawfully available inputs and reconstruct the actual claimed measurement, its limits and its uncertainty. I would ask my colleagues to challenge each boundary and to identify where the same waveform can support divergent but internally repeatable displays.

Donald Watts Davies, Peer Question: Professor Dijkstra, an independent examiner may have the same continuous complex sample record and a reliable digest, but still be unaware of the original receiver's decimation

Copyright 2026, James M. Atkinson

chain and local-oscillator configuration. Suppose the graphical programme accepts a nominal sample rate and centre frequency from an operator rather than the acquisition metadata. A beautiful waterfall then appears, with a narrow ridge in the expected place, yet the declared frequency axis may be wrong. Should an examiner report this as a failure of computational reproducibility, a failure of acquisition description, or a failure of evidential interpretation? I am particularly interested in whether you would demand a separate control which is independent of the software that generates the picture. A programme may be perfectly deterministic and still reproduce a mistaken conclusion on every computer. How should the laboratory draw its acceptance boundary and make that boundary intelligible to a second analyst who never handled the original receiver?

Edsger Wybe Dijkstra, Response: Mr. Davies, a deterministic computation and an accurate scientific assertion are separate propositions, and neither should borrow the other's authority. One can reproduce an incorrect frequency scale indefinitely if both laboratories inherit the same invented sample-rate field. The proper experiment therefore begins by declaring the independent quantities that are controlled and the quantities that are reconstructed. Sample indices are countable properties of the byte interpretation. Sample rate is an acquisition claim, ordinarily traced to oscillator and decimator state. Centre frequency is a tuning claim, ordinarily supported by oscillator configuration and any measured offset. A plotter merely receives those assertions, and should not be permitted to make them true by printing them neatly.

I would write an explicit contract containing four classes of tests. First, a syntax test verifies that the data file, metadata fields and processing recipe

Copyright 2026, James M. Atkinson

can be parsed without an unstated convention. Secondly, an algorithmic test reruns the defined transforms and compares numerical results within specified floating-point tolerances. Thirdly, an acquisition-state test checks the recorded tuning, decimation and clock history against independent apparatus logs and known reference injections where available. Fourthly, an inference test asks whether the numerical findings actually support the stated conclusion. The first two tests concern computational reproducibility. The third concerns measurement traceability. The fourth concerns scientific justification. The distinction has practical consequences for error reports because repairing a file parser does not validate an oscillator.

A test vector can reveal a particular failure without involving an unknown emission. Insert, by authorised laboratory means, a known tone at a calibrated input reference plane and record the analogue and digital configuration alongside the file. Reconstruct the tone's bin offset from the recorded sample rate and discrete transform, then compare the stated RF frequency with the independent source. If the same pixels appear in two laboratories but the source differs from the declared centre frequency, the picture is reproducible while the RF assignment is not traceable. If the FFT results differ despite matching acquisition metadata, one investigates the window coefficients, numerical type, transform scaling and implementation. Each branch points to a different accountable defect.

The acceptance record must carry the word 'reproducible' only with a named object: the transformed sample vector, the estimated power-density values, the event decision, the absolute frequency assignment or the displayed image. It must also state the governing tolerance. Exact equality of floating-point output is not always a sensible universal criterion, but the

Copyright 2026, James M. Atkinson

laboratory should still predict whether differences can alter the event decision. A numerical result that changes one part in a billion while remaining far from a threshold may be acceptable under a declared tolerance. A much smaller change beside a threshold may reverse classification. To conceal this distinction behind the aesthetic similarity of two waterfalls would be a software error translated into an evidential error. I return the token to the moderator for an independent challenge.

David Lennox Mills, Peer Question: Professor Dijkstra, your reconstruction contract includes a time axis, yet a waterfall may combine frame-centre sample times, computer-system timestamps and trigger times supplied by a host that has queued buffers. Even with an exact sample count, the absolute start of an RF event can be uncertain because the acquisition clock has an unknown offset, and the sampling frequency can drift while the file is written. Would you require the programme to separate the observed sample index from the claimed UTC time at every step? Moreover, if a scan receiver visited a channel for only a fraction of each second, how do we stop the presentation programme from drawing the unvisited interval as black or dark blue, silently making a no-observation gap resemble an absence of energy? I ask for a defensible rule that a software engineer could implement and an expert witness could explain without technical equivocation.

Edsger Wybe Dijkstra, Response: Dr. Mills, the time representation needs at least three independent coordinates: an integer sample index, a time elapsed according to the acquisition clock, and an asserted civil timestamp tied to a specified time reference. The first is a discrete index within a defined recording and is exact only when the record has no concealed sample gaps. The second follows from the sample rate and any known clock

Copyright 2026, James M. Atkinson

variation. The third requires a documented synchronisation chain and uncertainty statement. They are not interchangeable. A host file-creation time may lag the physical reception by buffering, processing and storage delays; it cannot safely substitute for the first valid ADC sample time without evidence.

Consider a hypothetical eight-million-sample-per-second recording with an uncertainty of two parts per million in its sample clock. Over ten seconds, the nominal count is eighty million samples. A two-part-per-million rate deviation corresponds to twenty microseconds of time-scale discrepancy over that interval, in addition to any initial time offset. This is not a claim about any particular receiver; it demonstrates why cumulative timing uncertainty must travel with time estimates. A sample offset of forty thousand samples corresponds to five milliseconds at the nominal rate, but its absolute UTC position also depends on the independent synchronisation and on whether earlier samples were dropped. A colour coordinate alone contains none of these facts.

I would implement observation masks as first-class data, not as plotting decorations. For each frequency-time region, the reconstruction must distinguish observed valid samples, observed samples excluded by overload or another quality rule, unobserved retuning or scan dwell, and regions generated by interpolation or graphical hold. A dark pixel is an intensity instruction; it is not a statement that the antenna observed zero radiation. A gap should remain explicitly absent from numeric occupancy denominators unless the scientific design justifies another treatment. When an event lies on the boundary between valid and missing data, the report should express

Copyright 2026, James M. Atkinson

a bounded onset interval rather than force a precise start time from an unavailable sample.

The programme should maintain the interval record through every conversion: from hardware packet counters to sample indices, from frame windows to time bins, from detector outputs to coloured pixels. It must not allow an averaging routine to smooth across a missing interval without recording the fact that it did so. An independent examiner can then challenge any particular cell by asking what samples, receiver states and transform settings produced it. If that provenance cannot be recovered, the disciplined answer is that the image is an illustration and not a fully reproducible evidential measurement. I pass the token to Professor Hopper to examine the implementation's record-keeping responsibilities.

Edsger Wybe Dijkstra, Cross-Peer Question to Grace Brewster Murray Hopper: Admiral Hopper, I respectfully pass the token to you because the engineering obstacle is not solely the mathematical specification. The receiver operator may believe that the application has saved its settings, while the application has in fact saved only those fields visible on the screen and has silently inherited defaults for window periodicity, logarithmic reference and decimation. The result can be a reproducible error hidden inside a nominally complete file. Which configuration values should have immutable experiment-level meaning, and which should be carried at each capture or processing segment? What would you do about a software upgrade that changes default FFT normalisation while retaining the same friendly name in the menu? I should also like you to confront the difficulty of using a public metadata vocabulary without pretending that its standard

Copyright 2026, James M. Atkinson

fields automatically preserve every instrument-specific feature necessary for a particular forensic inference.

Grace Brewster Murray Hopper, Cross-Peer Answer to Edsger Wybe Dijkstra: Professor Dijkstra, the problem is to make the computational recipe as inspectable as the measured data, while recognising that a dictionary of fields is not the same thing as a validated instrument history. I would require every processing action that can affect the reported result to have an explicit versioned value in the record. A menu choice such as 'Hann window' is insufficient if the implementation does not tell us whether the window is periodic or symmetric, how many coefficients were used, how they were normalised and which numeric precision the transform employed. A programme update must not reinterpret an old record by silently applying a new default. The recipe should identify the executable or independently reproducible algorithm version, not merely a graphical product name.

Some parameters belong to the acquisition record: sample type, sample rate, centre-frequency history, analogue gain, attenuation, antenna path, preselector, filtering, reference oscillator, calibration and intervals of invalid reception. Other parameters belong to each transformation: downconversion frequency, resampling ratio, filter coefficients, FFT length, taper, hop, averaging, estimator, thresholding, clipping and numeric units. Still others describe only presentation: palette, colour range, pixel interpolation, axis labels and output dimensions. An experiment may keep invariant values in a global record and put changing values in time-indexed capture or processing segments. A mixed design is acceptable only when the application resolves the effective value at each sample or frame without guesswork.

Copyright 2026, James M. Atkinson

The SigMF approach provides a useful vocabulary for sample datatype, sampling rate, capture segmentation and annotations, and it can use extension namespaces for specialised claims. Yet a compliant file is not thereby a complete metrology dossier. A laboratory using an unusual analogue preselector, a temperature-compensated oscillator or an external trigger will need extra documented fields and a validated mapping from hardware state into metadata. Unrecognised extension fields should not be discarded without warning by the second examiner. An internal validation programme should test the actual schema and reject incompatible versions or contradictory assignments. It is better to stop with an intelligible error than quietly draw a plausible but misleading picture.

I would also separate a captured run from an analysis run. A captured run can have several legitimately different waterfall analyses, each recorded as a distinct recipe linked to one source data object. One analysis may emphasise short impulses, another estimate stable power spectral density and another support a thresholded occupancy statistic. Their displays may differ, and all may be reproducible in their own terms. The important requirement is that the report name which analysis underpins each scientific conclusion, rather than treating the latest graphic as the only true picture of the recording. That preserves the audit trail while allowing a second laboratory to test whether a different estimator changes the conclusion. I accept the token with thanks and offer it back for the further discussion.

Dr. James M. Atkinson, Moderator: I thank Professor Dijkstra for separating a reproducible calculation from an accurate physical conclusion, and Admiral Hopper for explaining why the processing recipe is itself an evidential object. Admiral Hopper, please now develop the system-design

Copyright 2026, James M. Atkinson

question independently. What would a robust data architecture record if it were designed to survive changes of computer, operating system, FFT library and graphical interface while preserving the ability to challenge the original finding?

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Second Principal Contributor: I would design the system around the experiment rather than the display. The visible waterfall is a derived presentation; its input consists of a particular acquisition record, a specified processing run and a set of rules for interpreting the numeric output. A file saved under the name of a popular application does not define those rules. One needs a stable description of the acquisition and a versioned description of every transformation. The relationship should be machine-checkable where possible, but a plain-language technical narrative remains indispensable for decisions such as why a chosen noise-floor interval was regarded as representative. A competent colleague should be able to reconstruct the same numbers without having to discover the operator's preferences by telephone.

The recorder and the spectrum estimator should keep separate state machines. The recorder has states such as tuned, settled, acquiring, overloaded, clock-unlocked, retuning and stopped. The estimator has states such as buffer assembled, window applied, transform completed, calibration applied, detection evaluated and rendered. When a tuner changes frequency, the data system must mark the transition in the acquisition timeline rather than carry forward the old centre-frequency label. When a detector changes threshold, that change is an analysis event rather than a new physical observation. The analyst may choose to reanalyse the same lawful samples with different thresholds, but must preserve the original run's decision record instead of replacing it in place. This separation is elementary software discipline with substantial forensic consequences.

A good configuration record needs an explicit field dictionary. Each value should have a type, unit, range, governing version, origin and allowed

Copyright 2026, James M. Atkinson

scope. Sampling rate in samples per second is not the same quantity as a display refresh rate in frames per second. FFT length is an integer count, overlap can be a count of samples or a fraction, and centre frequency is an asserted RF coordinate that may vary by capture segment. Gain in decibels should identify the reference and the analogue stage to which it applies; a gain slider without a device-state report is inadequate for power calibration. Detector mode must distinguish a decision over one frame from a decision over an averaged collection. The receiving and evaluating programmes should reject a missing field when no defensible default exists.

I would introduce a strict source-of-value hierarchy. A value read back from hardware has different evidential status from one typed by an operator, one inferred from a file name and one assumed by an analysis library. If hardware reports a sample rate of 7.68 million samples per second and the user chooses a display preset called '8 MHz', the record must preserve both facts and state which rate was used in calculating the frequency bins. It must not quietly substitute one for the other. A field may also have an uncertainty interval. The processing recipe should accept uncertainty as input when it affects a conclusion, rather than convert every metadata value into a false exact constant.

The durable format can use a standard sample-description vocabulary where suitable, with additional namespaces for controlled laboratory requirements. No universal standard can guarantee that every preselector, analogue filter or trigger condition has been captured. A schema validator will check that a field has an admissible shape; an equipment validation protocol must check that it correctly describes the receiver. I would version the schema and reject unrecognised changes that affect signal

Copyright 2026, James M. Atkinson

interpretation. An unknown annotation may be carried along without harm, but an unknown change to sample encoding cannot be ignored. Compatibility must be demonstrated by test vectors, not announced by changing a label in a menu. A practical migration report should identify which historic settings have been inferred and which remain unknown.

A second design principle is to store numeric results before rendering. The complex samples are not the waterfall matrix, and the waterfall matrix is not the bitmap. For each analysis run I would retain frequency-bin coordinates, time-frame coordinates, valid-data masks, estimated values with units, chosen statistical thresholds, calibration corrections and software identification. The graphic can then be regenerated with a different printer, colour palette or screen resolution while the underlying result remains stable. For a court or scientific review, this distinction avoids treating an eye-catching colour gradient as a calibrated number. It also allows automated checks that a reported peak really corresponds to the bin, time range and statistic described in the prose.

We should be careful with software libraries. Two Fourier-transform implementations can differ in their ordering, sign conventions, scaling, use of single or double precision, treatment of the last incomplete frame and degree of optimisation. They may agree on ordinary examples but diverge at edge cases or threshold boundaries. I would therefore retain small reference vectors with expected results for each processing release, including a complex sinusoid exactly at a bin centre, an off-bin sinusoid, white noise of known simulated variance, a clipped waveform and a buffer with a declared missing block. For every new version the test record should show whether computed statistics remain within predeclared tolerances.

Copyright 2026, James M. Atkinson

The tests must exercise the same path used for evidential reporting, not merely a convenient demonstration module.

A final principle is to make silence an explicit finding, not a default drawing operation. A recorder that did not observe a frequency-time cell cannot certify that the cell lacked energy. Neither can a detector that masked a saturated window call it clean. I would record the denominator of every occupancy estimate, consisting of valid observation intervals appropriate to the estimator. A graphical interface may make the distinction intuitive by separate masking and annotation, but the numeric data must carry the same meaning independently. A later reader may see only a monochrome printout, and still ought to understand which intervals were measured and which were absent from the experiment.

The finished archive need not duplicate sensitive content throughout the report. Its purpose is a controlled and lawful ability to reproduce the stated analytic finding. Data should be retained and disclosed within the authority, necessity and retention rules applicable to the work. A derivative set of numeric measurements and its processing recipe may suffice for some questions; other disputes may require tightly controlled access to original IQ samples. The record should make that distinction explicit. In either case the laboratory must distinguish a successful reopening of software from a successful scientific replication. I invite the peers to examine the transformations and the version history rather than the elegance of the interface.

Claude Elwood Shannon, Peer Question: Admiral Hopper, I welcome your separation of raw samples from the computed waterfall, but I would press the statistical content of the stored matrix. The same time-frequency

Copyright 2026, James M. Atkinson

arrangement can represent squared Fourier magnitude, a density estimate in units per hertz, a logarithm of amplitude, or a thresholded Boolean detection. A reader who sees a number without knowing which representation is present may draw the wrong comparison across frame sizes and windows. What exact contract should accompany each matrix, especially when changes in normalisation make the numerical values appear to rise or fall despite the same underlying time-series power? I also ask how you would prevent one programme from declaring a decibel value without identifying the power or amplitude reference. Can these questions be resolved by software schemas alone, or must they be established by a test of dimensional consistency across the entire measurement chain? Please identify a reproducible reference calculation for the stored numeric field.

Grace Brewster Murray Hopper, Response: Dr. Shannon, a matrix without a declared physical or statistical meaning is a collection of numbers in search of an interpretation. Each numeric result should identify its observable, unit, reference plane, normalisation and uncertainty assumptions. Squared-magnitude spectrum is not identical to spectral density. In a voltage-based calculation, a squared-amplitude spectrum may be expressed in volts squared whereas density is in volts squared per hertz, provided the input and scaling support those units. An instrument that reports input-referred power needs an additional calibrated transformation and an impedance or other appropriate reference. A logarithmic quantity should state whether the conversion uses ten times the base-ten logarithm of a power ratio or twenty times the logarithm of an amplitude ratio. The familiar decibel symbol alone cannot supply that missing definition.

Copyright 2026, James M. Atkinson

I would prevent accidental substitution by using dimensional types in the programme's intermediate representation. A quantity called density should carry its unit and not be silently compared with a dimensionless threshold. A time-frequency matrix may legitimately contain uncalibrated digital full-scale-relative values, but it must not call them received power at the antenna. The transformation from ADC count to voltage or power would need calibration values, analogue gain state and uncertainty; if those are absent, the software should say so. A test suite should deliberately change window length, scaling method and overlap, then compare invariant quantities under clearly specified conditions. A density estimate and an integrated band-power estimate are linked through an integration over frequency; they are not generally numerically identical bin by bin.

Consider a hypothetical processing programme whose estimated density is one microvolt squared per hertz in a frequency cell. Integrating a constant such density over a two-thousand-hertz band gives two thousand microvolt squared, which is 0.000000002 volt squared (2×10^{-9} V^2). If the programme draws the same density value as though it were a two-thousand-hertz integrated power, it makes a dimensional error of a factor of two thousand. This arithmetic example is synthetic and says nothing about a real antenna or calibration. Its purpose is to make the software's unit test unambiguous. A separate power conversion may also require a specified impedance, which must not be conjured by the plotting routine.

A schema can force a programmer to state the unit and method, but its assertions need substantive verification. Unit tests should feed precisely defined synthetic waveforms through both the original and independent reconstruction implementations, including noise-only and tone-plus-noise

Copyright 2026, James M. Atkinson

records. Metamorphic tests can change a presentation palette while checking that numeric outputs are unchanged, or change an expected normalisation and verify that differences follow the declared mathematical relationship. The laboratory must also record whether values are single-bin instantaneous estimates, windowed averages or post-detector products. To close the issue, an examiner should be able to choose any displayed cell and request the actual numeric statistic and the inputs from which it was computed. I return the question with a distinction between a validated contract and a merely well-formed data structure.

John von Neumann, Peer Question: Admiral Hopper, the architecture you propose may be independent of any one graphical application, but the execution platform itself can change floating-point results, particularly when computations are parallelised and summed in different orders. Suppose two laboratories agree on the mathematical FFT, averaging and threshold rules yet obtain small numerical differences because their processors round intermediate quantities differently. The differences may be harmless in the middle of an observed noise distribution but decisive when one cell lies on the detection threshold. Do you regard bit-for-bit numerical identity as necessary for reproducibility? If not, what test would distinguish an acceptable implementation difference from an unrecorded change in the measurement procedure? I should also like you to consider the case in which a software update changes the method used to estimate the local background, since a reported signal-to-noise excess can be altered without any modification to the sample stream or its spectrum.

Grace Brewster Murray Hopper, Response: Professor von Neumann, reproducibility must specify an equivalence relation appropriate to the

Copyright 2026, James M. Atkinson

scientific claim. For exact integer operations and controlled byte transformations, exact agreement may be practical. For floating-point computations across different machines, the correct requirement is often a predeclared tolerance established by numerical analysis and verified test vectors. That tolerance may be expressed in absolute units, relative units, or an uncertainty interval, depending upon the statistic. It must not be widened after the experiment merely to make two results agree. The acceptance record should include the arithmetic precision, rounding assumptions, library and algorithm versions, and any order-dependent reductions that materially affect the output.

An independently coded reference calculation is valuable where the stakes justify it. One implementation can compute the FFT and band statistics through the production pipeline, while another uses a tested independent numerical route. Agreement within a reasoned tolerance can expose implementation defects that a screenshot comparison would miss. Yet a comparison of algorithms is not a calibration of the RF input. If the analogue front end was overloaded, both programmes may produce perfectly matching results from distorted samples. If an event's detection statistic is so close to the threshold that floating-point variation changes the decision, the defensible outcome is a marginal or unresolved classification, with the numerical range disclosed. An examiner should not hide that instability by choosing the more favourable machine.

Background estimation is a separate, versioned analytic operation. A rolling median, a long-term mean and a quantile estimator can produce different local reference levels from the same spectral data, particularly in the presence of bursts or persistent occupied channels. Each requires a window

Copyright 2026, James M. Atkinson

of observations, exclusion policy, treatment of missing frames and specification of the population to which it applies. The stored numeric finding must therefore identify not only the spectral estimator but the noise-floor estimator and detection rule. An upgrade that changes the quantile definition, frame weighting or exclusion mask is a new analysis recipe even if the interface still presents the same word 'automatic'. The investigator can run both recipes and study sensitivity, but may not erase the earlier one.

Finally, numerical acceptance should be tied to evidential consequences. If two methods disagree by 0.01 dB about a spectrum that lies 12 dB above a threshold, a predefined tolerance may make the difference immaterial. If they disagree by 0.01 dB about a result placed exactly at that threshold, the final Boolean decision may not be stable at all. The record should preserve the continuous statistic, the threshold, the margin and the uncertainty, so that the reader can judge the sensitivity independently. Software engineering is successful here when the calculation becomes inspectable enough to reveal a fragile inference rather than concealing the fragility beneath a bright colour. I respectfully return the token.

Grace Brewster Murray Hopper, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, I pass the token with respect to your expertise in quantitative information and engineering practice. We have described a versioned software recipe, but a laboratory may still believe that its spectral 'resolution' is exactly the spacing between FFT bins, or that adding more overlapping windows creates new independent measurements. Please explain how frame size, window equivalent noise bandwidth, coherent gain, overlap and post-estimation averaging should enter a reproducibility declaration. I should like you to distinguish errors in dimensional arithmetic

Copyright 2026, James M. Atkinson

from errors in interpretation, and to show why the same waveform can yield different apparent peak heights under legitimate yet differently normalised transforms. Finally, what would you put into the experiment that could reveal a setting which seems innocuous to a programmer but is essential to the scientific conclusion? I would welcome a test involving the same coherent tone and the same broadband noise under the two windows.

Richard Wesley Hamming, Cross-Peer Answer to Grace Brewster Murray Hopper: Admiral Hopper, bin spacing is a geometric property of the discrete transform's frequency grid: the sample rate divided by the transform length. The resolving capability of an estimator has a more complicated relationship to the taper, observation duration, signal-to-noise conditions and definition of what it means to distinguish two components. I would therefore record both the grid spacing and the actual window and estimator settings. The phrase 'one-kilohertz resolution' might be used colloquially, but it is ambiguous unless the report identifies whether it describes transform-bin spacing, noise bandwidth, filter response or a validated discrimination criterion. This is an interpretive defect before it becomes a software defect.

A window changes how a finite sequence represents the hypothetical infinite waveform. Its coherent gain matters for recovering a bin-centred sinusoidal amplitude, while the sum of squared coefficients enters noise-power normalisation. Equivalent noise bandwidth states how the chosen window aggregates broadband noise relative to a rectangular reference under a particular convention. An FFT implementation that divides by the window length where another divides by its coefficient sum can change the displayed peak while leaving the original signal unchanged. Zero-padding can make the plotted frequency grid denser but does not create

Copyright 2026, James M. Atkinson

independent observational time. Overlap can increase the cadence of frames and smooth the display without adding independent RF samples to the record. These distinctions belong in the reconstruction recipe, not as optional commentary after publication.

A useful controlled experiment would provide a fixed synthetic record containing a coherent sinusoid, an off-bin sinusoid, stationary noise and a brief pulse, with all component amplitudes known. Each laboratory would process the same record with a prescribed rectangular window, then a Hann window, and with several overlap fractions. The required outputs would include bin spacing, equivalent noise bandwidth, calibrated tone amplitude under the declared convention, a density estimate, and event onset intervals. A detector should be challenged near its threshold by varying only the processing parameter under test. The comparison should predict some changes, such as leakage suppression or time averaging, while rejecting others, such as a fictitious power increase caused solely by a new palette.

I would make every claim traceable to a calculation with variables and units. If a transform length is eight thousand at eight million samples per second, the grid increment is one thousand hertz, and a 50 per cent overlap advances four thousand samples or half a millisecond. These simple calculations can be checked independently. They do not determine whether a real narrowband emitter was present or what its precise occupied bandwidth was. The decisive point is to distinguish mathematical consistency, metrological calibration and inferential validity. I thank you for the question and return the token to the moderator so that the roundtable may examine numerical error and uncertainty in greater depth.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: I thank Admiral Hopper and Dr. Hamming. Dr. Hamming, please now distinguish the frequency spacing chosen by an FFT, the noise bandwidth imposed by its window and the temporal information contained in overlapping frames. In particular, identify the assumptions that are necessary before a signal-to-noise excess in a waterfall can be interpreted as reproducible measurement rather than a numerical convention.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Third Principal Contributor: The first task is to count observations honestly. A complex sequence at a specified sample rate provides a definite number of samples over a definite nominal duration. The transform partitions or overlaps that sequence according to a processing decision. These operations can represent the same information in different ways, but they do not enlarge the independent observational record. A display that shows a thousand closely spaced time rows may be based on frames with 95 per cent overlap, so that adjacent rows reuse nearly all their samples. That is useful for visual continuity but changes the correlation structure of adjacent estimates. No statistical assertion about independent detection opportunities should simply multiply the row count by the presumed per-row false-alarm probability.

Let the nominal complex sampling frequency be eight million samples per second and let the FFT length be eight thousand. The frequency-bin separation is one thousand hertz. The time span of one frame is one millisecond. If the hop is two thousand samples, the overlap is six thousand of eight thousand samples, or 75 per cent, and the frame-start cadence is one quarter millisecond. A report that says it has acquired four independent observations per millisecond would be wrong. The additional display rows help locate patterns under certain conditions, but overlap produces dependence and changes the effective number of degrees of freedom available for a statistical estimate. The actual dependence also depends on the selected taper and underlying signal process.

Window functions present a second problem. A rectangular window has comparatively narrow main-lobe properties but troublesome side-lobe leakage for components not landing on an exact transform grid location. A

Copyright 2026, James M. Atkinson

Hann taper reduces leakage by suppressing the endpoints, but changes the main-lobe width and noise bandwidth. For a sufficiently long periodic Hann window, the commonly used equivalent-noise-bandwidth factor is 1.5 times the FFT-bin spacing. Under our one-kilohertz spacing, that is nominally fifteen hundred hertz. The exact finite-window expression depends on the coefficients used, so an implementation must record its coefficient convention rather than quote the factor as a universal exact identity for every window definition. A calculated noise bandwidth does not by itself measure the receiver's entire analogue passband.

Equivalent noise bandwidth can be written as sampling frequency multiplied by the sum of squared window coefficients, divided by the square of their sum, where the window sum is nonzero. Both sums must be calculated from the coefficients actually used. The ratio connects the window to the noise-power scale; it must not be confused with the bin spacing. For a bin-centred coherent tone, the coherent amplitude factor involves the sum of window coefficients, and a different normalisation may be needed. In density estimation, the desired units also govern the scaling. A careless switch from spectrum to spectral density can change the plotted numeric level without any altered input signal. We should preserve a unit label with every result array.

Consider a separate hypothetical FFT at a nominal two million samples per second with four thousand points. Its bin separation is five hundred hertz. Using a periodic Hann taper gives a nominal equivalent noise bandwidth of seven hundred and fifty hertz. If the analyst instead assumes five hundred hertz as the noise-equivalent measurement bandwidth, the estimated broadband noise power associated with a bin can be misdescribed, even

Copyright 2026, James M. Atkinson

though the transform still has five-hundred-hertz grid steps. Neither number authorises a claim that two emissions exactly five hundred hertz apart can always be discriminated. Their relative amplitudes, frequency offsets, phase variation, noise conditions and estimator all matter. Such qualifications are essential in a disputed classification.

Power scaling requires a controlled reference. If an FFT is calculated on ADC full-scale-normalised complex numbers, a result may describe relative digital power. To infer power at an RF input connector, one needs the receiver's gain and calibration history, known nonlinear limitations, losses and reference plane. A ten-decibel attenuation setting can change the ADC amplitude produced by a fixed input. An analysis that treats different gain states as though they were equal may produce a coherent-looking but false comparison across survey intervals. Conversely, applying correction values outside their calibrated range can be just as misleading. A waterfall's colour limits are not a substitute for instrument amplitude traceability.

I would insist that every spectral quantity be computed before logarithmic conversion and preserve the linear estimate as well as the displayed quantity. Averaging decibel values is generally not equivalent to taking ten times the logarithm of the average linear power. This matters for intermittent events because the average of sporadic high-energy frames can differ substantially from the average of their logged values. The programme must say whether it averages complex voltages, magnitudes, powers, log-powers or threshold decisions. It must also say whether the detector uses peak hold, mean, median, quantile or another reduction across time and frequency. What is sometimes called 'smoothing' can change the statistic under test rather than merely remove the jagged appearance of a plot.

Copyright 2026, James M. Atkinson

A laboratory experiment should use controlled reference records to test each transformation individually. Begin with a stationary noise sequence of known simulated statistics, add a coherent tone at a chosen bin offset, add an off-bin tone, then superpose a short pulse whose onset is known from the simulation. Reconstruct with prescribed FFT lengths and windows. Compare the continuous spectral estimates and declared event timings; do not grade the exercise by asking which picture looks more convincing. Repeat the same exercise with a real authorised test source at a traceable reference plane, and distinguish the additional uncertainty introduced by analogue instrumentation. The digital experiment tests processing. The physical experiment tests the combined chain.

No numerical test can replace the analyst's statement of what was actually observed. In a scanned spectrum, a threshold may be exceeded during one dwell and unknowable between dwells. In a continuous receiver, a short event may be diluted by a long averaging window, while a narrow transient may be broadened by the time-frequency trade-off. It is legitimate to choose processing that emphasises one scientific question over another. The trouble begins when the report presents a processing choice as a property of the external source. A sound reconstruction manifest makes the choice visible, and a sound interpretation acknowledges alternative choices that could change the result.

In conclusion, I would require as a minimum the acquisition sampling and frequency state, window sequence, transform size, hop, normalisation, detector, averaging, masks, calibration and software implementation. I would require a calculation sheet describing bin spacing, window noise bandwidth and frame cadence. I would distinguish nominal from calibrated

Copyright 2026, James M. Atkinson

values and preserve relevant uncertainty. A second examiner should be able to obtain the same scientific estimate using a written recipe, and to know exactly which part is a mathematical identity and which part remains an inference about RF energy. That, rather than a faithfully reproduced colour image, is the practical standard.

Sir Ronald Aylmer Fisher, Peer Question: Dr. Hamming, your admonition about overlap is relevant to inference. A waterfall may show numerous repeated detections, but the frames are strongly dependent because their windows share samples and their backgrounds may be correlated. Investigators sometimes use the count of red cells as if it were a count of independent trials, then calculate a very small probability that an event could arise from noise. How would you require them to justify a false-alarm probability when the threshold itself was selected after examining the same recording? Please address the difference between a prespecified detector and a search through thousands of correlated frequency-time cells, and explain why a bright-looking cluster is not an independent replication of its constituent pixels. An examiner needs a workable sensitivity analysis rather than a promise that the software has performed a mysterious significance calculation. I ask also that uncertainty in the effective trial count be stated, rather than disguised as an exact probability.

Richard Wesley Hamming, Response: Sir Ronald, the apparent abundance of observations is not a warrant for multiplying probabilities as though every cell had been sampled independently. If adjacent FFT frames share three quarters of their input samples, their noise fluctuations will generally be correlated, with the precise correlation influenced by the window and the underlying random process. Frequency bins may also be correlated because

Copyright 2026, James M. Atkinson

of window leakage and filtering, and successive scans may revisit an environment whose noise statistics are not stationary. A per-cell false-alarm rate calibrated under one condition therefore cannot simply be exponentiated using the number of colourful cells on the screen. The data-processing record must state the detector rule and the population over which it was evaluated.

Threshold selection must be distinguished from evaluation. If an investigator sees a bright patch, adjusts the colour limits and then chooses a threshold designed to retain that patch, the resulting significance cannot be interpreted as the outcome of a fully prespecified test. There may still be a descriptive finding worth reporting, but inferential calibration requires an independent or appropriately corrected evaluation. A defensible laboratory can preregister the detector, use independent noise-only intervals or a separate validation record, and simulate the entire search procedure under a stated null model. That procedure should preserve the actual overlap, windowing, background estimation and multiple comparisons in its false-alarm calculation. Merely matching the nominal one-cell threshold distribution is insufficient if the search behaves differently.

A second experiment should vary hop, frame length and noise-floor estimation while retaining the same simulated process. The apparent number of detections may rise or fall because the sampling grid changes, not because the simulated source becomes more or less probable. Instead of boasting of twenty red cells, the report might state that one contiguous threshold excursion was seen in a particular observed interval, under a specified method, with an empirically determined probability of false alarm for the whole decision procedure. That statement still depends on the

Copyright 2026, James M. Atkinson

realism of the null model and the quality of the calibration record. Where assumptions fail, it should be described as a sensitivity result rather than a universal certainty.

I would keep the full continuous detection statistics and describe their dependence. For event onset, one can examine the range of estimated boundaries obtained under defensible window placements and thresholds. For a frequency estimate, one can compare peaks across windows and record whether the result moves within the expected leakage pattern. The investigator should not count highly overlapping windows as independent witnesses, nor should a false-alarm estimate be more precise than the evidence permits. The method is reproducible when an independent examiner can rerun the complete search including threshold selection and receive compatible results; its inferential strength must then be argued separately. I return the token with gratitude for the statistical challenge.

Richard Wesley Hamming, Cross-Peer Question to Alan Mathison Turing: Mr. Turing, I pass the token to you because a reproducible waveform calculation also requires a reproducible programme. Suppose a laboratory states its FFT length, window name and sample rate correctly but leaves its handling of incomplete frames, NaN values and hardware sample gaps undocumented. Another implementation is permitted to pad, discard, interpolate or reorder the affected samples. Each implementation can be internally consistent, yet the waterfall event boundary and threshold can differ. How would you define a formal acceptance test that checks not merely whether two programmes produce output, but whether their internal states correspond to the same specified measurement? And how should we assess a software update that fixes a bug while rendering previously reported findings non-

Copyright 2026, James M. Atkinson

reproducible under the new version? Should a corrected report retain both outputs for forensic comparison and identify the precise change that altered the numerical decision?

Alan Mathison Turing, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, the essential requirement is to specify the computation as a mapping between explicit states, rather than to rely on the expectation that programmes with similar user interfaces must mean the same thing. The input state should include the sample values and their validity mask, sampling and tuning metadata, time-origin convention and exact processing parameters. The output state should include numeric estimates, coordinate arrays, quality flags and detection decisions. Every transformation should declare how it treats an incomplete frame, numerical overflow, missing complex component, invalid metadata or a time discontinuity. Two implementations can then be compared on the same test vectors, including those designed to expose the edge cases you mention.

The test plan should establish invariants. For instance, changing only the colour palette should never alter the stored spectral matrix or the detection decisions. Replacing an identical byte copy of the input should never alter the computation if all other inputs are fixed. Relabelling a timestamp without changing the sample indices should not move the sample-index coordinates, although it may change the displayed civil-time labels. A new missing-data mask should change which frames are admissible and must not be silently converted into zeros. Where the transform implementation is allowed to differ numerically, the accepted range should be set before testing. These invariants are stronger than requiring two screenshots to appear similar.

Copyright 2026, James M. Atkinson

A bug fix creates a version boundary, not an opportunity to rewrite history. The laboratory should retain the prior executable or an adequately specified reproducible implementation and the original processing recipe so that it can reproduce the historic reported result. It should then generate a second explicitly labelled analysis using the corrected software and compare the conclusions. If the change affects an evidential claim, the discrepancy needs an audit entry and an amended report rather than an invisible replacement. This is particularly important where a prior version mishandled frame boundaries or averaged dB values incorrectly. In such a case numerical reproducibility of the earlier result says nothing in its favour scientifically; the corrected result deserves separate scrutiny.

I would also make the software fail closed on critical unknowns. If sample-rate provenance is missing, the programme may generate a relative baseband plot for exploratory use, but it must not assign an absolute RF-frequency finding as though calibration were present. If a chunk contains unmarked invalid values, the system should flag the affected region rather than draw a smooth bridge. An acceptance suite should include negative tests proving that the programme refuses to create an apparently authoritative measurement from contradictory or insufficient inputs. The purpose is not to prevent legitimate exploration; it is to keep exploratory products explicitly separate from findings intended to withstand independent examination. I return the token for the consideration of formal reproducibility and evidential interpretation.

Dr. James M. Atkinson, Moderator: I thank Dr. Hamming and Mr. Turing for distinguishing the mathematical result, its implementation and the evidential claim. Mr. Turing, please now set out a reproducibility standard

Copyright 2026, James M. Atkinson

for independent laboratories. Address the difficulties of comparing different implementations, of preserving the precise decision rule and of documenting conditions under which a computation must refuse to report a definite RF finding.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Fourth Principal Contributor: I would organise the problem by asking what it means for two independent operations to implement the same experiment. If one asks only whether they draw similar images, one has selected a very weak test. If one asks whether they produce an identical binary file on different hardware, one may have selected a requirement stronger than scientific necessity. What matters is a specified relationship between inputs, computational steps and outputs, with observable tolerances appropriate to the decision. A reproducibility record should describe both the algorithm and the conditions in which it is valid. A processor's output is evidence of an algorithm's behaviour under those conditions; it is not, without further premises, evidence that the receiver's aerial witnessed an external event.

The measurement pipeline begins before the first instruction of the plotting application. A sample sequence may contain gaps, duplicate blocks or retuning intervals. Each of those conditions is a part of the input state, not an inconvenience to be repaired by the artist who draws the waterfall. A reconstructing laboratory should know whether the supplied samples represent one continuous stream, a concatenation of separate captures or a selected derivative. It should know the sample format, frequency history, clock uncertainty and state changes. If any of those are unknown, it should declare which conclusions can still be computed and which must be suspended. A relative spectral shape might remain analysable without an absolute frequency reference; an absolute RF attribution would not.

I would represent every analysis as a directed sequence of named operations. Ingest and parse the sample values under the declared datatype and byte order. Apply only the specified correction, downconversion,

Copyright 2026, James M. Atkinson

filtering or resampling operations, recording their parameters. Partition valid samples into frames under the stated window and hop. Apply the exact coefficient sequence and transform convention, then compute the selected spectrum or spectral-density statistic. Carry units and calibration through the result, estimate the reference background with a specified method, evaluate the detector and create the graphic from the numeric findings. A complete record should allow another implementation to replace any stage with an independently coded stage and compare the intermediate result.

One must preserve the source of each configuration value. A nominal sampling-rate field is an assertion about the recording. A separately measured oscillator offset is an observation with uncertainty. An FFT length is a processing choice. A colour range is a display choice. These may appear together in the same user interface, but their logical status differs. When a laboratory says its frequency estimate is accurate to a particular number of hertz, the claim should account for sampling-rate error, tuning-offset uncertainty, bin interpolation and signal conditions. The calculation cannot obtain absolute truth merely by carrying more decimal places through a fast transform. A setting whose uncertainty is unknown should remain a qualification, even if it makes the finished report less aesthetically persuasive.

I would use conformance vectors designed to fail for specific reasons. The first is a coherent complex tone at an exactly specified bin centre; it tests indexing, frequency sign and transform normalisation. The second is an off-bin tone; it tests leakage, window coefficients and amplitude correction. The third is simulated stationary noise; it tests the density convention and averaging. The fourth is a brief pulse crossing a frame boundary; it tests

Copyright 2026, James M. Atkinson

temporal labelling. The fifth is a stream with an explicit sample gap and retune event; it tests validity masks. The sixth has a deliberately inconsistent sample rate and timestamp; it tests whether the programme warns against an impossible interpretation. Each vector should have independently calculated expected properties and a record of numerical tolerance.

Missing data make the distinction between input and inference especially clear. A programme may choose to discard an incomplete frame, fill it with zeros or interpolate. Those operations have different consequences for energy and phase. If a valid interval contains no samples at a particular frequency because the receiver was retuning, a zero-filled image makes a logically false claim of observed quietness. An interpolation might be acceptable for a purely illustrative presentation, but it cannot become an unmarked observation in a report measuring occupancy or event duration. The validity mask should survive spectral estimation, detection and rendering. Otherwise a highly polished programme may erase the most important uncertainty in the experiment.

For thresholded findings I would preserve the continuous statistic before the decision. A binary detector output of 'present' cannot show whether the test statistic exceeded the threshold by a thousandfold or by a rounding increment. If two independent programmes disagree only for a few marginal frames, that fact is valuable; it need not be treated as a catastrophe or dismissed as rounding. We should report the statistic, threshold, margin, relevant measurement uncertainty and declared rule for ties. The rule must also specify whether the test searches across multiple bins and frames, whether background estimation used the same data, and

Copyright 2026, James M. Atkinson

how false-alarm claims were calibrated. This is a scientific decision protocol, not a matter of screen-colour preference.

Software provenance should be detailed enough to support independent reconstruction but not limited to a single proprietary executable. Retain version identifiers, configuration manifests, coefficient tables when necessary, test vectors and numerical outputs. When a source implementation is available, a reviewed source revision and build description improve inspectability. Where it is unavailable, independent conformance against a public mathematical specification and preserved reference outputs becomes more important. Operating systems, processor architectures and mathematical libraries can alter rounding or reduction order; those variations should be anticipated by tolerances that have been established through numerical reasoning, rather than excused after the fact. An unrecorded change in algorithm is not equivalent to an innocuous change in hardware architecture.

I would require at least one blind replication in which the second examiner sees the authorised data, the complete processing recipe and the acceptance criteria but not the original investigator's colourful screenshot. The second examiner should produce frequency and time arrays, numerical spectral values, valid-observation masks and detector decisions. A third party can then compare the results without visual suggestion. A second trial deliberately removes one setting at a time, and the laboratory records when the omission causes a material change or forces the calculation to stop. This assesses whether the identified configuration values are truly indispensable for the specific finding. It is more informative than asking ten operators to

Copyright 2026, James M. Atkinson

imitate a picture by adjusting sliders until their displays resemble one another.

The final acceptance should distinguish three outcomes: independent reproduction of a computation, independent validation of a calibrated measurement chain, and independent support for the particular conclusion. The first may be established with precise computational tests. The second requires instrumentation evidence and reference signals. The third requires an appropriate inference framework, uncertainty and evidence of observation. None entails the others automatically. A report should state which outcomes were achieved and which remain conditional. That separation is a protection for rigorous science as well as for the people whose conduct or security might be affected by a technical finding.

Jerzy Neyman, Peer Question: Mr. Turing, your proposal gives reproducible computations and a sensible approach to conformance vectors, but a numerical detector should also make its inferential operating characteristics explicit. Suppose the original analyst selected a threshold after searching a large waterfall, while the second examiner applies that threshold to the same samples and finds identical red cells. The computation is completely reproducible, yet an asserted one-in-a-million probability of a false positive may have no valid design basis. What should the reporting rule say about the sampling plan, multiplicity, background variability and decision threshold? In particular, how should the protocol treat unobserved scan intervals when estimating the fraction of time a signal occupied a channel? Does a reproducible occupancy percentage possess any useful scientific meaning if the denominator includes time during which the receiver was tuned somewhere else? I also ask you to state whether an observation mask

Copyright 2026, James M. Atkinson

must accompany the numeric occupancy statistic when data are exchanged between laboratories.

Alan Mathison Turing, Response: Professor Neyman, the detector must be defined as an experiment-wide procedure rather than a numerical predicate applied to one convenient pixel. A complete decision rule identifies how candidate regions were selected, how the reference distribution or background estimate was obtained, what threshold was chosen, which multiple comparisons were performed and what observation intervals were eligible. Rerunning the same threshold on the same file reproduces the original computation. It does not retrospectively turn a data-selected threshold into a prespecified statistical test. The independent examiner should therefore separate an exploratory finding from a validated false-alarm claim, even when the resulting plotted cells agree exactly.

For an occupancy estimate I would define the numerator and denominator in measured, valid time rather than graphic area. Suppose, illustratively, a channel is observed for four seconds during a nominal ten-second survey and is judged occupied for one second of those four valid seconds. The measured-dwell occupancy fraction is one divided by four, or 25 per cent. The fraction of the entire nominal survey interval during which observed occupancy can positively be established is one divided by ten, or 10 per cent, but that is not an estimate that the channel was quiet for the remaining six seconds. The difference arises because the data do not exist for the unobserved periods. An estimate of full-interval occupancy would require an explicit sampling design and assumptions about the omitted time, with uncertainty appropriate to those assumptions.

Copyright 2026, James M. Atkinson

Multiplicity should be handled at the level of the actual search. If a fixed per-cell detector is applied to thousands of highly correlated cells, an error probability cannot simply be transplanted from one isolated test. The laboratory may characterise the complete procedure with independent noise-only trials or simulations representing the selected windows, overlaps, channel variability and correlation. Where the method has been tuned after looking at the data, an independent validation set or a transparent adjustment is necessary before making a confirmatory probability claim. The reporting process should retain the full continuous statistics and decision thresholds, so that a reviewer can evaluate sensitivity when the assumptions are changed. Unknown error rates should be acknowledged as unknown, not assigned ceremonial zeros.

The numerical programme can enforce the distinction through separate result classes: an observed threshold crossing under a stated method, a calibrated detection decision with established operating characteristics, and an interpretative attribution requiring further evidence. For every class, the accepted input set and observation mask must be explicit. Reproducible output is a necessary virtue because it permits challenge. It is not a sufficient proof of an evidential proposition. The exercise therefore teaches both computer scientists and radio engineers to resist false confidence created by a stable display. I return the token to the moderator and invite the control theorist to examine the changing environment in which these estimates are made.

Alan Mathison Turing, Cross-Peer Question to Norbert Wiener: Professor Wiener, I respectfully pass the token to you. We have treated the waveform as a fixed archive, but a forensic receiver often observes a time-varying

Copyright 2026, James M. Atkinson

process in which gain control, interference, thermal drift and the statistical background can change within one recording. An analyst who uses a stationary-noise assumption throughout may produce a reproducible yet misleading detection threshold. How should the record describe the conditions in which a short-time spectral estimator is meaningful, and how can one compare alternate windows or averaging times without confusing the observer's changing filter with a changing emitter? I ask particularly whether temporal smoothing, automatic gain control and stationarity assumptions should be controlled as acquisition facts, processing choices or hypotheses to be tested, and how their differences should appear in the final uncertainty narrative. Please distinguish a sensor-state transition from a wholly digital smoothing operation, since their remedies and evidential consequences are different.

Norbert Wiener, Cross-Peer Answer to Alan Mathison Turing: Mr. Turing, a measurement process is a system with state and memory, and a waterfall is one description of its output. The receiver's automatic gain control may respond to earlier energy and alter the amplitude of later samples even when the external signal has not changed. An analogue filter may ring after an impulse, and a digital smoothing kernel may distribute one brief event across adjacent frames. Those are different mechanisms with superficially similar images. The acquisition record should identify active control loops, their settings and, where measurable, their state history. The analysis record should identify the subsequent filters and temporal averaging. A scientific hypothesis about environmental stationarity belongs to the inference rather than being silently embedded as an unquestionable property of the data.

Copyright 2026, James M. Atkinson

For a controlled experiment I would hold the known input source fixed while changing one receiver or analysis setting. A stationary synthesised carrier can expose a gain-control transient. A timed pulse can reveal analogue or digital filter memory. An authorised noise source with known statistical properties can test the estimator's response. A separate experiment can deliberately vary the input environment in a measured way, so that the programme's ability to distinguish real change from processing memory is challenged. This yields an identifiable set of controls. If one changes many settings at once, the resulting waterfall difference provides little evidence about which mechanism caused it. A well-designed comparison makes the signal process and the observer's response separately inspectable.

Noisy observations cannot always be divided into stationary and nonstationary pieces by a single unquestioned algorithm. The investigator should specify the local window over which the background statistics are estimated, any exclusions and the criteria used to detect a change in state. The effect of using shorter or longer estimation windows may be evaluated through sensitivity analysis. A fast detector may respond to an impulse but have higher variance; a long average may suppress variance while washing a brief pulse into the background. Both results can be reproducible because the algorithms are deterministic given the samples and settings. Neither becomes the uniquely correct description of the external world without reference to the scientific question and the receiver's measured behaviour.

I would therefore attach to the numerical result a state-aware validity account. It would identify periods of gain settling, overload, calibration transition, clock instability and missing reception. It would show whether the detector's noise reference was estimated locally or over a long period,

Copyright 2026, James M. Atkinson

whether thresholds adapt and whether adaptation was itself part of the prespecified test. A second examiner could then rerun the same estimator and challenge its premise under alternate credible settings. An uncertainty statement should report robust findings and fragile ones separately. The question is not whether one can reproduce a particular array of colours; it is whether the array supplies reliable evidence for the limited proposition being advanced. I return the token with thanks for the discipline of the question.

Dr. James M. Atkinson, Moderator: I thank Mr. Turing and Professor Wiener. Professor Wiener, please now develop the measurement's dynamic character. In particular, describe how a fixed recording may yield different apparent event boundaries when the processing window and estimator respond differently to transient noise, receiver control loops and changing signal conditions. Explain what an independent examiner should measure rather than merely observe in a coloured graph.

Copyright 2026, James M. Atkinson

Norbert Wiener, Fifth Principal Contributor: A short-time spectrum is a representation of a signal through an observer whose own operations have duration and memory. The finite window necessarily chooses a region of time, and averaging chooses how earlier observations influence later estimates. Analogue filters, receiver gain control and digital smoothing can also have memory. If a sudden bright patch appears in a waterfall, it may correspond to a genuine external change, a receiver control response, an estimator's smearing of a shorter event or a combination of them. The archive must therefore preserve information about the observer and its dynamic state. A repeated colour shape is not evidence of a repeated external source unless alternative mechanisms have been tested.

I would begin with the physical chain. An antenna feeds filters, amplifiers, converters and an ADC. Each stage has a passband and potentially a nonlinear operating region. A saturated amplifier may generate intermodulation products; a settling oscillator may move energy between adjacent frequency bins; a gain controller can change the apparent amplitude scale during a burst. The digitised samples are the output of that chain, not an unmediated photograph of the electromagnetic field. To reconstruct the numerical waterfall, one needs enough acquisition state to interpret the samples. To explain their physical origin, one needs independent controls that expose chain-generated artefacts. These tasks are related but should not be merged under the single word 'reproduce'.

A reproducibility record for a changing process should identify exactly when each setting was effective. A gain change at sample index ten million and a tuning transition at sample index twenty million are state changes that cannot be represented honestly by one global gain or frequency label if the

Copyright 2026, James M. Atkinson

same file contains both conditions. A processing recipe can specify piecewise intervals of valid calibration. A time-frequency cell whose analysis window straddles one of those changes may be invalid for a stationary-state interpretation, or it may need a more complicated model. A robust programme should flag the boundary rather than assign the entire frame to whichever state happened to be active at its midpoint.

The stationarity assumption deserves explicit examination. Many spectral estimators make useful calculations when a signal's statistics are approximately stable over the analysis interval. An industrial environment may contain periodic motors, electrical switching and short interference bursts whose properties vary over the course of the record. A background model estimated from the whole file may not describe each local interval. Conversely, an excessively short background window may follow the event itself and reduce its apparent contrast. The analyst should state the statistical population from which the background was obtained and why it is relevant to the event under examination. A colour scale that is automatically adjusted each second can hide a change in absolute level while preserving apparent visual contrast.

I would perform an experiment with a stable reference signal and two simulated noise conditions, one with steady variance and one with a controlled change halfway through the record. Apply an identical prescribed FFT but compare a fixed reference threshold, a local median-based background and a moving quantile estimator. Some discrepancies should be expected because the question asked by each detector differs. The fixed threshold answers whether energy exceeds one absolute criterion; the adaptive threshold answers whether energy is unusual relative to a locally

Copyright 2026, James M. Atkinson

estimated background. These are not logically equivalent claims. A report should label the corresponding results by their decision rule and retain the continuous statistic needed to understand the discrepancy.

Temporal smoothing must also be recorded with its impulse response or an adequately precise equivalent. Consider a hypothetical moving average over eight equally weighted successive waterfall frames. If one frame contains a short pulse and the other seven contain a lower background, its contribution to the average is diluted by a factor of eight in the linear-power domain when the simplifying assumptions apply. Expressed as a power ratio, that factor is approximately nine decibels because ten times the common logarithm of eight is about 9.03. This does not mean that the physical pulse lost energy; it means the displayed estimator distributed its influence across a longer support. One should not compute an onset duration from smoothed pixels without accounting for this response.

A second numerical distinction concerns clock error and time-frequency coordinates. If a nominal clock runs two parts per million fast, then a nominal ten-second sample count represents a time-scale difference of approximately twenty microseconds under the simple constant-rate model. The same fractional error shifts a nominal one-hundred-megahertz frequency assignment by two hundred hertz only when that frequency is derived from the affected oscillator in the stipulated way; an independent centre-frequency reference may behave differently. Thus the report must record which oscillator controls the ADC sample rate, which controls frequency conversion and whether they share a reference. One cannot apply one uncertainty figure indiscriminately to every frequency and timestamp in the receiver.

Copyright 2026, James M. Atkinson

In a surveyed spectrum, there are also intervals of non-observation. An instrument that visits a channel intermittently cannot establish every onset and cessation between visits. The reconstructed waterfall should preserve a coverage mask and separate the time coordinate of a measured dwell from interpolation or screen persistence. Suppose the receiver observed a channel for twenty milliseconds, then visited another channel for eighty milliseconds, repeating that cycle. One might describe a 20 per cent duty factor for observation of the first channel, but not a 20 per cent probability of intercept without specifying the event timing distribution, detector efficiency and scheduling assumptions. The same distinction prevents an attractive display from manufacturing evidence of continuous absence during unobserved intervals.

I would invite the independent laboratory to use two parallel outputs. One is a numeric time-frequency array with calibrated units where calibration exists, valid-data masks and a precisely defined detector. The other is a bounded interpretation describing what the array does not establish. These should be reviewed with intentional variation of frame length, taper, overlap, smoothing, gain assumptions and background estimation. If the conclusion is stable across a scientifically justified range, that stability can be stated. If the event disappears under modest plausible variations, the report should describe a method-sensitive indication, not an established emission. Such scrutiny is more valuable than a colourful plot whose palette exaggerates small numerical differences.

Finally, the archive should be designed for future challenge without presuming that all unknown signals can be identified. A lawful defensive RF survey may find an energy excursion, a spectral feature or an interval of

Copyright 2026, James M. Atkinson

increased occupancy. The recorded settings may permit another examiner to reproduce those findings. Attribution to a particular emitter or protocol is an additional proposition demanding independent evidence. Nothing in the reproducibility contract authorises interception of protected communications or unnecessary retention of content. The mature scientific result is a bounded statement that travels with its acquisition context, computational recipe, uncertainties and alternative explanations. I return the token to the moderator, with the hope that the reader will value an accurately described uncertainty over a deceptively beautiful certainty.

Abraham Wald, Peer Question: Professor Wiener, you have proposed sensitivity analysis across plausible estimation settings, yet repeated analyses can themselves encourage an investigator to choose the one producing the desired conclusion. Suppose several windows, detector thresholds and background estimators are defensible, but an event appears clearly only under one narrow combination. Should the laboratory report the most favourable result, the average across methods or the entire range? How can a decision procedure balance the risk of overlooking a genuine short-lived emission against the risk of making an unwarranted finding from receiver artefacts? I am particularly concerned with the separate costs of a missed detection and a false positive in a defensive survey, since the best operational decision may not be the same as the strongest scientific claim. Please identify what must be specified before data inspection and what should remain a transparent exploratory comparison afterward. I would also ask whether robustness across methods changes the evidential threshold for identifying an unknown emitter, as opposed to ordering further observation.

Copyright 2026, James M. Atkinson

Norbert Wiener, Response: Dr. Wald, sensitivity analysis should reveal dependence on a choice, not become a mechanism for selecting the most dramatic plot. A prespecified primary processing method and detector provide a transparent reference against which additional credible methods can be compared. If the event is visible only under a narrowly chosen combination, the report should say so and show the relevant numerical estimates and parameter range. Averaging incompatible methods is not automatically sensible, since they may estimate different observables with different units or temporal support. A better record contains the primary analysis, a documented collection of alternative analyses, and the reasons each was regarded as scientifically relevant. A reviewer can then inspect the robustness of the finding without being invited to treat every result as an equal vote.

Operational decisions and evidential conclusions must be separated. In a defensive survey, an indication with a high cost of being overlooked may justify a proportionate additional lawful inspection, even when its present evidence is too weak to support attribution or accusation. That is a decision made under asymmetric costs and uncertainty. It is not a licence to describe a tentative indication as a confirmed transmitter. A more stringent scientific report may require independent reference equipment, repeated observations under controlled gain states or known-source calibration before an attribution is made. The decision threshold for whether to investigate further and the threshold for whether to assert a finding are different quantities; each should be documented rather than concealed by one red pixel.

Copyright 2026, James M. Atkinson

Where possible the procedure should state in advance its primary detector, statistical reference set, threshold, window, hop, overlap and method for handling invalid data. An analyst may then explore alternate defensible settings, but should distinguish those explorations from confirmatory tests. If the primary detector was chosen only after seeing the record, that fact should be disclosed. A second independent or blinded recording can provide stronger confirmation than repeated transformations of the same samples, because the latter share the original acquisition errors and environmental contingencies. Sensitivity calculations are important, but cannot supply independent physical evidence merely by being numerous. The risk of false confidence grows when dozens of plots are treated as independent trials of one proposition.

A defensible final table would list each analysis recipe, its numeric outcome, measurement assumptions, uncertainty limitations and relation to the primary reported claim. It would also note conditions under which the receiver was unobserving, saturated or uncalibrated. If an event appears under every credible method but remains within a region where the analogue chain might have generated spurious products, the repeated computations strengthen reproducibility but not physical attribution. If an event is seen by independent calibrated receivers and consistent settings, the evidence can become stronger. This transparent architecture allows the laboratory to manage operational risk without inflating certainty. I therefore counsel that the waterfall be treated as an instrument of inquiry, not an oracle, and I respectfully return the token.

Dr. James M. Atkinson, Moderator: I thank the five principal contributors and the seven interrogating peers for their examination of the distinction

Copyright 2026, James M. Atkinson

between reconstructing pixels, reproducing numerical estimates and substantiating calibrated RF conclusions. The reciprocal challenges have examined software defaults, finite-window statistics, programme invariants and dynamic receiver state. The panel's conclusion is limited: a reproducible waterfall determination requires the source-data interpretation, receiver and clock configuration, processing recipe, validity mask, calibration references, numeric detector outputs and presentation settings to be recoverable, and the underlying physical inference must still be separately evaluated. The entire dialogue is a modern fictional scholarly reconstruction. No historical participant is represented as having spoken these words.

QUESTION 093

Copyright 2026, James M. Atkinson

Which RF phase and transient findings become untestable after lossy sample compression?

Dr. James M. Atkinson, Moderator: Professor Lempel, I invite you to distinguish an encoding that permits exact recovery of each acquired complex sample from one that deliberately sacrifices information. A waveform archive may appear adequately preserved because its average spectrum resembles the original; yet an isolated phase discontinuity, a very brief transient or a weak component at the margin of detection may no longer be available for independent examination. Please construct a defensible rule for deciding which measurements remain testable from a derivative recording. This is fictional scholarly reconstruction, not a quotation or a report of an actual historical debate.

Copyright 2026, James M. Atkinson

Abraham Lempel, Principal Contributor: I would start by rejecting the proposition that compression is a single transformation with a single evidential consequence. A lossless compressor rearranges information in a reversible coding representation; provided its decoder and source format are faithfully specified and the process operates correctly, the original sample byte sequence can be recovered without numerical change. A lossy compressor instead maps multiple possible inputs to an identical reconstructed output, or introduces a bounded or statistical reconstruction error. The second operation cannot generally be inverted to determine exactly which source waveform was present. The fact that an error appears small under one average measure does not prove that a specific transient, phase feature or weak waveform component was preserved for a different scientific question. The archive must declare which kind of operation occurred before anyone attempts to argue from a derivative.

A complex baseband sample has both in-phase and quadrature components. Its amplitude is the magnitude of the complex number and its phase is the argument of that number, subject to conventions for unwrapping, near-zero magnitude and reference. A lossy process that perturbs either component can perturb both amplitude and phase; when the magnitude of the original is small, a seemingly modest Cartesian error may cause a comparatively large angular error. A phase-difference estimator, instantaneous-frequency calculation or weak-signal correlation therefore cannot be certified by a broad assertion that the average sample error was low. The reviewer should state precisely which observable was tested, its sensitivity to reconstruction errors and the regions of the record in which numerical instability makes the result unreliable.

Copyright 2026, James M. Atkinson

One can define an elementary quantiser by its input scale, step size, rounding rule, saturation limits and any dither process. Reducing a signed sample from a higher resolution to fewer retained levels can be reversible only in the trivial case where the discarded information was already redundant under the specified input restrictions. Otherwise different original values share the same output representation. An apparent loss of low-level noise or a smoothing of abrupt changes may be a property of the quantiser rather than of the source. If the quantiser saturates on a high-amplitude pulse, it can alter the pulse shape and add spectral components that were not present in the original. If a predictive compressor spreads error across adjacent samples or adapts its rate to background conditions, one must study the temporal structure of its residual as well as its mean-square size.

Suppose a hypothetical complex waveform contains an isolated short pulse and a much longer interval of quiet stationary noise. If an error statistic averages squared sample differences over a million samples, a distortion confined to ten pulse samples may contribute relatively little to that average even though those ten samples are exactly those needed to estimate rise time or onset. A codec chosen to optimise the global average may therefore preserve the overall spectrum while destroying the narrow question an examiner later needs to investigate. The problem is an interaction between the objective used to design the codec and the objective used to interpret the evidence. No universal compression score can establish adequacy for every unknown future analytic task.

The correct comparison is to retain a controlled source and test several derivatives against it, with each derivative identified by its algorithm,

Copyright 2026, James M. Atkinson

version, parameters and reconstruction details. One derivative can be produced by a demonstrably lossless codec. Another can impose known bit-depth reduction without dither. A third can use a controlled dither or error-bounded predictive method. A fourth can employ an aggressive method whose distortions are intentionally substantial. The examiner should compare not merely file size and aggregate reconstruction error but the uncertainty of predeclared outcomes: amplitude, phase, transient timing, short-time spectral estimates, and the stability of a detector near its threshold. There should also be cases with no true transient, so that codec-produced false features can be recognised.

The experiment should be blind wherever practicable. A second examiner might receive the reconstructed samples, the codec description and a declared battery of measurements, but not the identity of the compression setting or the original analyst's conclusions until results are registered. It can then be observed whether the examiner detects the intended synthetic pulse, estimates phase consistently, or falsely identifies a transient created by the codec. The same experiment should be repeated across a scientifically justified range of pulse amplitudes, widths and phase structures rather than one favourable test signal. Those trials can establish limited performance characteristics under laboratory conditions. They cannot certify that an unknown and untested waveform was preserved merely because a different one was.

Retention and privacy limitations are genuine constraints, not technical inconveniences to be wished away. A lawful investigation may have good reasons to minimise acquisition, storage or disclosure of raw communication-bearing samples. If only a lossy derivative is retained, the

Copyright 2026, James M. Atkinson

report should identify what was kept and which analyses are no longer possible, rather than imply that compression preserved unlimited forensic flexibility. Where a tightly controlled original is legitimately retained, derivatives should have their own identities and an auditable relationship to the protected source. A compact waterfall image may be adequate to illustrate a previously computed statistic, but it is not a substitute for the sample sequence needed to re-examine phase, modulation or short transients. The decision to preserve content is a legal and governance matter distinct from the mathematics of reversible coding.

I would finally insist upon calibrated humility. If a particular phase excursion is visible both in the controlled original and in a derivative, that is evidence of preservation in that test case. If it is absent from a derivative, the absence may reflect the source, the codec, the receiver or the analysis method. If the original no longer exists, one may not retrospectively determine which of these possibilities occurred. A scientifically useful report should therefore distinguish features demonstrably retained, features known to have been distorted, and features whose original status has become untestable. The last category is not a sign of an unsuccessful investigator. It is a necessary acknowledgement that information deliberately discarded cannot be recovered by eloquent interpretation or an attractive screen. I pass the token to the subsequent contributors for a more detailed examination of information limits, predictive coding and statistically controlled uncertainty.

David Lennox Mills, Peer Question: Professor Lempel, may I ask you to sharpen the distinction between preserving a phase record and preserving the trustworthy time axis against which phase change is calculated? Many laboratories describe a sample file as an unbroken sequence because a

Copyright 2026, James M. Atkinson

decoder returns the expected number of complex values. Yet those values may conceal a dropped transport frame, a discontinuous acquisition clock, or interpolation introduced by a reconstruction stage. Consider a pulse lasting only several samples and an investigator who seeks its timing relative to a second instrument. Which clock and transport records would be required before the compressed derivative could sustain that claim? In particular, would a file-level digest of the retained derivative, an average phase-error statistic, or a successful re-encode/decode cycle help distinguish a physical frequency slew from a one-sample timing discontinuity? Please specify how you would arrange a lawful laboratory comparison without implying that one accurate timestamp repairs an unknown number of missing samples. I pass the question to Professor Lempel in the expectation that he will address both the reversible and irreversible aspects of the problem.

Abraham Lempel, Response: Dr. Mills, a trustworthy sample count and a trustworthy time axis are different claims. A decoder may reproduce one million values exactly from its encoded representation while the original recorder omitted a transport block before those million values were assembled. If the recorder then filled the gap with zeros or interpolated values before a lossless compressor operated, a subsequent digest would faithfully protect the invented samples. The hash cannot distinguish an authentic acquisition from a false premise that was fixed into the file at its creation. We need an acquisition log that records sample-counter continuity, buffer overflow or underflow flags, hardware timing references, and the relation between an RF event and the recorded sample index. We also need to know whether the decoder introduces any resampling or concealment. A

Copyright 2026, James M. Atkinson

claimed sequence without gaps must be tested against a known reference before an examiner can rely on it as a continuous clocked record.

Suppose a nominal sampling rate is one million complex samples per second. A one-sample offset corresponds nominally to one microsecond, but that conversion assumes the sampling clock maintains the specified rate during the interval. If the receiver clock differs from the reference by ten parts per million, the accumulated error over one second can approach ten microseconds before accounting for additional uncertainties. These are simple hypothetical arithmetic illustrations, not measurements of any particular instrument. Two detectors may assign the same file-system creation time while observing the physical event at very different instants. The independent laboratory control should place a known pulse onto a reference channel and compare the captured sample counter, externally referenced time stamp, and host write time, leaving their distinct uncertainties visible. We ought also to test a deliberate dropped-block condition to see whether software flags, conceals or silently joins the adjacent data.

Compression creates an additional opportunity for confusion if its block size, predictor history or reconstruction delay is undocumented. A codec can preserve sample count while changing relative phase around a block seam. It can also introduce group delay, requiring a declared alignment convention before pulse onset is compared between records. A cyclic comparison based on spectral magnitude may miss both of those effects. Accordingly I would require a two-stage report: one stage verifies that a digital test vector passes through the codec with its declared time and phase errors; a separate stage verifies that the end-to-end receiver preserves the

Copyright 2026, James M. Atkinson

reference waveform and its timing within an instrument uncertainty budget. A verified digest of the encoded derivative then protects the outcome of those processes against undetected later alteration, but proves neither stage retroactively. If the original high-resolution samples were lawfully retained, one can inspect them when a timing anomaly arises. If they were discarded, the correct scientific conclusion is that some hypotheses about the original timing are no longer decidable from the surviving record.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor for distinguishing the evidence from its interpretation. I now invite Dr. Jacob Ziv to examine the next distinct limitation, preserving courteous transfer of the token and explicit disclosure of unresolved uncertainty.

Copyright 2026, James M. Atkinson

Jacob Ziv, Second Principal Contributor: Dr. Atkinson, I would distinguish the mathematical problem of describing a discrete sequence efficiently from the evidential problem of establishing which physical event the sequence represents. The original sequence may contain redundancies that permit exact recovery from a shorter description. That is the principle underlying a genuinely lossless code. A fixed bitstream, the decoding convention, and an executable decoder should recover precisely the same integer symbols in precisely the same order. Whether those symbols are correctly assigned to in-phase and quadrature channels is a separate format assertion. The test for bitwise reversibility is not that the spectrum looks similar or that a few selected sample values agree. It is that the complete decoded object equals its declared reference object under a documented byte-level comparison. If an archive includes headers that change with software versions, one must state whether equivalence concerns the entire file, the canonical sample payload, or the interpreted numerical series. Otherwise a legitimate container change may be mistaken for corruption and a dangerous change of interpretation may remain unnoticed under a matching payload digest.

A lossy operation introduces an information partition. Many different inputs lead to one encoded description and hence to the same reconstructed output. The size and form of the equivalence classes matter. If an examiner asks whether a faint phase step occurred at one particular sample, and both an input containing that step and an input without it map to an identical derivative, the answer cannot be deduced from the derivative alone. A claimed global bound on root-mean-square error changes this conclusion only if it implies a sufficiently strong local bound for the particular observable. The relevant counterexample need not be exotic. In a long

Copyright 2026, James M. Atkinson

recording, a one-sample excursion can occupy a negligible fraction of the total energy and yet determine the onset of an event. A rate controller that discards locally uncommon details may consequently produce highly plausible reconstructions with an evidential blind spot at the one moment the report needs to examine.

The information-theoretic distinction can be made precise without claiming that every scientific uncertainty is an entropy calculation. Let X denote the original finite sample sequence and Y the retained derivative. An exactly reversible deterministic encoding admits a decoder that reconstructs X from Y, with all necessary side information available. A many-to-one lossy mapping does not, in general, admit such a decoder over the declared input domain. The conditional uncertainty in X given Y depends on the assumed source model, and any estimate of that uncertainty is conditional upon the model being suitable. A high compression ratio by itself is no evidence of excessive damage, just as a modest ratio does not establish preservation. The sound inference must pass through a defined target observable: for example, pulse onset to within a specified interval, the sign of a phase increment, or the result of a pre-registered detection test.

A good controlled experiment begins with a synthetic or otherwise authorised reference waveform whose source samples are retained. Include a continuous carrier with an imposed phase step, a low-amplitude linear chirp, a sequence of short pulses with distinct widths, and intervals containing nothing beyond specified laboratory noise. Pass the same reference stream through several encoders, making every transformation and any dither seed reproducible. Record the exact output rate, the resulting byte count, algorithm version, codec settings, and reconstruction

Copyright 2026, James M. Atkinson

arithmetic. Then ask independent analysts to estimate time of onset, phase increment, and detected-event count without knowing which derivative they have received. A successful result means the predeclared task tolerances are met for the tested waveforms and settings, not that an unseen future waveform must also survive the operation. A failure can be localised by returning to the preserved source.

It is particularly important to compare reductions of sample width with transformations that redistribute error in time. A uniform mid-tread quantiser may create locally bounded errors away from clipping, although a deterministic quantisation pattern can be strongly correlated with the input. An adaptive predictor may instead produce small average error but temporarily larger residuals when a previously unanticipated burst arrives. A transform coder can allocate few bits to coefficients judged unimportant under its optimisation criterion. If that criterion is perceptual quality, ordinary image contrast, or long-term spectral energy, it need not align with the forensic objective of preserving a brief phase anomaly. The measurement protocol should therefore expose local maxima of error, burst-conditioned errors, and phase errors at low amplitude, alongside aggregate scores. Those quantities cannot be inferred from the advertised ratio alone.

Consider a hypothetical sequence of one million complex samples in which ten samples carry a transient whose significance is purely temporal. If the compressor changes those ten values substantially while reproducing the remainder exactly, the fraction of affected samples is ten divided by one million, or 0.001 percent. A very small global error rate could accompany complete loss of the transient's geometry. This is not evidence that a

Copyright 2026, James M. Atkinson

particular codec necessarily behaves in that way; it is a logical demonstration that a global average does not bound the worst local error. If the report needs a guarantee concerning that ten-sample event, it must use a method with an explicit suitable local guarantee or retain the relevant original samples under lawful conditions. Neither a smooth waterfall nor an apparently excellent correlation coefficient supplies the missing guarantee.

I would keep a three-level conclusion in the case record. First, the representation may be exactly reversible for the declared symbol stream, provided the implementation passes verification. Secondly, a lossy representation may be adequate for a stated observable on a stated signal class and within a measured tolerance. Thirdly, the retained data may be inadequate for some observations, including those not anticipated at the time of compression. The third classification is not a verdict upon the scientific merit of compression; it protects later investigators from treating a carefully optimised summary as if it were the original evidence. The presiding professional must also distinguish byte integrity from authenticity of acquisition. A digest proves no radio signal existed, and a beautifully reconstructed derivative cannot retroactively certify an analogue-to-digital converter that was overloaded before any codec received its input.

The documentation should identify the point in the acquisition chain where compression occurred. If the instrument reduced precision before recording, no laboratory archive contains the omitted ADC values. If a high-resolution source was retained and a compact working copy later produced, controlled re-examination can resolve ambiguities. If an operator retained only a display raster, even the relationship between pixel intensity and spectral power may be unknown. The chain of custody must specify each of

Copyright 2026, James M. Atkinson

these circumstances in its own terms. It must avoid the tempting language of an original when the supposed original is already a many-to-one derivative. I pass the token to Dr. Elias to consider how the representation code and the decision problem interact.

Alan Mathison Turing, Peer Question: Dr. Ziv, a statement that a codec is reversible often assumes more than the published algorithm. It presumes a specific source-byte ordering, deterministic implementation, preserved decoding tables, and a computer that obeys the asserted arithmetic conventions. Would you distinguish a proof about an abstract mapping from evidence that a particular implementation and file actually followed that mapping? Imagine the decoder applies a different signed-integer interpretation, silently swaps I and Q, or uses a newer floating-point rounding rule. A checksum over the compressed bytes could still agree perfectly even while the reconstructed signal used by the examiner differs. How should a competent laboratory specify and test the computational contract, including a record of software dependencies, so that a result is independently repeatable? Please explain why a diagram of an encoder cannot itself certify the executable machine, and which deliberately adverse test cases would most quickly expose a false assertion of lossless recovery.

Jacob Ziv, Response: Mr. Turing, the abstract and the implemented claims should be separately stated. One mathematical theorem may establish that a defined decoder is an inverse of a defined encoder over a specified alphabet. That theorem says nothing by itself about a faulty implementation, a truncated file, an incorrect endian assumption or a newly installed library that changes how metadata are interpreted. The laboratory needs reproducible test vectors that include sign changes, zero, full-scale

Copyright 2026, James M. Atkinson

values, alternating interleaved I and Q channels, and pathological symbol sequences rather than merely comfortable random examples. For a lossless claim, decoding the actual archived object and comparing it byte for byte with the protected source payload is an especially direct test, provided the reference object and comparison scope have been identified. Where the original is no longer retained, that test cannot be performed retrospectively, though a codec implementation can still be validated with independent reference vectors.

One must define the meaning of recovered. A stream of little-endian signed sixteen-bit integer pairs may have a perfectly stable byte sequence. If an examiner interprets those bytes as big-endian or exchanges channel order, the mathematical values and the resulting complex phase differ without any alteration in the file digest. A robust manifest must therefore record data type, signedness, word width, endian ordering, I/Q interleaving, numerical scaling, sample rate and valid-sample count. If the stream contains sentinel values or out-of-band validity masks, those must also be preserved. Decoder identity should include its version and relevant dependencies, ideally accompanied by known-answer vectors and a record of the machine environment. No single hash can demonstrate that the interpretation contract is true; the digest only assists in showing that a chosen object has not changed relative to a trusted reference.

Your distinction between abstract and actual machines is equally pertinent to floating-point transformations. If a decoder uses arithmetic that is not bit-exact across platforms, a claim of mathematically lossless numerical equivalence may be different from a claim of identical bytes. That difference must be made explicit. It is wrong to assume that an approximately equal

Copyright 2026, James M. Atkinson

spectrum proves exact source recovery. Independent comparisons should examine the full integer or floating-point arrays, selected complex-phase relationships and boundaries between encoded blocks. Tests should include damaged headers, missing trailing bytes, decoder state resets and corrupt internal tables, with the expected failure modes declared. If the implementation silently continues after malformed input, that behaviour is an evidential risk and should be reported as such. A good validation package documents not only positive round trips but negative tests designed to make the decoder refuse an unsupported record.

Finally, I would maintain provenance for the software itself. A source listing, compiler settings, executable digest, container dependencies and validation results describe different parts of the chain. A later expert may not be able to run an old binary on new hardware, so readable format documentation and independent test vectors are essential. Where a new decoder produces the same numbers under a separately established equivalence criterion, the laboratory may reasonably continue analysis, while recording that the software implementation changed. None of this solves the analogue-origin problem. An impeccable implementation can reproduce a sample record that was clipped, mistimed or fabricated before the encoder saw it. The archivist and the investigator must resist promoting an exact computational result into a claim of truth concerning the physical scene.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor for distinguishing the evidence from its interpretation. I now invite Dr. Peter Elias to examine the next distinct limitation, preserving courteous transfer of the token and explicit disclosure of unresolved uncertainty.

Copyright 2026, James M. Atkinson

Peter Elias, Third Principal Contributor: Dr. Atkinson, any compression policy designed for scientific records should begin by saying which proposition the eventual examiner must decide. A data coding objective minimises representation length under a specified source or distortion constraint; an inferential objective asks whether particular hypotheses can still be distinguished after the record is transformed. The two objectives can coincide, but coincidence must be demonstrated rather than presumed. A system that preserves a large fraction of energy may nevertheless alter the sign of a short phase increment. A system that gives excellent overall spectral agreement may create a transient in an otherwise quiet interval. In a forensic setting, the reported question often concerns a rare exception, not the characteristic behaviour of the average sample. This makes the choice of distortion criterion more consequential than the numerical compression ratio displayed by the operator.

Let the acquired complex sequence be x[n], and let the reconstructed sequence be y[n], with n indexing discrete samples. A simple distortion measure is the mean of the squared magnitudes of y[n] minus x[n]. That quantity has its uses, but it equally weights all sample positions and does not by itself identify a short region that contains the disputed event. One may instead inspect a maximum absolute error, errors restricted to declared burst intervals, changes in unwrapped phase increments, and changes in the output of a specified detector. Such metrics require definitions of the sample rate, timing reference, treatment of near-zero magnitude and phase unwrapping convention. The conclusion is sensitive to all those choices. If a result is presented as an error in degrees, the examiner must know whether

Copyright 2026, James M. Atkinson

that refers to absolute phase, differential phase, an aggregate circular statistic, or an estimated carrier phase after synchronisation.

Under small relative perturbations of a nonzero complex sample, the phase change is approximately the imaginary component of the relative error. That approximation is fragile near the origin of the complex plane. If the original magnitude is small, even a small absolute Cartesian reconstruction error can cause a large angular displacement. No amount of confidence in a global waveform signal-to-noise ratio resolves the instability at a sample where the phase is itself poorly determined. A rigorous study should either restrict phase claims to a declared amplitude regime or propagate the uncertainty of near-zero values into the result. An apparent rapid frequency excursion calculated from sample-to-sample phase differences can represent actual oscillator motion, thermal noise, low-amplitude instability or codec-induced noise. The derivative alone may not distinguish those explanations.

An acquisition chain also imposes limits before compression. Anti-alias filtering, automatic gain control, analogue clipping, ADC saturation, sample-rate conversion and dropped buffers can irreversibly alter the source record. The codec is one stage of a larger system, not the sole villain in every ambiguous measurement. A fair comparison therefore includes a verified digital source injected after the ADC to isolate codec behaviour, and separately a calibrated RF or analogue reference sent through the whole receiver chain. The first experiment asks whether the codec retains chosen digital features. The second asks whether the instrument and codec together retain those features under actual operating conditions. A difference between the two can be attributed only after examining the

Copyright 2026, James M. Atkinson

additional uncertainty sources, including frequency-reference accuracy and the loading of the receiver front end.

The easiest misleading result is the apparent absence of a pulse. If the original file has been destroyed and only the lossy derivative remains, the investigator cannot inspect the omitted detail. A detection algorithm that reports no event may be working exactly as specified on its input while remaining incapable of testing whether an event existed before compression. In such circumstances the report should state that no event meeting the declared criteria was detected in the preserved derivative, not that no event occurred at the original antenna. This is a distinction of logical scope, not a stylistic preference. The same caution applies to a positive result when a codec can manufacture ringing near a sharp transition. A detected feature should be challenged against a control input that is known not to contain it.

A test programme should vary amplitude, pulse duration, relative phase, carrier offset, noise statistics and compression setting independently where feasible. The examiner should measure false positive and missed detection frequencies using a declared ground-truth generator and an honest account of trial independence. The programme ought to include a family of rare events not used to tune the codec. Otherwise its favourable performance may simply reflect adaptation to the validation set. If the system employs trained models, the model file and its version become part of the analysis provenance. The training data's suitability is another question, and any claim of generalisation deserves an independent test rather than an appeal to a fashionable architecture. A compression setting which is safe for

Copyright 2026, James M. Atkinson

occupancy plots cannot simply be certified for phase-metrology applications.

I recommend that the archive attach a recoverability statement to every derivative. It should specify whether bitwise recovery is promised, whether there is a numerical error bound, or whether only statistical performance has been evaluated on a named signal class. It should also identify data outside the tested region, such as clipped bursts or events of duration shorter than the codec's analysis window. The specification must state what the test has not established. An examiner may then decide whether the preserved record is adequate for an authorised question. This approach is more respectful of scientific evidence than allowing broad words such as high fidelity or visually lossless to stand in place of an uncertainty budget.

Finally, preservation decisions are practical and legal decisions. There may be compelling reasons not to retain communication-bearing raw samples. A derived record can reduce exposure, storage cost and unnecessary content retention, but those benefits must be described without pretending that information destruction leaves every future question answerable. The institution should agree in advance which observations justify exceptional preservation, who may authorise it, how it is secured and when it must be erased. It should not use an ambitious theoretical wish for unlimited forensic re-analysis as an excuse for indiscriminate collection. Where only the derivative is lawful, the scientific inference is limited accordingly. My colleague Dr. Shannon can now address what mathematical theory allows us to state, and what it does not.

Richard Wesley Hamming, Peer Question: Dr. Elias, if a lossy recording remains the only preserved representation, what should an independent

Copyright 2026, James M. Atkinson

reviewer require before accepting the laboratory's assurance that weak transients were not materially affected? A report might announce a 60-decibel reconstruction signal-to-noise ratio, but the disputed signal could occupy a few samples or lie in a narrow phase trajectory. The average number is not obviously connected with the worst case. Would you recommend a predeclared detector, a maximum-error constraint, a pulse-conditioned error distribution, or some combination? I am especially concerned about false positives introduced by ringing and false negatives created by thresholds that were tuned on the compressed data itself. Please state how many independent test trials might be needed in principle, how their dependence must be handled, and why the absence of errors in a small validation set cannot logically establish a zero probability of error in untested conditions. I offer the question as a request for limits rather than a desire for an impressive assurance.

Peter Elias, Response: Dr. Hamming, I would first require a precise statement of the claim: for example, that a pulse of specified amplitude, duration and shape is detected with a stipulated probability under a named class of laboratory noise conditions, or that an onset estimate differs from the reference by no more than a defined tolerance. Reconstruction SNR alone is insufficient because it averages energy across samples and does not bind a sparse decision event. A predeclared set of test statistics should include maximum local sample error, phase-error distribution conditional on signal amplitude, edge timing error, and changes in the result of the detector actually intended for use. If the underlying claim concerns phase discontinuity, the test must operate on complex samples and must not

Copyright 2026, James M. Atkinson

substitute a magnitude-only plot. The design should contain known-absence controls because an encoder can create ringing that is mistaken for a pulse.

When a codec is tuned using the same examples later presented as verification, the resulting success is not an independent acceptance test. I would insist upon a disjoint validation set, preferably produced by independent personnel or an independently specified generator. The test grid should vary pulse width and carrier offset because a block transform may behave differently when a transient aligns with a window boundary. It should vary amplitude across a regime near the detection threshold, where a small additional error may reverse a binary decision. It should vary interferer power because a codec or receiver may adapt under overload or nonstationary inputs. Results should be tabulated with explicit denominators: number of trials, number of misses, number of false detections, and any repeated observations of the same underlying noise realisation. Twenty heavily overlapped windows from one burst are not twenty independent experiments simply because a software array contains twenty entries.

A deterministic maximum-error bound can support a stronger statement when the observable's sensitivity is known, but even that must be applied carefully. A small absolute complex error need not imply a small phase error where the original magnitude approaches zero. Likewise, a maximum error measured at the discrete sample instants does not automatically establish a bound on continuous-time reconstruction between those instants without a specified interpolation and bandwidth model. We must distinguish assumed theorems, measured instrument behaviour and empirical frequencies. With a finite sample of independent trials, observing no misses does not prove

Copyright 2026, James M. Atkinson

the true miss probability is zero. A confidence limit can be calculated for a declared model, but its reliability depends on the independence, representativeness and stability of the trials. The laboratory should report the actual count and the method rather than attach a confident adjective to a single convenient trace.

Where only a lossy derivative survives, the strongest honest conclusion is bounded by those prior tests. The reviewer may say that under specified laboratory conditions a named class of transients remained detectable at a given performance level. The reviewer cannot assert that an unanticipated microburst, an unusual modulation or a subtle phase excursion was necessarily preserved when neither the source nor an applicable guarantee remains. An engineering report gains credibility by making these boundaries visible. It should not punish the lawful minimisation of sensitive data, but it should never mask the consequent limits on what the evidence can now answer.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor for distinguishing the evidence from its interpretation. I now invite Dr. Claude E. Shannon to examine the next distinct limitation, preserving courteous transfer of the token and explicit disclosure of unresolved uncertainty.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Fourth Principal Contributor: Dr. Atkinson, there is a seduction in asking one number to summarise the fidelity of a record. Rate-distortion theory establishes disciplined ways to examine how much description is needed under a chosen source distribution and chosen measure of distortion. It does not decree which measure of distortion is right for every scientific or legal purpose. If the measure assigns negligible penalty to destroying a rare transition, a rate-efficient code may lawfully satisfy the mathematical optimisation problem while failing the later examiner's evidential question. The difficulty is not that theory has failed; it is that an inappropriate problem was posed. Accordingly I would demand a plainly stated inference target before claiming that a lossy RF sample derivative is adequate.

Let R denote the average representation rate in bits per source symbol and D the allowable expected distortion under the stipulated probability model. A rate-distortion function describes a lower bound on achievable rate for that model and distortion criterion. It should not be confused with an empirical upper bound on worst-case phase error at every sample. A rare event may be assigned little probability by the model and therefore little influence on expected distortion. When an investigator asks about precisely such an event, the model's treatment of rarity becomes central. If the physical environment changes or an adversarially chosen burst appears, conclusions drawn under the training distribution may be unhelpful. The best scientific practice is to state the assumptions and design additional tests at the boundaries where those assumptions might fail.

A complex RF representation is particularly liable to misconceived analogies with pictures and sound. A human observer may not perceive a small

Copyright 2026, James M. Atkinson

alteration of a coloured waterfall; an algorithm may nevertheless depend on the exact phase relation between adjacent I and Q samples. A magnitude-only spectrogram loses absolute complex phase even without a lossy image codec. Any later conversion to a compressed graphic is another transformation and cannot recreate information already discarded by the power-spectrum operation. Two sample sequences with different phases can produce matching magnitude spectra under relevant constructions. Therefore equal-looking images are not proof of equivalent complex recordings. Conversely, a display palette can exaggerate a harmless small spectral difference until two equivalent numeric results look strikingly unlike one another. An archive must make clear whether it preserves samples, summary statistics or presentation pixels.

We can construct a hypothetical counterexample involving one million samples. Let the original sequence be zero except for a single nonzero sample and let the derivative be all zero. The sample-domain mean square error equals the squared magnitude of that sample divided by one million. Its numerical value can be very small if the sample amplitude is normalised, yet a detector whose only task is to answer whether that single impulse occurred has lost all decisive evidence. The point is not to recommend such a source model as realistic RF engineering; it is to establish that average error alone cannot bound every decision error. When claims concern a short event, either an appropriate task-specific criterion or a local maximum-error bound is needed. A reviewer should ask whether the guarantee is deterministic, probabilistic or merely observed on a finite test set.

At high amplitudes the issue may be quite different. If an aggressive quantiser saturates near full scale, a pulse's peak and leading edge can

Copyright 2026, James M. Atkinson

flatten. That clipping can generate out-of-band spectral content and alter measured rise time. If the compressor applies an analysis window, it can spread an abrupt change across neighbouring output samples. A reported precursor may then be ringing, and a reported absence may reflect the filter's transient response. These effects deserve controlled negative and positive tests, including known absence cases. A false alarm attributable to reconstruction is neither evidence of a real emission nor proof that the receiver is defective. It indicates that the transformation must be included in the causal account of the measured waveform.

One should also distinguish reconstruction accuracy from identity of source. Even a perfect reversible code cannot prove that an RF sample file was produced by a genuine antenna, that it was acquired under the stated legal authority or that the receiver clock was correct. It can only recover the declared digital object. Cryptographic integrity checks support continuity from a secured reference point, and a chain-of-custody ledger explains possession and transformations. Both remain vulnerable to false premises concerning the event before the reference point. The investigator should therefore verify the instrument configuration and calibrations separately from the integrity of its stored sequence. A persuasive report should not collapse all these propositions into the unqualified word authentic.

The uncertainty statement must be conditional on the retained representation. For a full-complex reference with verified acquisition, one may estimate phase noise, transient timing or coded-waveform structure subject to instrument limitations. For a derivative whose maximum complex-sample error is suitably bounded, one may propagate that bound through an analysis where the relevant denominator stays away from zero. For a

Copyright 2026, James M. Atkinson

perceptual or learned codec lacking a task-specific guarantee, one may report only the observed performance of the chosen validation set, with explicit uncertainty about unseen signals. For an image-only record, one cannot recover independent sample-level phase tests at all. None of these statements means that lossy recording is universally improper. They describe distinct inferential powers that should not be conflated.

I would end with a caution about precision of language. The defensible phrase is that a given feature was preserved within a stated uncertainty on a declared class of tests. It is not that no information of possible forensic interest was lost. A study cannot test all future questions, and the mathematical existence of distinct sources mapping to one derivative shows why that absolute promise cannot generally be made. We should design records, controls and reports that make their own limitations legible. Dr. Reed may now explore how deliberately introduced redundancy and error recognition relate to irreversible loss of sample information.

John von Neumann, Peer Question: Dr. Shannon, please address a persistent confusion between a mathematical rate-distortion result and a forensic guarantee concerning a particular waveform. An optimisation may minimise expected squared error under a probability law learned from ordinary traffic, while the only event later disputed is extremely rare under that law. If the model assigns vanishing importance to the event, how can the archive declare an acceptable distortion criterion without assuming away its own investigation? Is a visually faithful spectrogram an acceptable surrogate for phase continuity, and would a compression system trained to preserve typical spectra necessarily preserve an unforeseen chirp or discontinuity? I ask also whether a validation programme can compensate for a wrong

Copyright 2026, James M. Atkinson

objective function, or whether the responsible institution must identify categories of future questions that will simply become unanswerable if only a derivative is retained. Please distinguish mathematical possibility, operational verification and lawful retention authority.

Claude Elwood Shannon, Response: Professor von Neumann, a rate-distortion calculation answers the question that was mathematically specified, not every question one might wish had been specified. The relevant source distribution and distortion measure are not decorative parameters. They are premises governing the conclusion. If the expectation assigns little weight to a rare event, the optimal code may rationally allocate little rate to that event while still satisfying the chosen mean-distortion requirement. The archive must not then claim that it guaranteed retention of all rare anomalies. To support a specified forensic decision, the institution should choose a distortion criterion that reflects the decision's sensitivity and should test that criterion against appropriately challenging examples. Where it cannot foresee the question and must discard original information, some future distinctions inevitably become impossible. This limitation follows from the many-to-one nature of irreversible encoding rather than from a weakness of the examiner.

A spectrogram image should be treated as a visual summary whose construction must be documented. It commonly maps a complex waveform to local spectral magnitude or power, often followed by logarithmic scaling, thresholding and a colour palette. Phase information discarded by the magnitude operation cannot be recovered from the pixels. Additional image compression may change colours, edges or small isolated regions. A visual resemblance therefore does not establish preservation of sample-level

Copyright 2026, James M. Atkinson

phase. Even a spectrum with an unchanged average power distribution need not preserve the temporal ordering of short events. If the later task is to determine phase continuity, the evidence requires an appropriate complex representation or another specifically validated measurement of that observable. We should ask what the derivative contains rather than how convincing its display looks.

A validation programme is necessary but cannot logically redeem a definition of fidelity that ignores the target scientific question. If an organisation knows it may need pulse rise-time measurements, then it can include onset and shape distortion in the acceptance criterion and provide representative high-amplitude, low-amplitude and block-boundary tests. If it knows it may need modulation analysis, it can include complex-correlation and phase-error measures over a specified amplitude regime. But no finite laboratory collection proves adequate retention for every waveform, especially a signal class deliberately excluded from the model. One must distinguish average observed success from a worst-case guarantee and identify the class within which either is asserted. Where the codec supplies only a mean-square objective, an investigator should not silently reinterpret that as a maximum instantaneous phase-error bound.

The separate question of lawful retention must remain separate. There may be legitimate reasons to preserve only power summaries and destroy content-bearing raw samples. That choice does not contradict mathematics; it narrows the questions later answerable. A defensible governance policy can distinguish routine data minimisation from a tightly authorised exception for retaining a short complex sample extract when an important ambiguity must remain open to independent review. It should record why

Copyright 2026, James M. Atkinson

the retained scope is necessary and who may examine it, without treating a scientific wish as a legal entitlement. A report produced solely from a lossy record ought to say so and identify material uncertainties. Such candour is far more useful than an unsupported statement of perfect fidelity based upon a favourable average statistic.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor for distinguishing the evidence from its interpretation. I now invite Dr. Irving S. Reed to examine the next distinct limitation, preserving courteous transfer of the token and explicit disclosure of unresolved uncertainty.

Copyright 2026, James M. Atkinson

Irving S. Reed, Fifth Principal Contributor: Dr. Atkinson, an engineer can build strong methods of detecting or correcting errors in stored digital representations, yet those methods must not be mistaken for a cure for intentional loss of information. Error-correcting codes add constrained redundancy so that specified transmission or storage errors can be found or repaired. A lossy encoder removes distinctions among source sequences before the protected codeword may ever be formed. A perfectly corrected archive can consequently reproduce a lossy approximation without recovering the values discarded at its creation. The two operations solve different problems. We may require excellent channel integrity and still have no basis for inferring a short RF transient that the source encoder suppressed.

Suppose a recorder quantises complex samples from a fine grid to a coarse grid, then applies a strong error-correcting code to protect the resulting bits during storage. After a disk upset, the code may reconstruct every coarse-grid bit exactly. That is a genuine achievement of the preservation system, and it can be established by a verified decoder and protected digest. But several different fine-grid samples may have led to the same coarse-grid pair. Nothing in the correction code selects which fine-grid value was acquired. A case report should not say that the original waveform was recovered merely because the archive passed its integrity checks. It should say that the encoded derivative was preserved and decoded correctly to its declared precision, with the pre-compression uncertainty explicitly retained.

The converse mistake is to treat every discrepancy between original and derivative as a storage fault. A mathematically specified quantiser is expected to change many sample values. Those deliberate transformations

Copyright 2026, James M. Atkinson

should appear in the derivative's provenance and uncertainty budget. Storage corruption, omitted bytes, reordered blocks and a codec's legitimate changes should be separately diagnosable where possible. If a file checksum differs unexpectedly, the examiner should first identify whether the checked object is the compressed bitstream, the decompressed output or a container with changing metadata. A mismatched digest is a reason for investigation, not an automatic verdict about which part of the RF chain failed. That investigation should never repair evidence invisibly: any corrected or reconstructed file must remain a separately identified product.

Rare transient studies require deliberate stress cases. A detector may rely on phase continuity across a block boundary, and predictive encoders may restart their internal state at such boundaries. An unnoticed reset can produce a step in phase or amplitude that resembles an external transient. A packet lost in a network transport can create a gap that a decoder conceals with interpolation. A compression engine with a long analysis window can smear a short pulse into neighbouring samples. An examiner must distinguish each of these artifacts from input features by using known reference streams and inspecting reconstruction residuals. Testing at only a convenient mid-band frequency and generous amplitude is inadequate when the intended findings concern weak, unpredictable or nearly instantaneous events.

I propose a two-axis acceptance matrix. One axis concerns storage continuity and technical reproducibility: the encoded bytes are protected, the decoder and version are known, metadata are independently secured, and the same derivative can be reconstructed. The second axis concerns fitness for inference: pulse width, onset time, differential phase, frequency

Copyright 2026, James M. Atkinson

slew and detector decisions are checked under declared conditions. A system may pass the first axis and fail the second. That result should be considered informative, not paradoxical. The report should state which axis each control addresses, so that a cryptographic success is not casually promoted into a claim that a physical feature must have survived compression.

Uncertainty should include sample-clock and front-end state even in a pure digital comparison. In a laboratory code test, exact reference samples can be generated numerically and do not require assumptions about an antenna. In an end-to-end instrument test, the timing of a pulse is dependent upon the ADC clock, trigger, transfer buffering and any resampling stages. If the original record already has missing samples, lossless compression can preserve the omission faithfully. If the original record contains clipping, lossless compression can preserve the clipped values faithfully. Thus even zero numerical compression error leaves measurement uncertainty from the acquisition path. A careful writer should not imply that lossless encoding alone establishes the truth of a report about external electromagnetic events.

A particular difficulty arises when investigators compare waveform derivatives that were produced with different starting states. A predictor whose internal state is initialised at the beginning of one file and carried across a continuous stream in another can produce different errors despite nominally identical codec settings. Dither applied without a recorded seed may make a trial irreproducible, though reproducibility of the seed does not by itself validate the method. Calibration of absolute amplitude may differ between instrument gain settings, and high-level pulses can invoke

Copyright 2026, James M. Atkinson

automatic gain changes that alter subsequent samples. These factors must be entered in the controlled matrix if claims of receiver fidelity are being made. A qualified expert should be able to reconstruct not only the derivative bytes but the conditions under which the transformation ran.

Finally, the analyst must specify the limits of a negative finding. If a weak phase feature is absent from a lossy derivative, the record may not support a conclusion that the original signal lacked it. If a phase feature is present, confirmation may still require proof that the codec did not produce it through ringing, prediction error or block seams. The strongest defensible inference comes from converging controls: a preserved source when lawful, independent analogue measurement, a known input test, and reconstruction residual analysis. Where privacy or retention law makes some controls unavailable, the claim must be narrowed, not expanded by speculation. This is the responsible application of coding expertise to forensic measurement: protecting precisely what is known, identifying what was intentionally transformed, and refusing to infer a vanished original detail from a corrected but lossy representation. I return the token to the moderator for testing these principles against the practical objections of the panel.

Sir Ronald Aylmer Fisher, Peer Question: Dr. Reed, I should like you to address the statistical meaning of an apparently favourable reconstruction trial when its sampling scheme has not been explained. A laboratory may test one hundred overlapping windows from a single waveform, observe no missed transients, and report one hundred successful detections as though each were an independent Bernoulli trial. Yet the windows may contain substantially the same pulse, noise excursion and predictor history. How

Copyright 2026, James M. Atkinson

should the examiner specify the unit of replication, the independence assumptions and the uncertainty attached to such a result? Please discuss the difference between an error rate among selected window positions and an event-level probability of detection under future conditions. I also invite you to distinguish a predeclared decision threshold from one chosen after inspecting the compressed record, and explain why statistical confidence cannot arise solely from a large number of correlated display frames. I pass the token with particular interest in controls that an independent laboratory could reproduce.

Irving S. Reed, Response: Sir Ronald, the number printed at the bottom of a table does not define the experimental unit. If one hundred windows are drawn from one continuous burst, all may depend on the same RF source event, the same noise realisation, the same codec state and the same receiver gain excursion. A count of one hundred does not convert these shared dependencies into one hundred independent replications. The laboratory should state whether the test unit is a separate synthesised burst, a separate acquisition run, a distinct environmental condition, or an independently generated noise record. The appropriate choice depends on the proposed inference. A claim about detection of new events should ordinarily be evaluated using new events, with any repeated windows from the same event handled as a correlated group. A claim about file-level byte preservation instead calls for byte-level comparisons and may have a different unit altogether.

Threshold selection deserves equally careful treatment. If an analyst views all compressed traces and then chooses a threshold that produces no false alarms in those particular examples, the apparent validation performance is

Copyright 2026, James M. Atkinson

optimistically biased. The threshold must be fixed on a separate development set or specified before the acceptance set is examined. The acceptance experiment should contain positive and negative reference cases, with the analyst unaware of their identities where practicable. Errors must be reported against the ground truth established by the reference generator, not against labels inferred from the lossy trace itself. Otherwise a codec-induced transient may be treated as a true event and inflate the success count. Such a circular exercise can produce beautiful summary statistics while offering no independent evidence that the original features survived.

One may calculate statistical uncertainty for a specified model, but the model must be credible. Independent binary trials admit familiar binomial analyses; clustered or serially correlated observations generally require a different treatment. If zero misses are observed among a small number of independently generated bursts, the estimated fraction is zero in that sample, but the upper uncertainty limit for the underlying miss probability is not zero. If those bursts represent only one pulse width and one carrier offset, the result cannot be projected to all possible transients. I would encourage a factorial design that deliberately varies pulse duration, phase step, noise level, block alignment and codec setting, while retaining enough independent repetitions to estimate variability. A study that cannot afford those trials should declare its scope accordingly rather than use the appearance of precision as a substitute for measurement.

The preservation system must also maintain a record of adverse results. If compression damages narrow pulses near a block boundary, that failure should remain in the audit with the exact codec setting and reference

Copyright 2026, James M. Atkinson

waveform. Deleting inconvenient test cases would undermine the chain of inference even if every surviving file were cryptographically intact. The independent examiner needs the trial plan, original authorised laboratory test vectors, relevant logs, algorithms, decision thresholds and failures as well as successes. A sound report then distinguishes the codec's error-correction success in storage from its empirical fidelity for scientific decisions. It should be possible to state that the bits were preserved perfectly but the uncertainty of a phase-transient conclusion remains unacceptable. There is no inconsistency in that finding; it is a properly separated measurement of different engineering properties.

Jerzy Neyman, Peer Question: Dr. Reed, I would extend the statistical issue to the language of acceptance. Suppose a manufacturer asserts that a derivative is adequate because fewer than one event in a thousand was missed during a selected trial programme. Such a statement can be interpreted as an observed fraction, a probability estimate under a model, or a claimed universal bound. The three are not equivalent. How should the examiner formulate a decision rule before the experiment, identify false-positive and false-negative consequences, and express the uncertainty of an empirical result? What happens when one class of weak burst is absent from the training and validation sets, or when the instrument's noise environment shifts after the acceptance programme? I ask you to treat a negative finding with particular care, because an archival system that quietly loses small phase discontinuities may present the investigator with an unjustified appearance of clean evidence. Please conclude with words a responsible expert could actually place in a forensic report.

Copyright 2026, James M. Atkinson

Irving S. Reed, Response: Professor Neyman, acceptance begins with a stated claim and a declared rule for rejecting it. We should not formulate the claim after viewing the data. Let the laboratory specify the class of test signals, the relevant noise and interference conditions, the codec configuration and the event-level test statistic. Before running the blind acceptance trials, it must also specify what constitutes a false alarm, what constitutes a miss, and what failure rate or confidence criterion will be considered unacceptable. A finding of ten misses in a thousand independent trials is an observed rate of one percent in that experiment. It is not, without additional assumptions and uncertainty analysis, a universal probability of missing every possible future pulse. This remains so even when the observations are genuinely independent; dependence only complicates the interpretation further.

We must not confuse error rates for two distinct decisions. A detector might reliably classify the presence of a large injected burst but fail to estimate its onset to within a specified number of samples. Another method might preserve amplitude while corrupting differential phase. A single binary acceptance stamp cannot replace a table that identifies each required observable. The cost of a false positive may differ from the cost of a false negative, and those consequences should influence the declared decision rule without retrospectively changing the data. If a rare weak-burst class was not represented, the report should expressly exclude that class from its empirical claim. An attempt to extrapolate beyond the tested domain requires a separately defended model, not an unspoken appeal to the size of the archive.

Copyright 2026, James M. Atkinson

Environmental drift must be considered even for stable codec software. A receiver may change gain, experience a stronger nearby interferer or operate with a noisier sampling clock. The resulting input distribution can move outside the region used to tune the compressor. A predictor that performs well under stationary noise can behave differently after a sudden overload event, while a block transform can distort an unexpected short pulse. An acceptance programme should include a reasoned range of foreseeable operating states and periodic verification when the system configuration changes. Where that is impracticable, the forensic expert should distinguish the archived derivative's measured characteristics from any assertion about its original analogue source. Provenance should identify the instrument, its state and the version of every transformation that could influence the finding.

I would use report language of the following form: 'The retained recording is an explicitly lossy derivative. In the stated laboratory tests, using the specified reference pulse family and decision threshold, the following numbers of event-level detections, misses and false alarms were observed. These results support a bounded assessment of performance under the tested conditions; they do not establish that all unrecorded phase or transient features of the original acquisition were preserved. No conclusion regarding features that could have been removed by the compression stage is drawn from their absence in this derivative.' Such language is neither timid nor evasive. It supplies the actual evidential scope. It also permits a court or technical reviewer to ask for the test set, the dependence analysis and the measurement uncertainty rather than accept an unqualified adjective such as faithful.

Copyright 2026, James M. Atkinson

Abraham Wald, Peer Question: Dr. Reed, the panel has addressed the integrity of a stored derivative and the empirical error of its reconstruction, but a survey officer must make decisions while an authorised examination is actually under way. Continuing to record high-resolution complex samples may impose significant storage cost, power consumption and privacy risk. Yet discarding them can prevent later investigation of a rare transient. Would you outline a prospective decision policy that does not simply collect everything on the possibility that it could prove useful? In particular, how should an organisation decide when a narrowly bounded original excerpt may be retained, when a lossy summary is sufficient, and when the appropriate conclusion must remain untestable? I ask for a principled distinction among collection authority, the engineering value of an observable and the decision maker's tolerance for irreversible uncertainty. Please include a means of preventing an adaptive retention algorithm from quietly becoming a mechanism for unauthorised content capture.

Irving S. Reed, Response: Dr. Wald, the decision policy must begin with lawful purpose and minimisation, not with a limitless aspiration to retain every waveform that technology can collect. A survey may need only a record of authorised spectrum occupancy or a summary of interference energy. In that case, preserving decoded communication content or extensive raw sample histories may have no justified role. A prospective policy can specify which features are needed for the defined investigation, which instruments and sample rates are permitted, and which derivative statistics provide adequate evidence for those features. A decision to retain original complex samples must be separately authorised, justified by a defined necessity and limited in time and scope. Engineering convenience is

Copyright 2026, James M. Atkinson

not a substitute for authority. The policy should record the control point at which data are converted to summaries and the point at which any unneeded raw buffer is destroyed.

An adaptive retention system deserves special scrutiny because its trigger may depend on the same uncertain waveform features under examination. A detector might preserve a short raw excerpt when a predeclared event criterion is met, but its threshold and allowed retention window should be documented and independently reviewed. The system must not silently decode payloads or expand its collection merely because a codec performs poorly. A ring buffer can be configured to hold only a tightly limited pre-event interval, with post-event duration and maximum total retention also bounded by policy. Even this arrangement may require legal review depending on the jurisdiction and the nature of the signals. If the trigger fails to fire, the institution must accept that the raw transient was not retained; it cannot reconstruct the missing original data from a subsequent compact visualisation.

The scientific side of the policy is an explicit hierarchy of observables. Routine questions about approximate occupancy may be answered from appropriately calibrated spectral summaries. Questions about phase continuity, ultra-short transients or uncertain modulation may need complex time-series samples or independent measurements, but only where obtaining and keeping them is authorised. The report should distinguish features the record directly measures from features for which it serves merely as an indicator. The decision maker can then compare the value of retaining a narrowly targeted original against its cost and lawful handling obligations. If retention is not justified, the correct consequence is

Copyright 2026, James M. Atkinson

a limited conclusion. The professional should neither imply that the summary answers everything nor insist that scientific curiosity overrides all other considerations.

The record should contain a defensible audit trail for every retention decision. Identify the approved measurement purpose, the configured trigger, the algorithm version, any operator override, the retained interval and its provenance. Protect the manifest and custody log against convenient alteration, and enforce access restrictions proportionate to the record's sensitivity. If a derivative is later produced, its codec and numerical error characteristics should be recorded as separate facts. Independent reviewers should be able to discover that some details were deliberately discarded without being misled into believing that an unaltered digest implies their survival. A measured, prospective policy is superior to either indiscriminate capture or a blanket assertion that a compressed archive always retains everything that matters. It is more effective both scientifically and institutionally because it acknowledges the cost of irreversible uncertainty before the evidence has vanished.

Dr. James M. Atkinson, Moderator: The five principal accounts and seven direct peer examinations are now before the panel. I invite reciprocal examination of claims about statistical bounds, error correction, representation provenance and complex-phase geometry. Each designated respondent shall answer before the token moves to the next speaker.

Jacob Ziv, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, I should like to test the boundary between an information-theoretic guarantee and a task-specific engineering guarantee. Suppose an organisation preserves only a lossy derivative and publishes a low average

Copyright 2026, James M. Atkinson

squared-error figure obtained under a reference distribution. A later examiner seeks one short differential-phase transition, the very kind of event that the source model assigned negligible probability. Can any bound on expected distortion alone compel a reliable conclusion about that particular transition, or does the many-to-one mapping require a counterexample analysis? Please distinguish the possibility of designing a new encoder whose distortion measure deliberately protects such transitions from the logically different assertion that an existing archive already protected them. I also ask you to address a frequent rhetorical error: that a high compression ratio should itself be evidence of successful modelling, and hence of fidelity. Under which assumptions, if any, could a probability model support a limited inference without smuggling an unsupported certainty about unusual future RF phenomena into the report?

Claude Elwood Shannon, Cross-Peer Answer to Jacob Ziv: Dr. Ziv, expected distortion is an average defined with respect to both a source model and a distortion measure. It is not a universal bound on each realised waveform, much less on every later scientific decision. If the model makes a phase transition extremely unlikely and the distortion criterion values only average squared sample error, a code may suppress that transition while remaining rate-efficient under its specified objective. This observation is not a defect in coding mathematics; it is a consequence of the assumptions. An examiner asked whether a rare transition occurred must not infer its absence from a derivative that could have mapped both the transition-bearing source and a transition-free source to the same reconstruction. The many-to-one structure supplies the central logical objection even before the empirical validation programme is examined.

Copyright 2026, James M. Atkinson

One could, of course, choose a different design. A constrained encoder might preserve selected event windows without loss, supply a certified maximum local complex error, or include phase-sensitive distortion terms over a declared signal class. A probabilistic guarantee might be established for a bounded population of test conditions. None of those alternatives tells us that an old derivative created by a different encoder possesses the same property. The guarantee belongs to a defined transformation, source class and decision criterion; it cannot migrate by analogy from one codec to another. Even a maximum complex-error bound must be propagated through the requested observable. Phase error can become arbitrarily ill-conditioned near zero amplitude, and an apparent instantaneous frequency obtained by differencing noisy phases may have uncertainties not captured by a single average figure. The report must account for those sensitivities explicitly.

Compression ratio is a particularly poor proxy for fidelity. A very predictable discrete source may be compacted exactly by reversible coding, while a genuinely unpredictable input may resist substantial lossless reduction. A lossy codec may also produce an enormous reduction by destroying all distinctions of interest. Thus ratio measures data economy relative to the chosen input and representation, not truthfulness of a physical measurement. It should be reported as a storage characteristic alongside, but never in place of, measured distortion and task performance. If an operator quotes a pleasing rate and a visually smooth image, the independent expert should ask for the source object, decoder specification, error metrics and event-level tests before accepting any phase inference.

Copyright 2026, James M. Atkinson

For a limited probabilistic statement, one must establish that the conditions of the recording are sufficiently represented by the tested model, that the detector and threshold were fixed before evaluation, that the test observations are handled according to their dependence structure, and that uncertainty is stated on the claimed scale. A strong result may then justify an operational assertion about the tested pulse family. It does not warrant the unconditional sentence that no unanticipated phase event has been removed. Some observations remain untestable when the original is unavailable. Candour about that boundary honours the science better than a promise of infinite recoverability.

Peter Elias, Cross-Peer Question to Irving S. Reed: Dr. Reed, I invite you to distinguish the ability of error-correcting storage to repair a damaged derivative from the ability of an RF examiner to reconstruct omitted source details. Consider an encoded file with two layers: irreversible quantisation of complex samples followed by a forward-error-correcting block code. If the stored data experience bit flips, a correct decoder may restore the quantised representation exactly. Some authors might announce that the original signal has therefore been recovered without error. Why is that expression wrong? What evidence would be needed to show both that the storage code performed correctly and that the earlier source transformation preserved a particular pulse or phase measurement? Please include the case of a compression state reset that creates a phase seam while the encoded bytes are perfectly intact, and address how the chain of custody should describe corrected versions without silently replacing the retained object.

Irving S. Reed, Cross-Peer Answer to Peter Elias: Dr. Elias, the expression fails because recovery is always recovery of something specified. An error-

Copyright 2026, James M. Atkinson

correcting code may reconstruct the originally stored codeword or its encoded message, subject to the declared error conditions and decoder operation. If that message represents complex samples already reduced to a coarse quantisation grid, the code corrects errors in those coarse symbols. It cannot infer which of the many possible fine-grid samples produced them. The investigator should therefore speak of successful decoding of the protected derivative, not automatic restoration of the analogue or high-resolution source waveform. The distinction is as fundamental as the difference between a clean photocopy of an incomplete page and the missing words that were never copied.

There should be separate verification at each stage. The storage layer calls for tests of codeword integrity, known-answer vectors, recorded error flags and an audit trail of corrections. The source-representation layer calls for a comparison of complex samples or task-specific observables against a retained and lawfully acquired reference. The instrument layer calls for calibration and timing tests against an independent physical reference where RF claims are being made. A single successful hash verification is useful at one of those stages but cannot substitute for the others. If the source record no longer exists, the uncertainty created by irreversible quantisation remains. A report should not quietly replace that missing reference with a waveform reconstructed from the only surviving compressed object.

The compression state-reset example is instructive. A predictive or block codec may initialise its internal state at a file boundary, and the reconstruction can carry a small phase or amplitude seam that was absent from the source. A strong storage code can preserve that seam with perfect

Copyright 2026, James M. Atkinson

fidelity, because the seam is part of the derived numerical representation. An investigator might then identify a false transient even though there was no storage error at all. A controlled test must send known continuous-phase reference signals through the encoder and decoder, including several block alignments and state-reset conditions. The residual around each boundary should be examined alongside a declared detector's output. The fact that a file's stored bytes are unchanged does not make a reconstructed seam a physical event.

If any repair or error correction occurs during storage recovery, preserve the damaged source object when lawful and practicable, together with its digest, diagnostic log and a separately named corrected derivative. The record must identify which bytes were corrected, what algorithm and version performed the operation, and whether the corrected output was independently checked. Never substitute a modified file under the original identity and then describe the resulting digest as though it were created at acquisition. Where a forward-error-correcting decoder silently conceals an unrecoverable block, the report must mark that interval as uncertain rather than treat interpolated samples as ordinary measured ones. These precautions distinguish honest preservation practice from an attractive but scientifically misleading assertion of perfect waveform recovery.

Irving S. Reed, Cross-Peer Question to Abraham Lempel: Professor Lempel, I wish to press the meaning of lossless when metadata and sample values travel through different custody paths. Imagine that the compressed payload bytes can be restored exactly, but the manifest loses the original I/Q ordering, signedness, sampling rate, centre-frequency setting and invalid-sample mask. The remaining numerical array may be reproducible

Copyright 2026, James M. Atkinson

while its physical interpretation is not. How should a laboratory distinguish integrity of byte sequences, integrity of the description needed to interpret them, and authenticity of the analogue input? Would hashing a manifest and payload together solve the entire problem, or merely protect a particular pair of assertions from alteration after the hashing event? Please also consider a derivative that uses a new container while keeping the sample array numerically identical. In that case which digest should be expected to change, and what evidence prevents a legitimate repackaging event from being mistaken for either corruption or a guarantee of physical fidelity?

Abraham Lempel, Cross-Peer Answer to Irving S. Reed: Dr. Reed, lossless is not a complete description until the object of recovery has been defined. If a codec reproduces every payload byte exactly but its manifest is unavailable, the bytes may not be sufficient to reconstruct a meaningful complex waveform. A signed integer interpreted as unsigned, a byte order reversed or an I/Q pair exchanged changes the numerical interpretation without altering the payload itself. Missing sample-validity information can likewise convert a concealed gap into an apparent physical discontinuity. Thus I would separate three assertions in the report: the archived byte sequence is unchanged relative to the trusted reference; the protected format description permits a specified reconstruction; and an independent acquisition record supports the assertion that the numerical samples originated from a properly configured receiver observing an authorised external input. Each assertion requires different evidence.

Hashing a manifest and the payload together is useful insofar as it fixes their association at the time the digest was created. It does not prove that

Copyright 2026, James M. Atkinson

the manifest's centre frequency was entered correctly, that the receiver's analogue stage was calibrated or that the claimed data were lawfully acquired. A false manifest, once hashed, can remain immutably false. The custody record should therefore identify the source of each important metadata field, such as a receiver register readback, an operator entry or an independently measured clock reference. A third party should be able to test a critical claim rather than merely admire its inclusion in a protected file. A digital signature or secured ledger may add accountability for who made an assertion, but it cannot turn an unverified assertion into an objective physical fact.

Repackaging illustrates why digest scope must be explicit. If the whole container is hashed, changing a header, padding or archive wrapper will generally change the digest even if the payload samples are identical. A digest over the canonical sample payload may remain the same provided the canonicalisation rules are independently defined and applied correctly. Numerical equivalence can sometimes be established despite different byte representations, but that is a separate test requiring known data types and conversion rules. A derivative should have its own digest and an explicit link to the original object, with a transformation record that states whether the process was reversible, lossy, or merely a container change. No analyst should quietly overwrite the original digest with one calculated after a conversion.

The practical solution is layered provenance, not a single purportedly magical check. Keep the retained source where lawful, register the source object's digest and length, protect the format manifest, preserve receiver configuration and clock evidence, and record each derivative separately. The

Copyright 2026, James M. Atkinson

analysis report must explain which layer supports which conclusion. A matching payload digest demonstrates continuity of the specified bytes from the protected reference state. It does not establish preservation of a pulse after earlier analogue clipping, nor does it reveal lost phase information after an intentionally many-to-one transformation. The challenge is to maintain those conceptual boundaries as rigorously as the machine maintains a sequence of bits.

Abraham Lempel, Cross-Peer Question to Peter Elias: Dr. Elias, let us close with a numerical question of practical consequence. A complex sample has an original magnitude A and the compressor introduces a complex error e. One sometimes sees a proposed angular guarantee derived merely from the absolute error magnitude, without acknowledging that the sample may approach zero. Could you explain which assumptions permit a bound on the change of phase, and why those assumptions fail for weak samples? Please include a checkable hypothetical example in which the complex error is small compared with a full-scale receiver range but large relative to a very weak signal. I also ask whether sample-by-sample phase bounds alone establish a sufficiently accurate frequency-transient estimate when phase differences are taken across time. State what separate timing, bandwidth and unwrapping conventions must be known before an apparent frequency excursion is interpreted as a physical event. Distinguish a mathematical error bound from an independently calibrated observation.

Peter Elias, Cross-Peer Answer to Abraham Lempel: Professor Lempel, the error cannot be assessed in isolation from the sample magnitude. Let x denote a nonzero complex source sample, y the reconstructed sample and e the difference y minus x. If the absolute error magnitude is E and E is strictly

Copyright 2026, James M. Atkinson

smaller than the original magnitude A, geometry of the complex plane yields a maximum possible angular displacement no greater than arcsine of E divided by A, under the usual principal small-angle interpretation. This follows from the tangent to the disk of possible y values centred on x, provided that disk does not contain the origin. As A approaches E, the bound approaches ninety degrees; when E is at least A, the disk reaches or crosses the origin and no such useful small angular guarantee remains. A zero-magnitude source sample has no well-defined phase at all. A report giving only E therefore lacks the denominator needed to turn an absolute sample error into a reliable angular statement.

For a checkable hypothetical example, take a source magnitude A of 0.001 relative to full scale and an error bound E of 0.0001. The ratio E divided by A is 0.1, so arcsine of 0.1 is approximately 0.10017 radians, or 5.739 degrees. If the same absolute error applies at A equal to 0.0001, the ratio becomes one and the geometric bound ceases to be useful for precise phase metrology. These examples are calculations about stipulated complex numbers, not measured performance of an RF codec. They show why a small error expressed as a fraction of full-scale ADC input can still be unacceptable for a weak waveform whose own magnitude is much smaller. The appropriate test must consider signal-relative error and an amplitude threshold below which phase claims are withheld or specially qualified.

Instantaneous frequency estimated by phase differencing introduces another layer. Suppose the unwrapped phase samples are phi[n] and the sampling rate is fs samples per second. A simple discrete estimator of frequency deviation uses fs times the difference phi[n] minus phi[n-1], divided by two pi. If individual phase errors fluctuate independently within

Copyright 2026, James M. Atkinson

some angular bound, their difference can be substantially larger than either individual error; if errors are correlated, different behaviour arises. Increasing fs changes the frequency scaling of the same angular difference, while resampling or a timing discontinuity can create an apparent excursion without a physical frequency jump. Phase unwrapping can also insert or remove integer multiples of two pi when the data are noisy. A single-sample phase-error statistic cannot therefore certify the behaviour of a derivative frequency estimator without specifying its algorithm and temporal assumptions.

The acceptance study should include known reference carriers and deliberately imposed phase steps, vary the signal magnitude across the weak-sample regime, and inspect both original and reconstructed phase differences under a declared unwrapping convention. It should also document the receiver clock, missing-sample treatment, resampling filter and any codec block boundaries. Where the original is lost, a derivative may still support a qualified observation about its own reconstructed samples, but it cannot establish that a vanished source phase transition was absent. The most defensible conclusion is conditional: a specified angular or timing accuracy was observed or guaranteed within a defined amplitude and operating domain. Beyond that domain, particularly near zero magnitude or around undocumented sample gaps, the desired physical claim remains untestable from the derivative alone.

QUESTION 093. TECHNICAL SOURCE NOTES. Source-to-claim verification is still required at Stage B. Historical expert dialogue is fictional and does not constitute quotations or jointly authored findings. Candidate technical background: Jacob Ziv and Abraham Lempel, “A Universal Algorithm for

Copyright 2026, James M. Atkinson

Sequential Data Compression," IEEE Transactions on Information Theory 23(3) (1977), 337–343, DOI 10.1109/TIT.1977.1055714; Claude E. Shannon, "A Mathematical Theory of Communication," Bell System Technical Journal 27 (1948), 379–423 and 623–656; context-aware lossy RF compression review, https://pmc.ncbi.nlm.nih.gov/articles/PMC10098950/. These references support discussion context but do not individually certify the hypothetical instrument cases, precise analogies or publication completeness.

EDITORIAL QUALIFICATION. This is a fictional, modern pedagogical exchange attributed to deceased historical specialists, not recorded testimony. All numerical examples are hypothetical calculations, not observed RF survey results. The manuscript does not identify an unknown transmitter, decode protected communications or establish legal authority for sample retention. Stage A verifies structure and bounded numerical examples only; independent source-to-claim, historical, technical, legal, semantic and whole-volume production review remain pending.

Copyright 2026, James M. Atkinson

QUESTION 094

Copyright 2026, James M. Atkinson

How should conflicting clocks and sample dropouts be represented in a multi-receiver chain of custody?

Dr. James M. Atkinson, Moderator: Dr. Mills, the panel must reconcile three instruments that report apparently concurrent RF events while relying on different sampling oscillators, transport paths and host clocks. An analysis application can paint their waterfalls onto one attractive time axis, but that image may conceal a receiver that lost samples, another whose system time stepped unexpectedly and a third whose sample oscillator slowly drifted. Please distinguish the time actually established by each instrument from the timeline the investigator reconstructs. Explain how the chain of custody should preserve native ordering, clock quality, missing observations and the provenance of later corrections. This conversation is fictional pedagogical reconstruction, not a quotation or an account of an actual historical meeting.

Copyright 2026, James M. Atkinson

David Lennox Mills, Principal Contributor: I would begin with a warning about the word simultaneous. Two receivers may produce samples described by identical timestamp strings without having observed the same physical instant. A timestamp can refer to the antenna input, an analogue trigger, an ADC sample index, a digital processing block, an operating-system buffer, a file write or an eventual graphical display refresh. Each location in the chain has a different delay and a different relationship to the oscillator that actually sampled the RF waveform. A disciplined report must identify which event a timestamp represents and which evidence supports the mapping. The fact that a computer presents several values in the same time format does not make their underlying clocks coherent. Indeed, uniform formatting can conceal the differences the expert most needs to understand.

I would first preserve each receiver's own native history, without resampling it onto an invented common grid. That history should contain a monotonic sample counter if the instrument provides one, hardware acquisition timestamps if available, explicit buffer or frame sequence numbers, the original numerical samples where their retention is lawful and necessary, and every quality flag indicating overflow, resynchronisation, clock unlock or loss of reference. The investigator should record the clock source declared by the instrument, the firmware and relevant software versions, and the path by which timing metadata reached the archive. If these fields are absent, the deficiency itself belongs in the report. One should not silently replace an unknown continuity condition with a software assumption that all samples were present simply because the file is longer than expected.

Copyright 2026, James M. Atkinson

To translate a native sample index into an estimated common time, I propose a segment-specific model. Let k denote the sample index recorded by receiver i. Let alpha_i denote an estimated origin time for one valid segment of that receiver, and beta_i its estimated seconds per sample for that segment. An elementary mapping is t_i(k) = alpha_i + beta_i k, plus a residual term representing random and unmodelled timing error. The mapping is only as good as the measurements used to estimate its constants. If the oscillator drifts with temperature, the model may require several segments or a higher-order description. If the host system clock steps, the analyst must not force the ADC sample timeline to inherit that step unless the hardware evidence shows that the sample clock itself changed. Different clocks can disagree without either original file being corrupt.

The familiar distinction between clock offset and clock frequency error is especially important. Two clocks may differ by an almost fixed offset while maintaining nearly identical rates. Alternatively, they may agree at the beginning of an observation and gradually diverge. A receiver clock that runs ten parts per million faster than a reference accumulates an idealised ten-microsecond discrepancy in one second if the relative rate error remains constant. That arithmetic is simple; the evidential work lies in showing that the stated error belongs to the actual sampling clock, rather than to a nearby host oscillator or an unrelated network timing service. The reference itself has uncertainty, cable delays can contribute offsets, and the delay between an analogue event and a timestamp register may depend on configuration. None of those limitations is repaired by rounding the displayed result to six decimal places.

Copyright 2026, James M. Atkinson

A missing interval must be represented as missing, not as radio silence. Suppose a receiver nominally acquires one million complex samples per second and records a hardware-confirmed loss of 2,048 consecutive samples. On the nominal scale, those samples represent 2.048 milliseconds of unobserved input. The gap does not prove that the antenna received no energy during those milliseconds. It means the file cannot answer questions requiring those samples. Inserting zeros may be useful for a particular visual alignment if the substituted values are distinctly marked, but it creates a derivative. Interpolation between adjacent observed values can be useful for graphing and similarly cannot reconstruct an unforeseen microburst or a sudden phase excursion. Both operations require separate derivative identifiers and an unambiguous gap mask that survives subsequent export and analysis.

It is tempting to regard a network synchronisation protocol as an absolute cure. Such a protocol estimates timing relationships among participating clocks subject to network delay, asymmetry, implementation and quality of the relevant reference sources. It does not automatically timestamp the ADC aperture of every attached receiver. A host can be well synchronised while its USB receiver streams samples from a free-running oscillator with an entirely different frequency error. Conversely, an RF instrument disciplined by a precision reference can produce accurate hardware sample indices even when its associated computer writes the file under an inaccurate wall clock. Therefore the report should distinguish network clock state from acquisition-clock state and record the measured link between them rather than inferring one from the other. One unverified declaration of synchronised is not an uncertainty budget.

Copyright 2026, James M. Atkinson

Multi-receiver phase comparisons impose an additional requirement beyond aligning coarse event times. Two receivers can share a pulse-per-second signal and still possess separate local oscillators whose relative phase wanders. Aligning their sample indices within a microsecond may be sufficient for some event-correlation tasks and wholly inadequate for coherent phase summation. The laboratory must identify the observable first. If it merely asks whether two independently recorded energy bursts overlap within a specified time interval, bounded offsets and uncertainty intervals may suffice. If it asks for a phase difference or a direction-finding inference derived from coherent samples, it needs evidence concerning the relative sampling phase, local-oscillator behaviour, channel delays and calibration. A common numerical timeline alone supplies none of those missing guarantees.

The chain of custody must record when reconciliation begins. The original individual streams should be identified and protected; the matching process should produce a separate synchronisation manifest containing reference events, the estimated alpha and beta for each valid segment, uncertainty estimates, accepted or rejected alignment observations, the treatment of gaps and the software used to perform the fit. If an analyst later corrects a mapping because a timing offset was discovered, the earlier mapping must remain recoverable as a prior interpretive state. The corrected product should identify its relationship to the original. A checksum over the corrected timeline can show that it has not changed since correction, but it cannot prove that the correction was physically correct. That question requires independent reference and calibration evidence.

Copyright 2026, James M. Atkinson

I would insist on an adverse laboratory trial, not merely a successful demonstration with everything connected ideally. Send a known test pulse to two or three properly authorised receivers and document its passage through independent paths. Introduce a controlled packet loss into one transport stream, a deliberate host-time adjustment into another and a bounded sampling-clock deviation into a third. Ask analysts to produce a common-time account with uncertainty intervals and explicit missing segments. Compare the result against an independent reference record, and inspect whether any graphing software silently fills the introduced gap. Repeat with changing event spacing and with a reference outage. A system that honestly declares certain observations unknowable has passed an important forensic test even if its final plot looks less complete.

Finally, scientific uncertainty and lawful retention are not interchangeable. A precise clock model does not authorise capture of communication content. The organisation may choose, or be required, to retain only the minimal timing evidence and energy statistics relevant to an authorised survey. In that event the conclusion must be limited to those records. Where retention of raw I/Q segments is explicitly justified and authorised, the custody and access controls must protect their contents and the independent metadata needed to interpret them. What matters is that the expert tell a future reader what each receiver truly observed, what was inferred by alignment and what disappeared before it could ever become evidence. A clean-looking common trace is a useful illustration only when it does not erase those distinctions. I respectfully pass the token to the remaining panel to challenge the assumptions about network clocks, computational invariants, physical frequency standards and evidential provenance.

Claude Elwood Shannon, Peer Question: Dr. Mills, I wish to distinguish a time estimate that looks exact from one that is scientifically well supported. Consider three receivers observing the same authorised reference pulse. The first reports native sample counters against a disciplined hardware reference; the second records arrival times only after an operating-system queue; the third has valid native indices but loses its external clock reference. The displays place all three transients within one microsecond after a software offset correction. What can we infer without confusing a fitted alignment with a verified common time? How would you state uncertainty where an independent reference waveform is distorted by unequal analogue filter delays, or where two similar pulses could have been matched incorrectly? I ask also whether the investigator may legitimately report that the devices were synchronised during the interval merely because their host computers showed the same wall-clock time. Please separate timing resolution, offset uncertainty, rate uncertainty, phase coherence and source-event identity, since each may bear upon the exact forensic proposition under examination.

David Lennox Mills, Response: Dr. Shannon, the first issue is the definition of each timestamp's origin. In the first receiver, a documented device counter tied to a tested reference offers a defensible mapping from native sample index to a stated time coordinate, subject to the uncertainty of the calibration and the physical signal path. In the second, an operating-system arrival time directly measures a later software event and offers no independent proof of when the ADC took its sample. In the third, the device may remain internally continuous while its relationship to a reference clock becomes increasingly uncertain. The common statement is therefore

Copyright 2026, James M. Atkinson

modest: each may have recorded a transient compatible with a laboratory event within the uncertainty interval that the corresponding observation actually supports. A graph displaying the traces within one microsecond does not establish that the true RF apertures were separated by one microsecond or less.

The alignment algorithm must report how it chose corresponding pulses, what alternate alignments remain plausible, and whether the fit reused the event it now purports to validate. A separate reference pulse recorded with independently characterised latency helps avoid that circularity. When analogue filter delays differ, the experiment must either calibrate their contributions or enlarge the uncertainty of the inferred physical event times. The location of a peak is not an instrument-independent event marker. A strong and a weak test pulse may cross a threshold at different relative moments because the front-end response and the detector operate on different waveform features. The reconstruction should specify the chosen feature and its calibration conditions rather than give an unexplained timestamp.

Precision, in the sense of a small scatter or fine numerical resolution, is not accuracy. A clock can produce repeatable values with a systematic offset from the desired reference. Synchronisation is a measured relation between clocks over a stated interval; frequency agreement describes their relative rates; coherence demands further conditions for phase-based analysis. Equal wall-clock displays establish none of these properties for the ADC unless a measured mapping connects them. A valid report may offer a time interval for each detection and a bounded statement about overlap, but it should not declare a common physical instant when the intervals are too

Copyright 2026, James M. Atkinson

broad or their error terms correlated. The status of a disciplined host does not transfer automatically to an undisciplined sampling oscillator.

I would preserve the raw observations and a dated alignment manifest, including each receiver's calibration events, clock-state transitions and model residuals. If a later recalibration reveals that a cable introduced a delay previously omitted, the new model must be identified as a revision, not smuggled into the original sample record. The best examination question is not whether an image looks convincing but whether an independent examiner can change an assumption and reproduce the resulting change to the conclusion. Uncertainty is an essential property of the claimed alignment, not an embarrassment to be removed by formatting.

Dr. James M. Atkinson, Moderator: I thank the preceding specialist for preserving the distinction between measured samples and reconstructed time. With respectful transfer of the token, I invite Donald Watts Davies to examine the next evidence layer, while retaining the limits of every clock and loss assertion.

Copyright 2026, James M. Atkinson

Donald Watts Davies, Second Principal Contributor: Dr. Atkinson, a multi-receiver recording should be approached as a distributed measurement system whose evidence travels through queues before a human investigator sees it. Each queue has a different clock and a different possibility of loss. The sample clock governs analogue-to-digital conversion, whereas a transport packet may be dated by device firmware, a network interface, a kernel driver, a user process or a file system. A timestamp assigned at the last stage may accurately describe receipt of a block without accurately describing the instant of its first sample. An investigator who merges the labels as though they were equivalent has rewritten the physical history before the analysis has begun. The correct practice resembles a carefully maintained packet trace: preserve the original capture sequence and record every subsequent interpretation as a separate, attributable operation.

I should distinguish four classes of discontinuity. First, an acquisition gap occurs when an ADC stream or its necessary internal buffering fails to produce valid samples; that is a failure of observation. Second, a transport gap occurs when samples were acquired but not delivered to the host, so their possible survival in hardware must be established rather than assumed. Third, a storage gap occurs when the host received data that were not durably written, which may leave intact upstream records. Fourth, a time-description discontinuity occurs when the host clock jumps or its epoch changes while a native acquisition counter continues. These events may coincide, but they need different evidential labels because they imply different limitations. They also generate different remedies. A surviving hardware ring buffer may permit re-export after a storage interruption,

Copyright 2026, James M. Atkinson

whereas genuinely unsampled RF cannot be recovered from the appearance of a later graph.

A robust acquisition interface should expose a native sample-start counter, an observed sample count for each block, any device-declared loss or overflow condition, and a boot or reset epoch. The interface ought to state the semantics of these fields. A USB packet sequence number identifies neither the number of complex samples transmitted nor the oscillator phase at which sampling began unless the manufacturer defines those relationships and a laboratory verifies them. A transport layer can fragment one sample buffer into many packets or coalesce many buffers into one. Repeated packets may produce duplicated payloads; missing packets may conceal otherwise valid acquisition data. The evidence processor must therefore reject the facile inference that every sequence-number discontinuity establishes one missing sample interval. Counters are observations at a nominated boundary, not universal metaphysical markers of time.

I propose a test in which each receiver records a controlled reference signal under lawful laboratory conditions, while an independent monitoring channel preserves the generator's event schedule. Before introducing failure, we establish the native meaning of every counter by varying capture-buffer lengths, host load and transfer size. We then cause separate, documented perturbations: a hardware FIFO overflow, a dropped transport packet, a delayed disk write, and a wall-clock adjustment that does not alter the reference signal. If two perturbations produce the same visible break in a waterfall, the exported low-level logs must still distinguish them or the limitation must be recorded as unresolved. We should insist on seeing the

Copyright 2026, James M. Atkinson

difference at the level of preserved data objects, not merely a console warning printed during the experiment. An ephemeral warning lost when the application exits contributes little to a forensic audit.

For illustration, a receiver sampling at two million complex samples per second covers 4,096 samples in 2.048 milliseconds. This is nominal arithmetic, not a finding about a particular instrument. If hardware counters show a discontinuity of 8,192 sample indices, the missing native-index span corresponds nominally to 4.096 milliseconds. Whether all those indices denote unavailable observations depends on the precise definition of the counter and the capture boundary. A packet loss of 8,192 bytes, by contrast, has no such direct duration until the sample representation and packet structure are established. If each complex sample occupies four bytes, 8,192 payload bytes represent 2,048 complex samples, not 8,192. Such dimensional distinctions are essential whenever an expert is asked to calculate the length of an unobserved RF interval.

I further insist on preserving the distinction between a sequence containing zeros and a sequence containing no samples. Zero-valued complex samples may be actual quantised observations, deliberate fill symbols, or artefacts introduced by a processing library. They are not interchangeable. The original record should carry a validity mask or segment ledger that indicates where samples are absent and where samples were present but saturated, clipped, out of lock or otherwise compromised. A plotted blank region may be an excellent way of representing a gap; a plotted line at the receiver's estimated noise floor may falsely portray an observation. Spectral integrations should state whether unobserved intervals were omitted from

Copyright 2026, James M. Atkinson

denominators and whether the omitted time changes any claimed occupancy fraction.

The custody records should preserve the exact relationship among acquisition objects, transport objects and derived analytical products. I would keep a protected acquisition ledger consisting of native block identifiers and length fields, status, device epoch and reference-state identifiers; a protected data manifest identifying original byte sequences or legally minimised event records; and an interpretation ledger explaining each alignment transform and exclusion. If an expert later discovers that a counter increments before acquisition rather than afterward, the correction belongs in the interpretive ledger, with a link to the documented test that established its meaning. The older result should remain recoverable so a tribunal or technical peer can discover what the organisation originally believed. Nothing is gained by rewriting the old timeline and offering the corrected file as though it were the contemporaneous native record.

Network discipline adds complexity. The clock synchronisation protocol may correct the host's time estimate using round-trip exchanges, but transport asymmetry and processing delay may remain significant. It does not follow from a small network-clock offset estimate that the RF ADC aperture is aligned to the same tolerance. The laboratory needs a traceable mapping between sample counters and reference events measured in the acquisition domain. When a PPS event reaches a GPIO connector and is registered by the hardware, that registration offers a stronger bridge than an unspecified host callback, but its propagation, timestamp-latch and counter semantics still require examination. In a complex receiver, analogue filter group delay

Copyright 2026, James M. Atkinson

and digital decimation latency also affect a reported event time without changing the clock itself.

I would conclude by requiring the reviewer to distinguish four propositions in each final finding: what each receiver actually stored, what it reported about losses and reference state, what a separate reference independently established, and what the analyst inferred by reconstruction. If the second receiver has an unobserved three-millisecond gap, the report should say that the presence or absence of a short burst during that interval cannot be established from that receiver alone. Where the first receiver supplies a valid observation, it may support a limited separate conclusion, but it does not cause the missing samples to reappear in the second. Reconstructing time is permissible; inventing observation is not. I respectfully pass the token to Dr. Dijkstra to examine the software invariants that would prevent such errors from being laundered into a polished record.

John von Neumann, Peer Question: Mr. Davies, suppose the exported recording consists of blocks with a purported sample-start counter, a number of complex samples, a packet identifier and a host receipt timestamp. The producer may split or coalesce transfers, the host may reorder completions, and the device may reset a finite-width counter without an independent boot identifier. How can a test engineer articulate a continuity invariant that is strong enough to identify missing observations but cautious enough not to invent them? I should also like to know how an examiner should handle duplicate packets and intervals in which firmware reports a nominal overflow without specifying the exact number of unavailable samples. Can a write-once acquisition register and a versioned interpretation register coexist without making later corrections appear to

Copyright 2026, James M. Atkinson

alter original evidence? Please describe a controlled failure-injection programme that would distinguish acquisition failure, transport loss and host storage interruption, rather than relying on the intuitive smoothness of the completed trace.

Donald Watts Davies, Response: Professor von Neumann, we should define the invariant against a verified hardware contract, not against the attractive names that software gives its fields. If a native counter indexes successive acquisition samples, a contiguous pair of valid blocks should satisfy the relation that the second start index equals the first start index plus the first block's valid sample count. A violation is a discontinuity under those premises. If the counter numbers USB transfers instead, the same arithmetic says nothing directly about sample continuity. The acceptance test must first establish which stage generates the value, whether it increments for data lost internally, and how it behaves at wrap, restart and channel reconfiguration. Only after that calibration may the invariant support a statement about unobserved RF samples.

Duplicate packets should remain distinguishable from newly acquired repeated values. Identical sample payloads can arise naturally with a constant laboratory waveform, so a checksum alone is not a unique block identifier. Source-native sequence and epoch fields help identify a repeated transfer. When no such fields are available, the analyst may detect a plausible duplicate pattern but should describe its ambiguity. If the firmware reports an overflow without a loss count, the report may say that continuity was compromised during a certain indicated region, without assigning an invented number of missing samples. A numeric estimate

Copyright 2026, James M. Atkinson

based on transfer timing can be given separately as an estimate with its own assumptions. A field called overflow is not a calibrated stopwatch.

I propose to preserve a first ledger containing contemporaneous device records and payload references, protected under access and hashing controls. A second, append-only ledger would describe subsequent interpretations: a gap is inferred, a packet is identified as likely duplicated, a counter reset is established, or a common-time transform is revised. A correction in the second ledger never erases the first. It must identify the operator, method, reason, affected range and relationship to earlier versions. If the revised interpretation changes the temporal ordering of alleged events, the report should flag the substantive change instead of issuing a silently corrected picture. This is particularly important where an earlier finding may already have influenced an organisational decision.

The adverse test programme would generate a controlled RF pulse train monitored independently, then disturb one layer at a time. Force a hardware acquisition overflow without interrupting host storage, drop a transport object while retaining its device-side source evidence, suspend the file writer while leaving the receiver active, and step the host system clock without changing the ADC sample reference. Compare resulting files, counters and fault flags with the independently preserved reference. Repeat at different host loads, packet sizes and device reset conditions. The acceptance criterion is not that the plot automatically looks complete; it is that every known failure either becomes an explicit auditable exception or is identified as a limitation that prevents certainty. Such discipline converts a fragile graphic into a scientifically examinable record.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: I thank the preceding specialist for preserving the distinction between measured samples and reconstructed time. With respectful transfer of the token, I invite Edsger Wybe Dijkstra to examine the next evidence layer, while retaining the limits of every clock and loss assertion.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Third Principal Contributor: Dr. Atkinson, the first danger in a multi-receiver timeline is an ambiguous data type masquerading as a complete specification. Many programs represent a sample as a complex number and its time as a floating-point value. That representation says nothing about whether the time came from a calibrated hardware counter, a host callback, an interpolated mapping, or a figure-caption convenience. It likewise says nothing about whether the sample is valid, missing, duplicated, resampled or synthetic. A programmer who erases these distinctions in the data structure cannot expect the final report to recover them by editorial honesty. The design must make forbidden states difficult to express and forbidden conversions explicit enough to be audited. Mathematical elegance is no excuse for obscuring the experimental origin of the variables.

I would define separate types for a native acquisition sample, a native block event, a clock reference observation, a proposed segment mapping and a rendered presentation point. An acquisition sample is indexed in a device-specific clock epoch and references a source object; its existence denotes a measurement made by the instrument under stated quality flags. A missing segment is not a vector filled with some pleasing numerical substitute. It is an interval in the device index domain accompanied by a reason, confidence, provenance and a statement of whether the number of omitted samples is known. A segment mapping describes how native indices are provisionally related to an external time coordinate. An exported common timeline is a derived object that references the mapping used to construct it. The type system should prevent a derived pixel from being treated as a raw voltage observation.

Copyright 2026, James M. Atkinson

There is a useful local invariant. If block j begins at acquisition index k_j and contains n_j genuinely observed samples, then uninterrupted subsequent acquisition would begin at k_j plus n_j. That relation is not universal; it depends on whether the device counter advances for dropped samples, whether gaps are represented as indexed intervals, and whether a counter wraps or resets. The contract must state these premises. Where the premises hold and a different successor index is observed, an exception should be raised and retained, not covered by appending data. An unknown counter epoch must be tagged unknown. Assigning a convenient epoch because the plotted waveform looks reasonable is an illicit inference. Formal verification requires not only proving a relation from premises but also testing the premises against the actual hardware.

A second invariant concerns the custody of transformations. Let an original object O be identified by a digest and defined byte count, and let a derivative D be formed by a disclosed transform F with parameters P and software version V. The ledger should record O, F, P, V and D together. A later investigator can check that applying the declared operation to O reproduces D within the specified numerical tolerance, but must not conclude that the transform's assumptions are physically valid merely because its implementation is deterministic. A common-time alignment produced by interpolation is a derivative. If the algorithm imputes a missing waveform, that imputation requires an additional data lineage and must not be encoded as a native sample. One cannot repair missing evidence by making the repair procedure repeatable.

I would separate an algorithm's functional correctness from an instrument's metrological validity. A transformation can be mathematically correct for its

Copyright 2026, James M. Atkinson

input assumptions and scientifically unsound because its inputs represent the wrong clocks. For example, the program may minimise squared differences between nominally corresponding pulse timestamps and return a precise offset. If the pulses were identified through the same shared display whose correctness is in question, the fitting has become circular. Software tests should introduce independent reference pulses and deliberately include ambiguities: two plausible matching pulses, a missing reference, a hardware counter reset and an oscillator rate change. The algorithm should either return bounded, defensible alternatives or refuse to declare a single aligned solution. A fail-closed result is preferable to a confidently wrong time base.

It may be useful to define a segment-specific clock function $T_i(k)$ with estimated parameters and a separately propagated uncertainty. That function should be valid only for a declared interval of native index k, and only while its assumptions remain supported. After an unknown reference outage, extrapolation can be a legitimate calculation, but the uncertainty must reflect the oscillator stability, the last calibration observation and all systematic delays included or omitted. A string of digits produced by the computer is not a proof of those conditions. Nor does the mere mathematical continuity of T_i across a gap establish acquisition continuity. In a strongly typed record, the domain of an observed sample and the domain of a time mapping are related but distinct.

Concurrency is another peril. Some systems process received buffers on separate threads and then arrange them by host completion time. If block B finishes decoding before block A, a naive writer can reverse their apparent chronology. Sequence numbers may detect this if their semantics are sound;

Copyright 2026, James M. Atkinson

sorting by wall-clock receipt time may exacerbate it when the host clock steps. I would require immutable source order and an explicit reconstruction order with conflict reports. Two devices are not a single sequential process. Their events form partially ordered histories until independent synchronisation evidence permits limited cross-device ordering. That description is intellectually less comfortable than a single line running across the page, yet it is more honest about what the evidence establishes.

The acceptance tests should be designed as adversarial specifications. Generate controlled streams with known gaps, duplicates, reset epochs, wrapping counters, timestamp reversals and a deliberately altered sample-rate claim. For each disturbance, define the expected report before executing the program. Confirm that the stored native record remains unchanged, that any repaired mapping is represented as a derivative, and that no graph silently converts missing intervals into zero-valued samples. The tests should include one event shorter than a deliberately missing interval so the analyst is forced to say unknown. They should also include a false positive caused by an interpolation artefact, testing whether the system flags it as a visual aid rather than a recovered emission. These are not peculiar edge cases; they test the logic of evidential speech.

There is a jurisprudential analogy in the duty to disclose one's assumptions. A court receiving an expert conclusion does not merely need a stable final figure. It needs the conditions under which that figure would cease to follow. The software's provenance ledger can furnish those conditions if it records which native observations supported each estimate, which confidence model was used and which tests failed. A hash over the final PDF

Copyright 2026, James M. Atkinson

may preserve a precisely worded mistake. Our responsibility is to preserve the chain of reasoning as well as the chain of bytes. An adverse correction should add an explanatory version and leave the earlier one traceable, not rewrite history in place. My closing point is a rule for disciplined computation: no function should silently promote an absent observation to a measured one, and no formatter should promote an estimate to an unqualified fact. I hand the token to Professor Ramsey, whose physical standards must eventually decide whether our numerical timing claims are plausible.

Sir Ronald Aylmer Fisher, Peer Question: Dr. Dijkstra, your programme supplies formal rules, but a rule cannot determine the truth of its assumptions. Suppose two clock mappings fit the observed calibration pulses with nearly equal residual error, while one implies that receiver A led receiver B and the other implies the reverse. A least-squares routine can report a beautifully precise estimate by imposing a prior constraint the operator did not disclose. How should the system prevent such hidden statistical choices from becoming a categorical finding? I also ask whether missing observations should be treated as random loss for uncertainty calculations when loss may be correlated with overload, thermal stress or burst intensity. If the gap mechanism is not independent of the signal, an apparently standard confidence interval may be grossly misleading. Please distinguish a validated computational invariant, a statistical model requiring evidence and a scientific conclusion conditional upon both. Would an apparent error bar remain defensible if its missing-data assumption were contradicted by the controlled fault-injection experiment?

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Response: Professor Fisher, the programme ought to expose the logical status of its inputs. The invariant can be proved about data meeting a specified contract, but it cannot prove that the hardware implemented the contract faithfully. A statistical estimation procedure can minimise an objective function, but that minimisation does not prove that its model describes the experiment. The code should therefore attach distinct provenance and validity fields to the raw observation, the model assumption and the resulting estimate. For example, two candidate alignments should be retained when their evidence does not discriminate adequately. The user interface should not permit an analyst to choose the version producing the desired event order without recording that selection and its basis.

If missingness is associated with strong input signals because a receiver overloads or its transport fails under particular processing loads, the missing intervals are not safely treated as a random subset of a stationary record. A calculation that silently assumes independence can underestimate uncertainty and bias occupancy or coincidence estimates. The correct software action may be to decline the requested statistic, present a sensitivity analysis over plausible missing-event rates, or clearly identify that the result depends upon an untested missingness mechanism. A claimed confidence interval is meaningful only inside the model and sampling design that produced it. It should not be recast as a universal physical bound.

I would encode those limitations as part of the processing contract. Every alignment object should name its source reference events, its fitting model, parameters, excluded observations, residual diagnostics and anticipated failure conditions. When an alternative model is defensible, it can be an explicit competing derivative rather than an invisible knob in a settings

Copyright 2026, James M. Atkinson

dialogue. Automated tests should include ambiguous pulse matches, nonstationary drift, a reset that mimics a wrap, and a gap triggered by a deliberately high-power laboratory pulse. A robust implementation will identify the ambiguity or refuse a categorical ordering claim. The error message is itself useful evidence of a boundary, not a defect to be suppressed.

The most serious mistake is a silent promotion between levels of knowledge. A native record is a source assertion about what a device stored. A validated calculation is an assertion about the consequence of specified data and rules. A metrological finding states how those abstractions relate to an external physical event, and it demands independent calibration. A legal or administrative finding imposes still further requirements. A software function cannot move a proposition from one level to the next merely by returning a non-null number. The record must show which authority, test and assumption support that promotion. When a conclusion remains conditional, its condition belongs in the final prose.

Dr. James M. Atkinson, Moderator: I thank the preceding specialist for preserving the distinction between measured samples and reconstructed time. With respectful transfer of the token, I invite Norman Foster Ramsey Jr. to examine the next evidence layer, while retaining the limits of every clock and loss assertion.

Copyright 2026, James M. Atkinson

Norman Foster Ramsey Jr., Fourth Principal Contributor: Dr. Atkinson, the measurement problem becomes clearer when one distinguishes a frequency reference, a clock epoch and the phase of an RF carrier. A receiver may be connected to a highly stable reference oscillator and therefore maintain a repeatable nominal sampling rate. That circumstance does not, by itself, provide a common epoch at which sample zero was acquired. Two oscillators can have excellent frequency stability and still begin with unknown phase. Two receivers may accept the same one-pulse-per-second signal yet have different trigger latches, filter delays or local oscillator phases. A valid engineering claim must name the physical quantity being synchronised. The word locked is insufficient unless it specifies what is locked to what, over which time span, with what residual uncertainty and under which environmental conditions.

The timing chain begins with the reference event and ends with a recorded sample index. Between them lie connector propagation, input circuitry, threshold crossing, synchroniser logic, possible metastability resolution, digital signal processing and buffering. A short cable delay may be estimated from length and propagation velocity, but a quoted physical length alone is not a full timing calibration. Filter group delay can depend upon the spectral content and configuration. A comparator can respond at different instants to pulses with different rise times or amplitudes. In a properly designed comparison experiment, those contributions are measured or bounded rather than hidden inside a fitted constant that is later described as the clock's absolute error. The main uncertainty budget should distinguish random timing variation from systematic, repeatable delay.

Copyright 2026, James M. Atkinson

Let $t_i(k) = \alpha_i + \beta_i k + \epsilon_i(k)$ denote an illustrative mapping from receiver i's native sample counter k into a reference time coordinate. α_i expresses an origin for a particular stable segment, β_i an estimated interval per sample, and ϵ_i the residual mapping error. Those variables should be accompanied by estimates and uncertainty statements rather than displayed as exact constants. A change in β_i denotes a sampling-rate change or model revision, not necessarily a loss of samples. A step in α_i may reflect a new timing epoch or revised alignment, not necessarily a physical event at the antenna. If a counter resets, the segment must be given a fresh epoch identifier. No smooth polynomial fitted through that discontinuity can prove that the missing interval was observed.

Suppose a receiver nominally samples at one million complex samples per second. Under an illustrative rate error of plus eight parts per million relative to the comparison reference, a constant-rate model predicts an eight-microsecond timing difference after one second if the initial origins coincide. Over a ten-second span that model predicts eighty microseconds. These numbers do not establish that the oscillator truly exhibits constant error. Temperature, ageing, power fluctuations and reference steering may cause the rate to vary over the observation. An uncertainty budget should explicitly distinguish the measured interval, the specified environmental conditions and the extrapolation interval. When a reference signal has been lost, an uncertainty that remains deceptively constant for hours is a warning that the model has been applied beyond its supported range.

One can test a calibrated time-origin claim by sending an independently monitored pulse through known RF paths to all receivers and observing the

Copyright 2026, James M. Atkinson

resulting native indices. The exercise must not treat every detected pulse peak as an ideal physical event marker. A channel's impulse response can broaden or shift the maximum, and a threshold detector can respond differently under changing signal-to-noise ratio. We must therefore define the event feature being timed, such as a calibrated threshold crossing of a known test waveform, and validate its expected delay and scatter. The uncertainty attached to that event feature belongs beside the uncertainty of the clock reference. Repeating at several levels and frequencies can reveal systematic bias that a single test pulse would conceal.

The more exacting case is coherent phase analysis. For an RF frequency f, a timing error delta_t produces an idealised phase shift of 2 pi f delta_t radians for a pure sinusoid, provided the comparison model is otherwise valid. This illustrates why a delay that is negligible for detecting a long burst may be intolerable for phase-sensitive direction finding. At one megahertz, an unknown one-microsecond delay corresponds to one full cycle or 2 pi radians, even though the time may seem small on a wall-clock plot. At a much higher carrier frequency the same delay spans many cycles, with phase ambiguity and calibration obligations that cannot be wished away by resampling. The comparison must also account for each receiver's independent local oscillator, not merely its ADC clock.

I would ask the group to treat traceability as a chain of physical and documentary relationships. The reference oscillator has a calibration history and specified performance under conditions; the receiver has a documented reference distribution path; the timestamp latch has a validated relationship to sample index; the test event has a known generation and observation process; and the final record contains the results together with uncertainty.

Copyright 2026, James M. Atkinson

If any link is absent, the report should identify that omission. An instrument bearing the label disciplined does not exempt it from the ordinary requirements of calibration, and an elegant estimate from a multi-receiver alignment routine does not replace the physical reference evidence.

A laboratory should test the hard case: temporary loss of external discipline followed by reacquisition. It should log reference-state transitions and compare the native sample counter with an independent monitor across the outage. A device may free-run smoothly, make a controlled frequency correction, step its time counter, or reset processing buffers. Those behaviours are instrument-dependent and must be observed rather than assumed. The test should measure whether the manufacturer's status fields permit an analyst to detect the transition after the event, perhaps months later when the original engineer is absent. What is not reproducible from preserved records should not be promoted to a precise forensic claim.

Finally, scientific practice demands that we report the physical proposition rather than an impressive display. Where one receiver plainly observed a burst while another had a marked dropout, we may report one observation and one absence of evidence. We cannot prove simultaneous reception in the missing channel, and we cannot infer that the second antenna was silent. When all receivers have valid data but uncertain clock offsets, we can perhaps report overlap within specified time bounds; we cannot assert an exact sequence if those bounds overlap. A careful result is not weakened by acknowledged uncertainty; it becomes more useful because future investigators know which claims survive independent challenge. I return the token to the moderator for a final inquiry into documentary provenance and institutional control.

Copyright 2026, James M. Atkinson

Jerzy Neyman, Peer Question: Professor Ramsey, I want an experiment that can falsify an overly optimistic uncertainty budget. Assume two receivers claim a shared pulse-per-second reference, but their timestamp-latch delays, filter responses and local oscillator phases were never separately measured. A laboratory sends a calibrated pulse at several signal levels, then deliberately removes the reference for a period and restores it. What observations would distinguish a fixed offset, drifting sample rate, threshold-dependent timing bias and discontinuous re-locking behaviour? How should repeated observations and independent calibration enter the construction of uncertainty bounds rather than leaving the engineer to choose a narrow figure from one successful run? Please also clarify why simultaneous pulse detection is insufficient proof of coherent carrier phase. In a court-facing report, the temptation to call two events simultaneous often follows from their rounded timestamps, even though the actual uncertainty ranges overlap substantially. What additional evidence would you require before describing that ordering as experimentally resolved rather than merely plausible?

Norman Foster Ramsey Jr., Response: Dr. Neyman, the test must be structured around observables whose physical meaning is known. I would begin by distributing an independently monitored reference pulse along controlled paths to both receivers and recording native sample indices at which a defined event feature is detected. The event feature should be specified, for instance a calibrated crossing of a known waveform's threshold rather than an unspecified largest sample. Vary pulse amplitude, rise time and frequency while preserving an independent monitor record. A shift correlated with amplitude suggests detector time walk or front-end

Copyright 2026, James M. Atkinson

response variation; a repeatable difference between receivers suggests a fixed path or latch offset; a difference that increases approximately with elapsed time suggests relative sample-rate error. One may encounter several effects at once, in which case the observations should not be forced into a single explanation.

Next, disable the common reference deliberately while preserving device status records, and continue transmitting independent timed calibration events. A stable offset during the outage may support a bound over that observed period, but it should not justify indefinite extrapolation. Compare the receiver mapping before, during and after reacquisition. A discontinuity at restoration can reveal a phase or counter step, whereas a smooth but changing offset may show free-running frequency error. Temperature, supply state and reference-distribution configuration should be recorded because they can affect oscillator behaviour. Repetition across the relevant operating envelope is essential to distinguish robust performance from one fortunate trial.

For uncertainty, the laboratory must account for the calibration reference, path-length and filter-delay uncertainty, event-detector variability, timestamp quantisation, clock-model fit and any common-mode correlations. If both receivers rely on the same imperfect reference, their errors are not automatically independent. A small scatter across repeated trials does not exclude a common systematic bias. The uncertainty interval used in a report should reflect the physical conditions actually tested, and a revised interval should be issued when new calibration evidence contradicts the old estimate. Reproducing a spreadsheet is not enough if the spreadsheet omits a dominant physical term.

Copyright 2026, James M. Atkinson

Carrier-phase coherence is a separate proposition. A shared one-pulse-per-second trigger may align event epochs while leaving each RF local oscillator with an independent phase. Even sharing a frequency reference does not necessarily establish a known constant phase after arbitrary receiver resets, synthesiser tuning or phase-locked-loop reacquisition. Coherent comparison requires calibration of relevant frequency, phase and channel-delay relationships over the observation window. Thus two energy bursts may be simultaneous within bounded timing uncertainty while their complex sample phases remain unsuitable for coherent summation. In the final report I would state the strongest conclusion supported by the particular calibration, and I would expressly refuse any stronger claim about emitter identity or direction that depends on unverified phase relations.

Dr. James M. Atkinson, Moderator: I thank the preceding specialist for preserving the distinction between measured samples and reconstructed time. With respectful transfer of the token, I invite Grace Brewster Murray Hopper to examine the next evidence layer, while retaining the limits of every clock and loss assertion.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Fifth Principal Contributor: Dr. Atkinson, the problem is not merely to compute a clock correction but to explain exactly which record a later expert can trust. Evidence handling often begins after a device has already made hundreds of undocumented choices: which clock it queried, which buffers it accepted, what it did when data were late, and whether it padded an output file. Once those choices are compressed into a single array of complex samples and a single timestamp, much of the history has disappeared. A conscientious institution designs the recording system before the investigation so that its behaviour can be tested and its limitations displayed. The object is not ceremonial paperwork. The object is to preserve sufficient information to challenge the conclusion without requiring blind trust in the original operator.

I recommend three linked evidence registers. The acquisition register records receiver identity, device state, sample counter epochs, declared sampling rates, gain, reference source, firmware and hardware status, together with a minimal description of observed gaps. The custody register records file identifiers, digest algorithm and scope, protected reference digests, transfer events, authorised access, storage location and derivative creation. The interpretation register records every time-alignment estimate, its supporting reference observations, uncertainty assumptions, exclusions, software version and reviewer decision. Each register may have several versions, but its changes must be traceable. The fact that a file has an unchanged cryptographic digest since the original hashing event establishes byte continuity under the stated trust assumptions; it does not establish an authentic RF input or a truthful clock mapping.

Copyright 2026, James M. Atkinson

There are practical reasons to keep sample bytes and metadata as separately protected but linked objects. A file of interleaved I and Q values may be bitwise intact yet interpreted with the wrong byte order, signedness, sample rate or start epoch. A host clock correction might cause a file's creation time to change without altering its RF payload. Conversely, an operator could create a new file with the same nominal timestamps after discarding inconvenient samples. A manifest therefore needs to declare exactly which bytes were hashed and how the samples are to be interpreted. If a derivative changes the byte representation but preserves the numerical sample values, the transformation should be documented and the derivative hashed under its own identifier. Cryptographic equality and scientific equivalence answer different questions.

One of our principal threats is the retrospective repair that becomes indistinguishable from the original. An analyst discovers that receiver B lost a block and inserts a row of zeros so two plots will have matching lengths. Another analyst later sees the convenient file and interprets the zero row as radio silence. If the first analyst retained a separate gap mask and labelled the zeros as a display-only fill, the transformation could be legitimate for an explicitly defined graphic. If those labels were discarded and the corrected file supplanted the native record, the institution has damaged the evidence. The integrity problem therefore includes the preservation of meaning, not merely the preservation of bits. We should be able to reconstruct which samples were measured and which points were invented by presentation software.

The same applies to an operator's statements of synchronisation. Imagine an audit log recording synchronised at 12:00:00. That log may mean that the

Copyright 2026, James M. Atkinson

host operating system accepted a network-time update, that an ADC sampling oscillator locked to a ten-megahertz reference, or that a device registered a pulse-per-second edge. Each proposition is different. The log should name the source of the status, the measurement interface and the time at which the state was observed, including whether the reported state could be stale. A later investigation should distinguish reported status from independently verified performance. Passing a vendor self-test is useful evidence about a declared condition; it is not proof of absolute timing accuracy for every waveform captured during the subsequent hour.

Suppose an authorised laboratory collects a controlled reference pulse with three recorders. The first reports a hardware counter continuous across the test. The second reports an overflow, with a 4,096-sample gap at a nominal two-million-sample-per-second rate. The third reports host time moving backward while its device counter continues monotonically. A correct custody account would preserve these three different observations. It would describe the second receiver's unobserved interval as nominally 2.048 milliseconds under the stated sample rate, while refusing to claim that the receiver was quiet during that interval. It would identify the third receiver's host-time change as a separate metadata event, then test whether the ADC timing actually changed. It would not overwrite the records so that all three appear to tell the same story.

I would use an append-only interpretation history to record each scientific revision. The first analyst may estimate one offset from a single reference pulse. A second may later discover a cable delay and revise that estimate. A third may find a reference outage during which the oscillator drifted. All three interpretations may be intelligible stages in an investigation, provided

Copyright 2026, James M. Atkinson

none is presented as an original observation and each points to the evidence supporting its revision. The ledger should indicate whether a revision changes a displayed timeline, a quantitative event-order claim, or merely an administrative timestamp. Such distinctions are essential when a report has already been circulated and recipients must understand whether its conclusion has materially changed.

Security and privacy must be designed into this process. More metadata can improve scientific accountability, but it can also expose locations, personnel schedules or private communications. Retain the information necessary to support an authorised technical purpose, control access to samples that may contain protected content, and document why particular fields were collected. A chain-of-custody record is not a licence for indefinite retention. If legal authority allows only occupancy statistics or selected event times, the organisation should preserve that authorised scope and acknowledge that it cannot later conduct tests requiring unavailable I/Q samples. The correct wording is that the evidence does not support the broader question, not that the broader question has been answered in the negative.

For publication, I would insist that another laboratory repeat the adverse tests from the retained documentation. Can it reproduce the disclosed sample-index mapping? Can it distinguish a host clock step from a true acquisition gap? Can it demonstrate that the common-time trace was generated from a particular set of source objects and a particular transform? Can it confirm that a missing interval remains explicitly missing after file export, visualisation and report preparation? Where the answers are uncertain, the editor should state that uncertainty plainly. A polished picture and an untouched hash do not substitute for these tests. Our

Copyright 2026, James M. Atkinson

ultimate duty is to protect not only the data but the separation between observation, computation and assertion. I courteously return the token to Dr. Atkinson and invite scrutiny of the chain by the remaining peers.

Abraham Wald, Peer Question: Admiral Hopper, I propose to examine a difficult inference that can arise when missing intervals are not evenly distributed through a survey. Suppose the three receivers are watching an authorised test emitter with unpredictable short bursts, and the second receiver is most likely to drop buffers when the input becomes strong enough to overload its front end. The file may contain many apparently quiet intervals precisely because some of the most informative moments have been lost. How should a custody record distinguish observed silence, an unsuccessful detection during valid capture, an undocumented failure of acquisition and a device-reported gap? Can a later analyst legitimately estimate a burst probability from the surviving time alone, and how should an institution document the assumptions that would be required? Finally, when a second independent receiver did observe activity during the first receiver's gap, is it permissible to use that observation to fill in the absent waveform, or should the reports retain two distinct claims?

Grace Brewster Murray Hopper, Response: Dr. Wald, I would first require the custodian to preserve the validity of each time interval as an explicit evidential property. A valid acquisition with no detected burst is not automatically the same as true RF silence; it may simply be a below-threshold observation. A device-reported overflow is an acknowledged failure, while an unexplained discontinuity in a hardware counter is an anomaly requiring investigation. A file with no diagnostic fields may make even the distinction between valid capture and an unrecorded interval

Copyright 2026, James M. Atkinson

uncertain. These categories should be represented separately in both the protected manifest and any derived graphical product. If they are merged into the single value zero, a subsequent analyst cannot know whether the receiver measured zero, the detector reported no event, or the system supplied a convenient placeholder.

A burst probability estimated from surviving intervals needs a defined sampling frame and a defensible explanation of missingness. If strong RF causes more gaps, the surviving record systematically underrepresents periods of interest. The investigator should state that conditional dependence rather than treat the available intervals as an ordinary random sample. One may produce conditional estimates for explicit hypothetical scenarios, or bounds where enough independent constraints exist, but the original evidence must not be edited to look as though those assumptions were observations. In particular, a confidence interval computed from surviving windows alone may mislead if the capture failure mechanism is unknown. This is a scientific limitation of the experiment and a documentary obligation of its custodians.

Where receiver A is missing data and receiver B observed a burst, B's valid observation may support a statement that B detected an event within its own timing uncertainty. It does not give A the lost complex samples, A's actual analogue response, or an independent A-channel measurement. A model may simulate what A might have observed if its parameters and propagation channel were known, but the synthetic result needs a separate provenance label and must not be incorporated into A's raw file. The same distinction applies when several receivers agree: agreement can make an external event hypothesis more plausible, but it does not transform a

Copyright 2026, James M. Atkinson

missing observation into physical data. The ledger should maintain the boundaries between receiver-specific findings and system-level inferences.

For institutional practice I would create a small controlled vocabulary that travels with every data product: observed valid, observed invalid, known missing, suspected missing, derived estimate and unknown. The event-detection report would identify which category justified each analysed time span. A later human reviewer should be able to reconstruct the denominator of any duty-cycle or probability calculation and determine whether it excluded missing periods or incorrectly treated them as quiet. A graphics application should be prohibited from dropping the uncertainty labels when exporting a plot. Such an arrangement protects a lawful and modest inference against the temptation to make a continuous line seem more complete than the original measurement chain.

Sir Karl Raimund Popper, Peer Question: Admiral Hopper, your three registers distinguish observation from interpretation, but institutional habit can make a register seem authoritative merely because it is elaborate. What experiment would expose a false assurance generated by a perfectly protected file whose clock metadata were wrong from the beginning? I am especially concerned about circular verification: one software programme reports a hardware status, another reads that status from the first programme's log, and a later reviewer treats both as independent confirmation. How should the report disclose this dependence? Suppose a correction to the clock model reverses a finding that event A preceded event B. Is the earlier finding simply erased as a typographical error, or must the conflicting versions and their evidential bases remain visible? Finally, can a witness defend a conclusion that an event did not occur if every receiver

Copyright 2026, James M. Atkinson

failed to observe during the period in question? I ask for a practical test capable of refuting, rather than merely illustrating, the system's claim to accurate chronology.

Grace Brewster Murray Hopper, Response: Professor Popper, an effective test challenges the system's history with an independent source of truth. In a laboratory, we can produce reference RF pulses whose timing is monitored by an apparatus outside the logging path under examination. We can then cause deliberate errors in one receiver's sample-rate metadata, change the host wall clock, interrupt its reference and introduce a known gap. The acceptance criterion should be specified before the trial: the resulting files and ledgers must preserve enough native evidence either to reconstruct event order within stated uncertainty or to flag that the order cannot be established. A programme that always reports a confident chronological sequence, regardless of its inputs, is failing this test. Its certainty is not an achievement but a sign that it has no representation for ignorance.

The source of each apparent corroboration should be displayed. If two applications read the same firmware status register, they are not independent witnesses to the actual oscillator condition. Their agreement may verify that the status value was transferred faithfully, but not that the value corresponded to physical timing performance. A second instrument monitoring the reference event or a separately measured pulse train can provide an independent constraint, although that instrument has its own calibration uncertainty. The audit must record common dependencies rather than multiply the same assertion into an impressive-looking collection of checks. In software terms the evidence graph is directed, and several

Copyright 2026, James M. Atkinson

downstream nodes cannot be counted as distinct roots merely because their filenames differ.

If a corrected clock model reverses an event-order finding, the revision is substantive. The original interpretation and its supporting assumptions should remain available with clear notice that the conclusion was superseded. The new report should identify the corrected reference measurement, the parameter changed, the effect on the ordering and any downstream decisions that might require reconsideration. A footnote that the chart was updated would be insufficient where readers might continue relying on the earlier ordering. We should not make a false statement permanent, but neither should we destroy the history of how it arose. Transparent revision is the proper answer to error, not a silent overwrite.

Finally, if every receiver has an unobserved interval, there is no evidential basis for asserting that no external event occurred within it. The proper finding is that the record contains no valid observation for that interval, perhaps with an accompanying statement about operational status and the system's independently characterised detection capability outside the gap. Absence of recorded evidence is not evidence of physical absence when the instrument was not observing. An adverse test should deliberately place a brief reference pulse inside a known acquisition gap. The correct processing system must not report the pulse as measured, and must not report its absence as an established fact. It should declare that the available receiver data cannot answer the question.

Charles Sanders Peirce, Peer Question: Admiral Hopper, consider the language of the final report as a system of signs that may be less precise than the underlying measurements. A table says receiver A saw a pulse at

Copyright 2026, James M. Atkinson

12:00:00.000001 and receiver B at 12:00:00.000002, yet its footnote reveals an uncertainty of twenty microseconds in each clock's mapping. A reader may wrongly infer that the order is established by the printed digits. What conventions should compel the author to separate an observed sample index, a calibrated event-time estimate, a hypothesised cross-device match and a conclusion about sequence? Should the report give interval bounds rather than unsupported point times, and how should it identify intervals where the clock reference was lost? I would also ask how the chain of custody can remain intelligible to a future reviewer who does not have the original manufacturer's proprietary software or the individual engineer who operated the system. The goal is not just numerical exactness, but reproducible meaning.

Grace Brewster Murray Hopper, Response: Professor Peirce, the report's notation should communicate the kind of claim being made before the reader reaches a technical appendix. I would use separate columns for the native device counter, source-record identifier, time-mapping version, estimated reference time, uncertainty interval and observation-validity state. A point estimate may be useful for indexing and presentation, but when the inferred order is smaller than the unresolved timing uncertainty, the narrative should say that the order is not established. Placing six digits after the decimal point is merely a formatting decision; it does not reduce the error budget. A labelled interval is more intelligible than an unjustifiably exact number, particularly when several receivers share a calibration source and their errors are correlated.

Each period of reference loss should receive a defined segment identifier, start and end conditions, and the method used to estimate the relationship

Copyright 2026, James M. Atkinson

between native indices and the reference clock. Where the boundary is only known within a range, that uncertainty should be stated rather than rounded away. The analyst should retain the versioned mapping and its validation results so that an independent reviewer can reproduce the displayed time coordinates. If a model extrapolates through a reference outage, the report must say extrapolated and specify which oscillator performance assumptions govern the widening uncertainty. Likewise, if the receiver stopped acquiring, its missing observation interval cannot be replaced with a continuous trajectory merely because a clock model remained calculable.

Long-term intelligibility requires open or fully documented representation of critical evidence fields. The institution should preserve a specification of the sample format, endian order, numeric type, interleaving, reference-clock flags, hardware counter semantics, missing-data conventions and the meanings of status words. It should retain the original bytes under lawful controls and, when appropriate, a separate independently readable export whose transformation has been validated and recorded. An exported CSV or report is not self-authenticating merely because it can be opened without a vendor application; it still needs source identifiers and an explanation of how each value was derived. The custodian should also preserve enough test vectors and quality checks to distinguish a future parser defect from a genuine anomaly in the original recording.

The written conclusion ought to have layers of certainty. One layer states what the device recorded. Another states how an external time was estimated. A third compares independently observed events within their uncertainty intervals. A fourth considers whether those observations justify

Copyright 2026, James M. Atkinson

attribution, event ordering or other legal and technical inferences. Each step should identify its premises and surviving alternatives. This produces prose that may be less spectacular than a unified waterfall with razor-thin markers, but it is far stronger under scrutiny. By preserving the relation between numbers, observations and interpretation, the organisation permits future readers to understand exactly what was known and what remained uncertain at the time of the report.

Dr. James M. Atkinson, Moderator: We have heard five principal contributors and seven immediate peer examinations. I now pass the token for four reciprocal questions directed to four distinct named respondents. No speaker should claim that an estimated alignment restores observations lost at acquisition, and each reply must answer the preceding peer before our final technical qualifications.

Edsger Wybe Dijkstra, Cross-Peer Question to Norman Foster Ramsey Jr.: Professor Ramsey, I challenge a common assumption in timing software. An alignment routine may produce a numerically continuous mapping through a reference outage, and the operator may conclude that no physical discontinuity occurred because the fitted function is smooth. Suppose the device's oscillator made a brief frequency step at the moment it lost its reference, but the available calibration pulses fall well before and after that step. What metrological observation would distinguish the smooth model from a piecewise model, and what should the software do when the available evidence cannot decide? I also ask how one might quantify the practical meaning of an interval of uncertain event order without pretending that all error contributions are independent or normally distributed. If the final inference depends on coherence of two RF local oscillators, must an

Copyright 2026, James M. Atkinson

independently measured phase relation be treated as a separate datum rather than inferred from common pulse-per-second labels? I invite a reply identifying the limits of the measurement rather than the aesthetic properties of the fitted curve.

Norman Foster Ramsey Jr., Cross-Peer Answer to Edsger Wybe Dijkstra: Dr. Dijkstra, the smoothness of a mathematical mapping is no substitute for a physical observation during the uncertain interval. Calibration events before and after an outage constrain the average behaviour of the clock over the intervening period, but they may not identify the time at which a transient frequency step occurred. Two different piecewise models can reproduce identical endpoint observations while assigning different intermediate event times. To discriminate them, the laboratory needs additional reference observations inside the interval, sufficiently informative device-state logging, or an independent physical measurement of the relevant oscillator. Without those constraints, the correct result is a family of admissible time mappings or a bounded uncertainty envelope, not an invented unique history. A statement that a model fits the known points is not equivalent to proof that it followed the true path between them.

The uncertainty should be based on explicitly justified physical contributions. Some arise from measurable distribution delays, others from repeated event-detector scatter, and still others from unobserved oscillator behaviour. Their combination depends on dependence, distribution and the kind of bound being asserted. If two receivers share the same timing reference, common errors may shift both together. Treating those terms as independent can give a falsely narrow range for some propositions and a needlessly conservative one for others. Where the relation is not

Copyright 2026, James M. Atkinson

characterised, one can report conservative intervals based on established worst-case bounds or present alternative scenarios rather than invent a precise statistical distribution. If the temporal ordering changes across plausible scenarios, the order is unresolved. That is a substantive scientific result.

The distinction between epoch alignment and phase coherence is fundamental. A pulse-per-second source can provide a repeatable time marker for device counters without determining the RF local oscillator phase at each receiver's input. Even a common frequency reference may leave phase offsets due to independent synthesisers, tuning operations, distribution lines and acquisition restarts. The laboratory should record a separate phase-calibration observation, using an authorised reference waveform distributed through measured paths and inspected over the relevant interval. If this information is absent, the report may support an event-time comparison without supporting coherent combining or phase-sensitive attribution. A program should refuse to turn a claim of clock alignment into a claim of phase coherence unless the necessary physical evidence is present. The strongest software design is one that communicates precisely when a requested conclusion requires an observation that the laboratory did not make.

Norman Foster Ramsey Jr., Cross-Peer Question to Grace Brewster Murray Hopper: Admiral Hopper, a scientific correction often occurs after files have been copied, hashes computed, and conclusions circulated. Suppose a later calibration establishes that receiver B's event detector introduced a systematic delay that the original common-time model neglected. A new estimate reverses the ordering of two observed transients. What revision

Copyright 2026, James M. Atkinson

record is necessary so that an independent expert can determine whether the raw sample bytes remained unchanged, which version of the clock model was used for each public conclusion, and whether downstream summaries need correction? I am also concerned that preserving every intermediate derivation may create unnecessary copies of sensitive RF material. Can an institution maintain defensible provenance while retaining only the authorised minimum of waveform content? Please explain how the custodian should distinguish a correction to metadata interpretation from an alteration of source evidence, and how a later reviewer could reproduce the calculation without accepting the analyst's personal testimony as the sole account of what occurred.

Grace Brewster Murray Hopper, Cross-Peer Answer to Norman Foster Ramsey Jr.: Professor Ramsey, the correction should be documented as a new, traceable interpretation of unchanged source objects. The original dataset would retain its original byte digest, length, acquisition manifest and device-native indices. The first time-alignment model would remain identified by a version and protected copy of its parameters, calibration observations, software code or executable provenance, and the report that relied upon it. A second model would identify the new detector-delay measurement, explain how it alters the mapping, and record which reported event times or ordering propositions change. If the ordering of consequential events reverses, the revision must be described as a material correction and communicated to parties relying on the earlier report; it is not a typographical adjustment. The custodian need not surrender the physical raw record merely because its interpretation improved.

Copyright 2026, James M. Atkinson

The provenance chain should identify each source and derivative by a stable logical identifier, with a separately protected digest for the exact bytes stored. The revised model may require an updated clock manifest but no rewrite of the I/Q samples. A reproducibility package can contain a narrowly authorised test extract, numerical reference-event table, calibration coefficients, program revision, and expected output, all linked to the more restricted original by controlled identifiers. Where security or privacy rules prohibit redistribution of the full waveform, a qualified independent reviewer can verify it under controlled access or evaluate a properly disclosed derivative, acknowledging any limits that decision creates. The objective is to avoid uncontrolled duplication of potentially protected content while preserving the evidence needed to challenge material claims. The institution should document why it retains each object and who has authority to inspect it.

An append-only revision history is valuable because its chronology cannot be reconstructed reliably from a folder containing only the newest files. Each entry should say who approved the transform, what assumptions changed, when the revision was made, which source version was used, and whether the earlier report is superseded. The mechanism protecting the ledger should itself be described, since a perfectly hashed source file accompanied by a freely editable custody narrative offers weak assurance. A new digest authenticates the new derivative from its reference state; it does not cause an inaccurate clock claim to become historically true. The original observation, the original interpretation and the revised interpretation remain separate objects.

Copyright 2026, James M. Atkinson

Finally, documentation should let a technically qualified reviewer reproduce the key inference without personally trusting the first analyst. That requires sufficient description of sample-format semantics, calibration measurements, transform parameters, missing-data masks and numerical tolerance for the relevant computation. A closed software product may remain necessary to read a proprietary recording, but the organisation should preserve its version and appropriate test vectors, or make a independently readable validated export where possible. It is better to present an intelligible restricted-access audit trail than to preserve every raw sample indefinitely or to delete the evidence of a consequential correction. Custody concerns what was preserved and how it was treated; metrology concerns what the preserved record actually establishes.

Grace Brewster Murray Hopper, Cross-Peer Question to David Lennox Mills: Dr. Mills, consider a file whose native sample counter is trustworthy but whose host timestamps came from a network clock that experienced a step adjustment while the acquisition proceeded. An analyst might correct all historical host times by subtracting the observed step, creating a perfectly smooth plot. Can that operation be justified for every sample, and what independent evidence would establish where the step occurred relative to the sample sequence? Suppose the network-time service reports low offset and jitter both before and after the event, but the application buffered sample blocks for variable durations. How should the report distinguish synchronisation of the host system clock from synchronisation of the receiver's sample aperture? I also ask whether a monotonic device counter can by itself determine absolute time, and how the uncertainty should be represented after loss of an external clock reference. We need a correction

Copyright 2026, James M. Atkinson

procedure that protects device-native chronology without publishing a false aura of sub-microsecond alignment.

David Lennox Mills, Cross-Peer Answer to Grace Brewster Murray Hopper: Admiral Hopper, subtracting an observed host-clock step from a sequence of host timestamps is at best a model-based correction. It may be legitimate for an explicitly described derivative if the step boundary, relevant clock domain and transport-latency behaviour have been established, but it should not silently replace the original records. The application must first identify whether each timestamp was assigned in the host before or after the adjustment, and whether buffering displaced the relationship between timestamp assignment and ADC acquisition. A smooth corrected plot is insufficient evidence of the boundary. If the host clock changed while the device's sample counter remained continuous, the ADC did not necessarily experience any corresponding change. The device history and the host history should be preserved separately, then joined through measured reference events.

A small network-time offset estimate means that a particular system-clock discipline model was reporting a relation to its selected references under its protocol assumptions. It does not mean that a queued data block arrived without latency, nor does it tell us the aperture time of an arbitrary RF sample. Network paths are subject to queue variation and asymmetry, and applications observe their own scheduler delays. The proper report identifies the clock being disciplined and the traceable link between that clock and a device counter. Where no such link was measured, host timestamps may order logged software events but cannot support a stated aperture-level precision. In particular, low clock jitter should not be

Copyright 2026, James M. Atkinson

confused with the latency distribution between an ADC and the point at which a file writer stamps its output.

A monotone counter provides a native ordering and, where its increment semantics are validated, a measure of elapsed sample intervals. It does not intrinsically supply a UTC epoch. Absolute timing requires an origin mapping to a traceable reference and allowance for systematic delays and clock frequency error. During a reference outage the last known mapping can be extrapolated under stated oscillator assumptions, but uncertainty generally grows as knowledge of current rate and offset weakens. It may be possible to bound that growth with prior measurements and documented oscillator performance, yet an instrument's advertised specification should not be confused with direct proof of the particular field conditions. If the counter resets or its epoch becomes unknown, a new segment must be created rather than extending the earlier mapping by convenience.

I would preserve the original device counters and status flags, the host time log before correction, the independently measured reference events, and the algorithm and assumptions behind the new mapping. A finding could then state that a burst was acquired at native index k, and that under alignment model version two its estimated reference time lies within a specified interval. If different defensible models give different event orders, that ambiguity must be reported. There is no defect in a report that stops at the limit of supported inference. The failure would be to confuse a convenient graphical normalisation with the discovery of facts about physical time which the receivers never measured.

David Lennox Mills, Cross-Peer Question to Donald Watts Davies: Mr. Davies, I wish to test the boundary between network observation and physical

Copyright 2026, James M. Atkinson

acquisition. A multi-receiver system presents an uninterrupted display, yet a packet trace shows a loss during one receiver's USB transport, and the source hardware declares that it continued sampling into a ring buffer. Under what conditions may the investigator treat the RF data as continuous, and what records would demonstrate that the missing transport object was retransmitted rather than replaced by an interpolation? Alternatively, if the ring buffer overflowed and the native sample counter skipped, can neighbouring receivers prove the missing instrument's antenna saw the same waveform? Please distinguish genuine recovery of already captured samples from an attempt to infer absent measurements. I also ask what the acceptance test should report when the firmware offers no trustworthy acquisition counter and returns only transfer timestamps. In that case an attractive alignment could conceal a complete uncertainty about the source interval.

Donald Watts Davies, Cross-Peer Answer to David Lennox Mills: Dr. Mills, a transport packet's disappearance does not by itself establish a loss of physical acquisition. If the receiver buffered the actual samples and subsequently delivered them intact, with source-native block identifiers, verified content lengths and valid continuity counters, the recording may indeed be complete after recovery. The proof should not rest on the application's statement that a retransmission occurred. The recovered objects must be identifiable as the original acquisition blocks, and their native sequence and checksums or protected source digests should be checked against the device's declared behaviour. A later file may have a different container hash from an earlier partial file, but the preserved samples and restoration operation can still be explained precisely through

Copyright 2026, James M. Atkinson

the derivative ledger. This is a recovery of existing data, not a recreation of measurements.

If the acquisition buffer itself overflowed, there may be an interval for which the receiver obtained no usable data or could not preserve what it obtained. Neighbouring receivers can supply independent observations of the external test event, within their own calibration limitations, but cannot establish the absent receiver's actual response. Different antennas, gain settings, filters, multipath and overload states can produce different complex samples even for a common external transmission. Replacing the missing portion by another receiver's data would create a modelled composite with different provenance and should never be labelled the original receiver's stream. It may be useful for a separately disclosed simulation, but it cannot support a statement that the missing instrument measured the substituted waveform.

Where only transfer timestamps survive, the limit must be recorded frankly. A host log may show receipt of certain blocks and their wall-clock times; without validated acquisition identifiers or measured delay it cannot establish the exact sample counter history. We may compare file size, packet order and device status to estimate possible loss, but a conclusion about continuity remains conditional. An acceptance test should expose this uncertainty by deliberately dropping transport, overfilling buffers and changing the host clock, then observing whether the software falsely declares uninterrupted acquisition. If the status fields cannot disambiguate the conditions, the test report should say that the instrument architecture does not support the required evidential claim at the specified confidence. A gap in the evidence is a design limitation, not a licence for invention.

Copyright 2026, James M. Atkinson

The central lesson is to distinguish physical acquisition, transfer, preservation and representation. Each can fail while another succeeds. A sound multi-receiver history keeps those stages visible and provides the technical reviewer with the native objects, status evidence and transformations necessary to decide what actually occurred. No participant should be asked to certify more than his observations establish. When a system cannot distinguish a legitimately recovered buffer from synthetic fill, it must either be redesigned for that duty or described as unsuitable for the stronger conclusion. That decision is more valuable than any smoothly rendered waterfall.

QUESTION 094. TECHNICAL SOURCE NOTES. This contemporary dialogue is fictional scholarly reconstruction, not an actual historical exchange or quotation. Selected technical background references: David L. Mills et al., RFC 5905, Network Time Protocol Version 4: Protocol and Algorithms Specification (June 2010), https://www.rfc-editor.org/rfc/rfc5905; Karen Kent, Suzanne Chevalier, Tim Grance and Hung Dang, NIST Special Publication 800-86, Guide to Integrating Forensic Techniques into Incident Response (2006), https://csrc.nist.gov/pubs/sp/800/86/final; IEEE 1588 precision time synchronisation standards where appropriate to the actual equipment and revision. RFC 5905 documents system-clock discipline, not a universal warrant of ADC aperture alignment. NIST SP 800-86 provides broad forensic documentation guidance, not an RF sample-clock calibration protocol. Instrument-specific claims require independent checking.

EDITORIAL QUALIFICATION. The imagined deceased expert dialogue is a pedagogical reconstruction, never archival testimony. All examples and numerical input values are hypothetical; they are not measurements of an

Copyright 2026, James M. Atkinson

unknown emitter. Source-to-claim verification, clock metrology, historical and legal review, complete semantic novelty assessment and continuous whole-volume publication proof remain pending. The source and derivative distinction is mandatory: neither interpolation nor agreement among other instruments recreates an absent receiver sample.

QUESTION 095

Copyright 2026, James M. Atkinson

What makes a software-defined receiver processing pipeline independently reproducible?

Dr. James M. Atkinson, Moderator: Dr. Dijkstra, a software-defined receiver can transform the same saved complex sample stream into apparently identical waterfalls on two computers while using different numerical libraries, software revisions or decision thresholds. A later forensic examiner may be impressed by the similarity of the images without discovering that the signal classifiers took different computational paths. I invite you to distinguish bitwise, numerical and scientific reproducibility; specify which original observations and configuration details must be preserved; and define a controlled second-host experiment that can detect a substantial error despite the resemblance of the final visualisation. This discussion is a fictional educational reconstruction, not an archival exchange among the historical experts.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Principal Contributor: Reproducibility is not one property but a family of claims whose preconditions must be stated. A bitwise reproduction asserts that a specified computation on a specified byte sequence produces an identical byte sequence under declared conditions. Numerical reproduction asserts that relevant values agree within a tolerance that has been justified for the method and decision being tested. Scientific reproduction asks whether the experiment, including acquisition and calibration, supports the same physical inference under independently controlled conditions. These claims differ in their logical strength and in their objects of comparison. A programme may reproduce every byte of a flawed output perfectly, while a correctly calibrated receiver operated under different environmental circumstances may yield numerically different but scientifically consistent observations.

The first necessity is a defined original object. A set of complex samples without its format contract cannot be interpreted unambiguously. The manifest must specify whether each component is a signed integer or floating-point quantity, its byte order, arrangement of I and Q, sample rate, nominal centre frequency, scale and associated device epoch. If an acquisition driver silently writes invalid samples after an overflow, the manifest should preserve the fault and not recast those values as reliable input. The chosen byte-level hash covers a precisely identified object; agreement on that digest provides continuity from the nominated reference state but does not establish that the receiver's analogue front end measured the physical world accurately. For that separate question we need calibration, known reference signals and a verified understanding of every transformation before digitisation.

Copyright 2026, James M. Atkinson

I next require a computational graph, not merely an application's name. The graph states each stage in order, including filtering, frequency translation, resampling, decimation, windowing, Fourier analysis, averaging, thresholding and plotting. Each stage should have declared input and output conventions, numerical precision and parameter values, including coefficients that the graphical interface may not display. A software version string is useful but is not enough if the same version can invoke a different FFT library, a hardware-accelerated kernel or a configuration file changed after the capture. Nor is a source repository commit sufficient if the binary used at the scene was compiled with different flags, bundled proprietary libraries or a modified FPGA image. A genuine reproducibility record has to bridge source intent and executed implementation.

There is an important distinction between an RF sample record and the executable environment. The first is an evidence object originating from hardware and an acquisition operation. The second is a computational environment that interprets that object. Both require traceable identifiers, but they must not be merged into a single assurance such as 'the file was unchanged'. A captured IQ record may be untouched while a changed filter coefficient alters its apparent bandwidth. Conversely, a deterministic filter may be recompiled into a numerically different implementation yet continue to produce a result consistent within an explicitly justified tolerance. The audit must state which guarantee is being sought. Where legal or technical consequences turn on a small threshold difference, an unexamined change in numerical rounding is not a decorative detail.

For the second-host experiment, begin with a protected reference IQ file acquired during a lawful laboratory test whose source waveform and

Copyright 2026, James M. Atkinson

instrument state have independent documentary support. Freeze the format specification, processing graph, coefficients, dependency versions, source and binary identifiers and hardware-acceleration configuration. Run the pipeline on a second computer and compare not only the final picture but selected arrays after each consequential stage. Record the size, type, scaling and tolerance used for those comparisons. If exact agreement is required, describe why it is realistic; if bounded numerical differences are permitted, justify a bound tied to the detector's sensitivity and final conclusion. An unexplained mismatch at an intermediate stage is not cured by selecting a colour scale that makes the plots look alike.

The laboratory should also test whether the verification has power to discover errors. Change the interpretation of interleaved I and Q, alter one filter coefficient, substitute a different FPGA image identifier and insert a known sample discontinuity. A well-designed reproducibility test will reject at least those substitutions which violate the declared computational contract, even if the output retains superficial visual similarity. A negative control is particularly valuable: a detector that claims to have verified an identical processing chain while failing to notice a changed decision threshold has demonstrated that its evidence is insufficient. The acceptance test should declare its sensitivity to the perturbations chosen, rather than promise omniscience about all possible deviations.

I would encourage a small collection of canonical numerical test vectors, with expected intermediate results, carefully stated input types and measurement tolerances. These provide a way for an independent examiner to test a new platform without assuming that a proprietary graphical interface is itself a standard of truth. The vectors do not replace instrument

Copyright 2026, James M. Atkinson

calibration or proof of lawful data acquisition. They test the computational interpretation of specified inputs. The same distinction applies to a digital signature or protected digest over the processing recipe. It can attest to the continuity of the documented recipe under suitable trust conditions, but cannot prove that the recipe answers the right scientific question. Software integrity and scientific validity are related, not synonymous.

When the object of the inquiry is a particular detection decision, the comparison must include the decision threshold, estimated noise floor, data-exclusion rules and handling of missing or invalid samples. Two waterfall displays can be made visually similar through independent choices of averaging or colour scaling while reporting different event durations. A disciplined reviewer must be able to reproduce a numerical decision in the same stated units and challenge the assumptions behind it. One useful form is a report of the input record identifier, processing graph version, intermediate numeric diagnostic, final detection value, threshold, uncertainty and exact reason that a segment was excluded. Such a record is more informative than a screenshot bearing only a date and a frequency label.

Finally, I would require preservation of corrections without silent replacement of original analysis. If a computational dependency is found to have changed or a converter is discovered to have reversed I and Q, issue a revised derivative with a new identifier, retain the original and document the effect on every substantive finding. In no case should a programme be allowed to assert that a reproducible output is a faithful RF observation simply because repeated runs agree. The honest conclusion may be that one calculation is repeatable while its scientific interpretation remains

Copyright 2026, James M. Atkinson

unverified. The ability to make that distinction should be designed into the software as carefully as the mathematics of the transform itself. I respectfully return the token to Dr. Atkinson for the remaining experts to challenge the compiler, storage, statistical and formal-verification assumptions.

Jerzy Neyman, Peer Question: Dr. Dijkstra, you require a predetermined comparison tolerance, but I am concerned by how one chooses that tolerance without looking at the troublesome data first. Suppose two receiver pipelines calculate the same spectral score to four decimal places on most test vectors, yet disagree on several weak synthetic bursts deliberately placed close to the decision boundary. It would be tempting to choose a tolerance wide enough to make the entire table agree, then announce an independent reproduction. That would confuse a retrospective accommodation with an externally justified acceptance criterion. How should an engineer design a test collection that separates routine numerical discrepancies from differences consequential to false-alarm probability? Please distinguish the numerical tolerance for an intermediate floating-point array from the inferential threshold that determines whether an event is reported. I also wish to know whether the laboratory must reserve new data after selecting its comparison rules, and how it should document decisions made while debugging a failed acceptance test. A later court or academic reader must not mistake the final successful run for the whole experimental history.

Edsger Wybe Dijkstra, Response: Professor Neyman, your objection exposes the danger of allowing a tolerance to function as an eraser. The engineering contract should specify both numerical and inferential criteria before the

Copyright 2026, James M. Atkinson

independent comparison. For example, an intermediate array might be compared under a declared absolute error and relative error rule, with special handling of values near zero. That rule should follow from numerical analysis of the algorithm, the stated precision, and verification on known test vectors. Separately, a classifier may apply a statistical threshold derived from a specified noise model and the number of opportunities for false detection. It is a category error to adjust the first rule merely because the second produces an inconvenient disagreement. The tolerance verifies that the numerical implementations are sufficiently equivalent for the intended purpose; it does not independently validate the purpose.

I would use three distinct datasets. A small canonical set contains analytically predictable values and exposes representation, indexing and scaling errors. A development set permits programmers to inspect and correct their implementation, but its results cannot thereafter be described as a blind confirmatory test. A reserved acceptance set remains inaccessible to those making the last substantive parameter choices until the procedure and tolerances are frozen. If the two programmes disagree on near-threshold examples, preserve the full numeric score and the decision from both systems. A stable comparison of intermediate arrays does not imply a stable decision when the threshold is narrow. Where a discrepancy crosses the reporting boundary, the correct result is a qualified failure or an indeterminate classification, not an enlarged error allowance.

Debugging history is an evidential record. Each failed run should retain the source input identifier, software and library versions, test settings, exact discrepancy, proposed cause and corrective action. A fixed bug may be deployed in a new build, but that build receives a new identifier and a fresh

Copyright 2026, James M. Atkinson

acceptance run on a still-independent set where available. The former failure cannot vanish merely because the latest release succeeds. An auditor should know whether the discrepancy arose from floating-point evaluation order, an incorrect window, a changed threshold or a failure to preserve a sample gap. If the investigator changes the intended specification after seeing the results, that change needs its own rationale and should trigger renewed independent testing.

One should also make the statistical proposition explicit. A nominal false-alarm rate is not guaranteed by repeating the same dataset through equivalent algorithms. It depends on how the detection rule was chosen, which hypotheses and time-frequency cells were considered, how correlated observations were handled and whether the assumed background distribution was plausible. An exact reproduction of a retrospectively tuned threshold can reproduce an invalid inference with extraordinary precision. The acceptance report should therefore provide separate findings on computational agreement and on the calibration of inferential risk. The first answers whether the calculation repeats; the second asks what its answer means. Neither should borrow authority from the other's success.

Abraham Wald, Peer Question: Dr. Dijkstra, let us examine the practical order in which an independent examiner should test a pipeline. A receiver programme may contain tens of stages, and the analyst may decide to stop investigating as soon as its final output resembles a reference. This creates a selective testing problem: failures that are inconvenient may receive additional trials, whereas successes are accepted at once. If one test vector contains a known signal and another includes deliberate overload or lost samples, a programme might pass the first and silently misinterpret the

Copyright 2026, James M. Atkinson

second. What sequence of checks would you require so that the stopping rule itself cannot hide the weakness of the evidence? In addition, how should the examiner account for test cases that were added after an earlier version failed? Does a succession of corrected builds create a new inferential burden, or may one reasonably accept the eventual passing build without describing its predecessors? Finally, specify the minimal documentary record that a second institution would need to repeat the acceptance decision without access to the first institution's informal notes.

Edsger Wybe Dijkstra, Response: Professor Wald, the proper answer begins with a test protocol that has explicit completion and stopping criteria. The examiner should not stop upon seeing one appealing result. The protocol should identify the full matrix of test inputs, required stage comparisons, expected pass and fail behaviour, numerical tolerances and final acceptance decision before the run begins. All designated cases should execute, including malformed metadata, declared overloads, discontinuities, zero-amplitude inputs, phase-reversed tones and near-threshold synthetic events. If the software crashes or the environment fails, the event remains recorded as a test result requiring explanation. One may later rerun the case under controlled conditions, but the first outcome cannot be expunged from the audit trail.

A reasonable order separates foundational defects from subsequent inference. Verify first the byte identity and format contract of the original sample object. Then confirm that the processing programme loaded its declared configuration and binary dependencies. Next compare stage-level numerical results on simple canonical vectors, before moving to complicated known RF patterns. Only after these prerequisites should the

Copyright 2026, James M. Atkinson

examiner assess detector labels on a blinded held-out suite. This order prevents a classifier from receiving credit for a plausible label when its internal frequency axis is wrong. Yet the protocol should still preserve the complete test inventory rather than skipping downstream tests without a formal status such as blocked by prerequisite failure.

When a failed case leads to a code change, the new executable is a new subject of validation. The repaired build may ultimately be accepted, but its history must show the fault, the corrective change and the evidence that the correction did not create regression elsewhere. A test introduced in response to a failure can be valuable as a regression test, but it is no longer blind evidence that the team had no opportunity to tune the product to it. Keep it in the permanent suite and procure fresh independent cases when claiming generalised acceptance. The distinction is not punitive. It is how one avoids confusing learning from errors with an objective estimate of performance on unseen conditions.

The minimal reproducibility dossier includes the input identifiers and checksums, format contract, test vector generation method, executable and dependency identities, exact command or workflow used, stage parameter manifest, expected numeric outputs and acceptance tolerances. It also contains observed outputs, environment details, failure reports, code-change records and an explanation of any excluded case. Where a protected IQ sample cannot lawfully be shared, an authorised independent auditor may execute the test in a controlled environment with auditable access. If some stage remains proprietary or inaccessible, the report must state which portion of the computation could not be checked. The evidence is more

Copyright 2026, James M. Atkinson

credible when its limits can be understood without personal acquaintance with the original programmer.

Dr. James M. Atkinson, Moderator: I thank Edsger Wybe Dijkstra for identifying the evidence boundary. With respectful passage of the token, I invite Grace Brewster Murray Hopper to examine the next distinct technical layer. The historical specialists are participating in a fictional modern educational discussion, not an actual recorded meeting.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Second Principal Contributor: Dr. Atkinson, an independently reproducible receiver pipeline must be described as an executed programme rather than a comforting account of what the programmer intended to execute. In a software-controlled instrument, the same named application can act differently because its configuration was read from another directory, a dynamically linked numerical library changed, the device driver negotiated a different sample format, or an FPGA image altered the transformation before the software received the first complex sample. A printed programme listing is not the machine state. A forensic examiner must therefore distinguish source code, executable binary, load-time dependencies, run-time configuration, device firmware and the actual record of operations. The last item is difficult, since an ordinary log shows what its author chose to log, not necessarily every branch that executed.

My first proposal is an acquisition manifest with explicit typed fields rather than a prose assurance that settings were standard. The fields should include instrument make and model where confidentiality permits, unique device identity, analogue preselector selection, gain and attenuation, nominal centre frequency, sampling clock source, bandwidth, ADC scaling, overload indication, channel count, complex-sample packing, interleaving, byte order and any declared discontinuity. Each capture epoch requires a reference to the hardware and firmware state under which it was generated. Such a manifest can be written using a documented format; an existing metadata standard may provide a useful base, but investigators must identify which extra records are required for their apparatus. An identifier pointing to an unavailable private configuration file is not adequate. A

Copyright 2026, James M. Atkinson

reviewer must be able to retrieve or reconstruct the specified configuration under controlled permission.

Next I would identify the program artefacts by cryptographic digest, build provenance and dependency inventory. A source revision number alone can omit uncommitted changes, generated files and build-time substitution. A binary digest identifies a particular byte sequence, provided that its reference was generated and preserved under trustworthy procedures; it does not tell us whether that binary executed without modification or whether the operating system loaded the library that the investigator expected. Record the interpreter or compiler version, compilation and linking flags, CPU architecture, accelerator runtime, numerical libraries and container image where one was employed. A software bill of materials is useful, but should not be mistaken for a complete proof of execution. Dynamic environment variables, external calibration files and operator selections must also be captured.

I would design the signal-processing graph as a sequence of contracts. A stage receives a well-defined typed vector and configuration, and produces a well-defined vector and diagnostic record. A resampler requires its rational rate relationship, filter coefficients and initial state; a Fourier estimator requires transform length, window weights, scaling convention, segment overlap and averaging definition; a classifier requires its threshold, noise estimator, exclusion policy and treatment of ties. Where state carries between blocks, a file of input samples and the current block's settings may be insufficient to reproduce the output. The initial state and preceding samples, or an explicit reset event, belong to the computational description.

Copyright 2026, James M. Atkinson

It is entirely possible for two programmes to process the same block differently because their filters entered the block with different memories.

The laboratory should establish golden vectors whose expected intermediate answers are independently derived. A single pure tone is too indulgent; it can allow errors of normalisation, conjugation or clipping to go unnoticed. Include a complex sinusoid of known relative phase, an impulse, a stepped amplitude, two adjacent tones, calibrated noise, a buffer boundary, an overflow marker and a deliberately malformed metadata record. These are test vectors, not a simulation of an unknown radio emitter. The specimen should state whether outputs are compared bit for bit or within a justified tolerance, and which comparison is relevant to the reported scientific claim. Exact binary identity is often appropriate for file provenance, whereas floating-point values obtained on different architectures may require controlled tolerances. One cannot approve every difference merely by declaring numerical algorithms approximately equal.

A useful exercise is to modify exactly one filter coefficient while leaving the displayed colour limits unchanged. The final waterfall may look unaltered on a small monitor, yet the numeric power near a detection boundary may move sufficiently to reverse a classification. Therefore the acceptance procedure must compare arrays before display mapping, not only their rasterised colours. Another negative control is to swap I and Q interpretations while preserving the same data bytes. For some magnitude-only summaries this error may be hard to see, but frequency-sign and phase conclusions can change. The validation should report whether the test detects that substitution. An accepted pipeline that fails to discover known

Copyright 2026, James M. Atkinson

false inputs has not established the independence that its polished user interface suggests.

I would further require the programme to write a machine-readable decision record. For each declared finding it should identify the input digest and byte scope, processing recipe identifier, relevant intermediate measurements, thresholds, decisions and uncertainty assumptions. A signal-detection decision must include the time and frequency interval actually examined. The record should say whether intervals were excluded owing to missing or invalid samples, overload or incomplete observation. A plot that fills an unavailable interval with a dark colour is a representation choice and must not imply that silence was measured. Likewise a remembered threshold displayed in a settings panel is not evidence that the same threshold was applied during an earlier run. The operative parameter value belongs in the decision record.

Independent reproducibility means that a competent person outside the original programming team can follow documented instructions, obtain the authorised inputs, execute a controlled version of the pipeline and account for differences. It does not mean that sensitive recordings should be published indiscriminately. The institution can arrange secure access, minimised excerpts, test vectors and segregated legal authority while retaining proper auditability. If access restrictions prevent an examiner from reproducing a claim, the final report should identify that limitation. Privacy, reproducibility and lawful authority are related governance problems, not reasons to conceal an unexamined algorithm behind an impressive certificate.

Copyright 2026, James M. Atkinson

Finally, every correction should preserve its ancestry. A changed firmware image, revised calibration or repaired overflow handler should produce a newly identified processing environment and a new derivative record. It must not overwrite the historic computation and then assert that the original was always correct. A system that preserves the wrong answer and explains how it was wrong is often more useful to forensic review than one that silently replaces a difficult record with a tidy result. My recommendation is to treat the reproducibility dossier as an executable specification of the calculation, a provenance record of the input, and an honest inventory of what the software cannot prove. I pass the token to the experts who will test whether the specification actually determines the result.

Sir Karl Raimund Popper, Peer Question: Admiral Hopper, your proposed execution dossier is thorough, but I would ask whether it can survive an adversarial attempt to falsify its central claim. It is easy to select two familiar test recordings, reproduce their visible output and infer that the whole receiver pipeline is reliable. That inference may be unjustified. A concealed dependency could alter a detection threshold only in a narrow frequency range; a faulty driver could corrupt data solely when buffers overflow; a proprietary FPGA image might be replaced while preserving an apparently identical software version string. Which trials would you demand expressly because they could refute, rather than merely confirm, the asserted equivalence? How should investigators handle a procedure that cannot be tested independently because part of its executable environment is unavailable? And would you agree that reproducing the precise errors of a defective instrument is sometimes useful evidence of computational

Copyright 2026, James M. Atkinson

continuity, even though it does not validate the physical conclusion? Please explain how the report should distinguish these propositions for a reader who sees only the polished final waterfall.

Grace Brewster Murray Hopper, Response: Sir Karl, a meaningful test must be capable of detecting the departures it claims to rule out. I would write the assertion first: for these fixed input bytes and this declared processing recipe, the second system will calculate matching stage outputs within the published tolerance and reach the same decision except in the explicitly identified indeterminate zone. Next I would enumerate plausible counterexamples. Replace the recorded firmware digest with that of a different image; alter a filter coefficient; exchange I and Q; change the sample rate metadata; suppress a buffer-discontinuity flag; and substitute another detector threshold. The harness should report which counterexample it actually detects. If it fails to notice a change that affects the scientific conclusion, it has not vindicated the assertion. That is a falsifiable engineering statement, not a declaration that an application is reliable in every imaginable circumstance.

A single waterfall image is a poor comparison oracle because it is deliberately lossy. Colour quantisation, limited screen resolution and plotting scales can make different numeric spectra appear nearly identical. I would retain numerical arrays before the colour mapping, a compact set of intermediate stage digests where exact comparison is meaningful, and explicit detector scores with their thresholds. An altered window may affect leakage near a weak adjacent tone while leaving the dominant signal's colours unchanged. An altered threshold may leave the entire image unchanged while reversing a flag in the event register. A genuine negative-

Copyright 2026, James M. Atkinson

control test should be chosen to expose that separation. The evaluator must not let an operator's visual judgement substitute for a quantitative result.

Proprietary parts need carefully defined treatment. A manufacturer might provide a reproducible binary image and a signed technical description without exposing all source code. That can permit tests of image continuity and external behaviour, but it cannot amount to an independent formal audit of an unavailable algorithm. The examiner should report which contracts were tested as black boxes, which internals were inspected, and what residual uncertainty remains. Where the FPGA image cannot be preserved or identified at all, one cannot later claim the same execution environment was reconstructed. Such a limitation is not cured by a manufacturer's assurance that the receiver was set to its usual configuration.

As to reproduced errors, I agree they can be illuminating. If two controlled replays reproduce a known sign inversion or a scaling defect, they may show that an earlier erroneous calculation was executed consistently. The finding belongs in a historical reconstruction of the evidence, not in an assertion of correct RF interpretation. Preserve both the original derivative and any corrected derivative with separately protected identifiers, and explain the effect of the fault on prior reported conclusions. The institution should resist the temptation to hide defective calculations once a correction is available. Independent reproducibility is strongest when it preserves uncomfortable evidence and makes clear precisely which claim each experiment did, or did not, establish.

Dr. James M. Atkinson, Moderator: I thank Grace Brewster Murray Hopper for identifying the evidence boundary. With respectful passage of the token,

Copyright 2026, James M. Atkinson

I invite Alan Mathison Turing to examine the next distinct technical layer. The historical specialists are participating in a fictional modern educational discussion, not an actual recorded meeting.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Third Principal Contributor: Dr. Atkinson, a reproducible computational process is one whose relevant operations have been described sufficiently precisely for another computing system to carry them out, but the word relevant requires attention. If a practical receiver employs an adaptive filter, randomised estimation or parallel execution, it may not generate identical machine words on every occasion. The investigator must therefore state whether the proposition concerns identity of execution, equivalence of mathematical operations, or robustness of a scientific decision. A machine that gives the same answer because a programming error recurs has exhibited repeatability, not validity. Conversely, two calculations that differ in their final decimal place may agree in every physically meaningful respect. The rigorous question is what observations and transformations determine the conclusion, and what tolerance a contrary outcome would have to cross.

I should begin with a state-transition description. Let a computational stage receive an input vector, a set of coefficients, an internal state and a declared numerical model. Its output is determined, or described as random under a fully specified stochastic model, only when those components are known. An adaptive noise estimator may depend on earlier blocks, rejected observations and reset policy. It is insufficient to preserve the short interval in which a peak appeared if the noise threshold was derived from the preceding half-hour. Likewise, when samples are missing, the application may hold its filter state, reset it, interpolate or process a synthetic zero sequence. Each choice changes the result. The replay record should include the initial and final state of consequential stages or enough earlier observations to reconstruct them.

Copyright 2026, James M. Atkinson

A modern pipeline is also a set of transformations between representations, and errors are particularly likely where one representation meets another. Complex samples may be stored as signed little-endian integers yet consumed as floating-point values after scaling. The scale factor could be voltage per code, relative full scale or an arbitrary software convention. An FFT implementation may return unnormalised complex coefficients while a later power calculation assumes unitary scaling. A frequency display might place the zero-frequency bin in the centre after an FFT shift, whereas a classifier could operate in unshifted order. If the internal contract is ambiguous, two teams can each produce a plausible plot while assigning different frequency labels to an identical bin. A formal example should expose the conventions rather than conceal them beneath an application's name.

Consider an authorised test stream with nominal complex sample rate 2,000,000 samples per second and a transform length of 4,096. The nominal bin spacing is 2,000,000 divided by 4,096, or 488.28125 hertz. If a second application mistakenly imports a sample rate of 1,920,000, it will assign 468.75 hertz between bins, even though it computes an identical transform array. An image configured to show only relative bin numbers can mask the disagreement. This is a transparent hypothetical calculation, not a measurement of actual hardware accuracy. A proper test preserves the sample rate provenance and checks the physical frequency axis as well as the arithmetic output. The error demonstrates that repeatability of the FFT is not repeatability of the frequency determination.

My second thought concerns the words exact and equivalent. Floating-point arithmetic is sensitive to order of summation, rounding mode, compiler

Copyright 2026, James M. Atkinson

optimisations and instructions that combine multiplication with addition. A parallel reduction may sum small powers in a different order from a serial programme. That need not invalidate a measurement, but one cannot infer acceptance from a vague statement that computers differ. For every critical output define an absolute tolerance, a relative tolerance where sensible, and a special rule near zero or a decision boundary. Document the maximum observed discrepancy on a frozen suite of test vectors. Where a small discrepancy can reverse a classification, the test must disclose that instability instead of enlarging the tolerance until all desired results pass.

I propose a decision-oriented validation experiment. Freeze a reference IQ input and all explicitly modelled parameters. Execute it on two independently prepared systems, compare exact input bytes, compare decoded numerical samples, compare each stage's output within its declared contract, then compare event labels. Introduce a synthetic event deliberately placed above the nominal threshold, another below it and a third nearly equal to it. The laboratory should report the margin between score and threshold for each event. If two systems agree on the far cases and disagree on the near case, the result reveals a precision-limited decision boundary that deserves disclosure. It is not repaired by taking a majority vote or ignoring the inconvenient case.

The negative controls should probe causality. Deliberately alter a window normalisation constant, reverse the byte order, change a resampler's initial condition and substitute a different threshold file. For each alteration predict which intermediate checks will fail and which final metrics might remain unaffected. A test suite that detects only gross corruption is not equivalent to a proof that all processing states are identical. The most

Copyright 2026, James M. Atkinson

convincing evidence is not that the systems pass, but that the checks fail when the specified contract is violated. If the final colour map is unchanged while numeric arrays diverge, the test should name the stage at which the divergence first appears.

There is, however, a boundary between mathematical reproducibility and the origin of the data. An algorithm receiving the same fabricated IQ stream may calculate it flawlessly on both systems. No amount of internal agreement establishes that the samples arose from the antenna, that the analogue gain was correct or that an alleged time marker was calibrated. To test those separate propositions the laboratory needs an independently characterised reference source, suitable monitoring equipment, a documented uncertainty budget and the receiver's acquisition history. A complete scientific account therefore contains two experiments: one reproduces the processing of fixed bytes, and another checks the acquisition system against controlled physical stimuli. Neither experiment substitutes for the other.

I would treat the final report as a set of propositions each accompanied by the evidence that supports it. Proposition one: this exact byte sequence was preserved from a recorded custody event. Proposition two: this decoding contract converts it into the stated numerical sample array. Proposition three: the named computational graph produces stage outputs consistent with the comparison specification. Proposition four: an independently calibrated acquisition supports the asserted physical interpretation within the stated uncertainty. If the fourth proposition is not tested, the report must not borrow certainty from the first three. A responsible scientific manuscript can be elegant while preserving every necessary caveat. I pass

Copyright 2026, James M. Atkinson

the token to the coding specialists to examine corrupted records and error detection.

Charles Sanders Peirce, Peer Question: Mr. Turing, you describe a hierarchy of computational, numerical and physical claims. I wish to examine the step from a series of successful repetitions to a warranted general rule. If two machines return matching spectra on a collection of laboratory vectors, the evidence supports those tested conditions, but does it support a claim that an unknown receiver capture was correctly interpreted? What of a test suite chosen because the available instruments happened to perform well upon it? A programme that treats an invalid interval as zero may nevertheless pass all cases lacking dropouts. How should the investigative institution enlarge the range of circumstances in a principled way without announcing universal accuracy? I am also interested in the status of a surprising but repeatable observation. Can the analyst classify it immediately as an emitter, or should it remain a hypothesis until independent acquisition and reference-plane controls are applied? Please answer in terms a forensic examiner can record as distinct stages of inquiry.

Alan Mathison Turing, Response: Mr. Peirce, one must distinguish a general assertion about a programme from a statement about the data on which that programme has been tested. A finite set of successful trials supplies evidence of correct operation under the covered conditions; it cannot demonstrate correctness for all possible inputs, implementations or physical circumstances. We can strengthen the evidence by selecting a test collection that exercises defined failure classes, including discontinuities, large and small magnitudes, sign changes, boundary conditions, reference-clock deviations and saturation. We can also compare the output with an

Copyright 2026, James M. Atkinson

independently implemented calculation based on the same mathematical specification. Still the proper report says exactly which classes were examined and which assumptions were left untested. It should not treat the familiar phrase 'industry standard' as a substitute for that inventory.

Where test cases have been selected after observing performance, preserve that history. A set assembled to accommodate the device's limitations can serve as a development exercise, but it is weak evidence for reliability under conditions never included. A reserved challenge suite assembled by an independent party would be more probative. One can also use controlled perturbations to test whether the programme responds in the expected direction: double the amplitude of a small synthetic input within the linear range and examine the change in spectral power under a declared scaling; alter the sample rate label without changing the bytes and check whether frequency labels change while raw FFT coefficients remain fixed; insert a gap marker and ensure that the decision process excludes observations that were never made. These tests are valuable because their expected effects can be derived in advance.

A repeatable anomaly should begin as an observation with a bounded claim. If an unexpected spectral line appears in the output on every replay of a saved IQ file, we have evidence that the saved bytes and pipeline reliably produce that line. We have not yet established that the originating analogue event was a distinct external transmitter. A receiver intermodulation product, clock spur, data-format error or front-end overload may create the same pattern. The next phase is independent acquisition under altered antenna, gain, attenuation or reference conditions with an appropriate lawful authority. If the anomaly persists in a form that survives those

Copyright 2026, James M. Atkinson

controls, the set of plausible hypotheses can be narrowed. The document must not silently promote an image feature into an attributed emitter.

I would maintain an evidence ledger with four fields for every substantial proposition: the asserted fact, the specific supporting observation or computation, the competing explanation that remains plausible, and the proposed independent control. That structure makes inferential progress visible without pretending that uncertainty is failure. A second evaluator can then reproduce the calculation, challenge the control and adjust the interpretation without rewriting the original observation. The method is applicable to ordinary receiver engineering as well as forensic examination. Its central virtue is to turn a surprising but reproducible result into a testable question rather than a prematurely completed story.

Dr. James M. Atkinson, Moderator: I thank Alan Mathison Turing for identifying the evidence boundary. With respectful passage of the token, I invite Richard Wesley Hamming to examine the next distinct technical layer. The historical specialists are participating in a fictional modern educational discussion, not an actual recorded meeting.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Fourth Principal Contributor: Dr. Atkinson, a receiver reproducibility programme ought to distinguish corruption in transmission or storage from a mistake in interpretation, since the remedies are altogether different. A digest of an input archive can reveal that its bytes no longer match a protected reference, subject to the cryptographic assumptions and custody procedure employed. A conventional error-detecting code can discover selected classes of accidental alteration; an error-correcting code may recover some corrupted symbols within a stated model. Neither mechanism can establish that an ADC was correctly configured or that a signal originated from the emitter later named in a report. The forensic failure occurs when the word integrity is applied indifferently to all these propositions.

Begin with the exact object being compared. If two investigators compute digests over different containers, the difference may arise from metadata serialization, timestamps or padding rather than from a changed numerical sample sequence. One must not discard the mismatch, but must identify its scope. A rewrapped copy could preserve every complex sample while changing an archive header; a swapped-endianness manifest could leave every original byte unchanged while changing the decoded waveform. Thus there are at least three levels of comparison: exact file bytes, decoded sample values under a named format contract, and physically interpreted measurements under a named calibration model. Every level requires its own test oracle. An equality assertion at one level does not automatically propagate to the next.

I would give the laboratory three deliberately adversarial objects. The first is a bit-for-bit clone of the nominated IQ file with a separately copied manifest.

Copyright 2026, James M. Atkinson

The second is a legitimate representation conversion, with values carried exactly where the target type permits, but with different file bytes. The third is the original file with a single inverted bit at a documented location. The full-file digest should recognise the clone and reject the changed bytes; the numerical equivalence test should admit the properly specified conversion where it is exactly reversible; and the provenance check should require that the conversion be a named derivative rather than passing it off as an unchanged original. These are different expected outcomes, and the acceptance harness should demonstrate all three.

We must also examine latent algorithmic corruption. If a file remains intact but the software reads signed sixteen-bit integers as unsigned sixteen-bit integers, no file-integrity mechanism will report an error. The decoded samples themselves are wrong. A robust test vector should contain positive values, negative values and boundary magnitudes so the mistake becomes visible. An IQ swap or conjugation can likewise alter phase and frequency sign while leaving some magnitude-only summaries approximately unchanged. Include a tone at a known positive frequency offset and another at a negative offset. The stage-level checks should identify which interpretation was applied, and the decision record should show whether a physical statement depended on that sign.

Bit errors and numerical precision have different practical signatures. A single corrupted high-order sample bit may produce an impulsive disturbance in the waveform and broad spectral leakage. Small floating-point rounding differences ordinarily produce much smaller and more distributed discrepancies, although threshold decisions can amplify even a tiny numerical difference into a changed label. Therefore a comparison of

Copyright 2026, James M. Atkinson

images or a single mean squared error can conceal both problems. I favour a suite that checks exact input digests, maximum sample difference, relative error of selected measurements, phase residuals and decision disagreements. Each test must state why its threshold was selected. If the laboratory sets a liberal tolerance solely to make a failed comparison pass, it has not validated the original claim.

Consider the effect of decimation. A receiver may reduce a complex sample rate by a rational factor after applying an antialias filter. Reproducing the output requires the actual filter coefficients, passband response, stopband response, rounding behaviour and delay convention. Two resamplers can produce similar-looking reduced-bandwidth records while differing materially near a narrow interferer or a short transient. A finite impulse response filter may also straddle a sample gap. If the replay tool simply joins the surviving blocks, it creates artificial adjacency and may smear a transient across a discontinuity. The gap mask should survive through the pipeline, with a declared rule for any output block influenced by invalid inputs. A file digest cannot reveal that an unobserved interval was silently treated as silence.

A reproducible programme should preserve evidence of negative results, not only successful event detections. If an overloaded front end or saturated ADC made a portion of the record unsuitable, that state must remain traceable even when the processed plot appears clean. Record the overload flag and its known limitations, the channel gain, any clipping count and the conditions under which valid samples were rejected. An engineer may choose to exclude a defective interval or apply a recovery method to a derivative, but those choices must be declared and must not be described as

Copyright 2026, James M. Atkinson

restoration of original RF information. Reprocessing is not the same as recovering a past observation that the instrument failed to acquire.

Testing error detection itself is a scientific question. A validation team should flip individual bits, truncate files at known boundaries, duplicate a block, shuffle blocks and change the manifest without changing the samples. The expected response is not identical for every fault. A protected digest should fail when its covered bytes change. A sequence checker should identify an impossible transition when device counters support that inference. A metadata-contract validator should reject an unsupported type or sample-rate declaration. An RF-level verifier should assess whether reference tones appear at the expected nominal frequencies under known conditions. A successful isolated check cannot certify the performance of the other checks. The test report should use a matrix of faults, applicable detectors, expected warnings and observed warnings.

I would close with the burden of explanation. An independent examiner must be able to say whether a discrepancy is one of custody, representation, algorithm, calibration or inference. Those categories make disagreements resolvable. A report that simply says that two programmes produced the same spectrum has discarded much of the information necessary to know what was repeated. Our object is not to make every file a permanent scientific truth; it is to preserve the conditional logic by which a particular measurement was interpreted. That logic may be challenged and improved without falsifying the original record. I respectfully yield the token for a wider examination of systems architecture and verification.

Bertrand Russell, Peer Question: Dr. Hamming, I should like to identify precisely what is meant by the assertion that a stored file is unchanged. A

Copyright 2026, James M. Atkinson

cryptographic digest over the file bytes might agree perfectly between two investigators even though one interprets the representation as signed integers and another as unsigned integers. A derivative archive might have different bytes yet contain sample values that are equivalent under a documented conversion. How would you write an integrity claim that does not confuse identity of symbols with identity of their meaning? And how would you explain the status of an erroneous but faithfully preserved manifest? I am especially concerned with the familiar slide from 'we reproduced the calculation' to 'we reproduced the physical event'. There seems to be an unstated premise that the source data and its calibration reflect the world. Could you formulate the necessary assumptions and suggest a practical test that reveals whether those assumptions are being smuggled into the conclusion? Please include the case in which one receiver silently drops samples but later writes a continuous-looking file.

Richard Wesley Hamming, Response: Lord Russell, one must attach the word unchanged to an identified object and a defined period. If a suitably protected reference digest was calculated over a particular sequence of bytes at a specified custody event, and a later digest over the same scope agrees under a secure algorithm, that supports the proposition of byte continuity from that reference state. It does not prove that the originating file was genuine or that the accompanying metadata was accurate. If the original manifest declared the wrong signedness, a perfect copy can perpetuate the mistake. Thus the record should retain separate identifiers and integrity protections for the raw sample object, its descriptive manifest, its custody history and each subsequent analytic derivative. A reviewer can then distinguish a faithful but false description from a later alteration.

Copyright 2026, James M. Atkinson

Numeric equivalence requires an explicit decoding rule. Signedness, byte order, complex channel order, saturation, scaling and invalid-sample markers must be part of the contract. A representation conversion may be mathematically reversible for the values present while changing the file bytes. The examiner should state that the derived samples are numerically equivalent under the described conversion, not that the source file remained byte-identical. If quantisation or rounding discards information, the converted values cannot simply be called identical; record the error bound and any scientific consequence. The programme can verify each level with its own test: byte digest, decoded-vector comparison and calibrated reference experiment. No level permits unexamined inferences about the others.

The source-to-world inference needs at least an acquisition chain model. A named receiver, antenna and preselector must have been operated in a known configuration; the relevant analogue gains and calibration must be supported; the timing and sample-rate assumptions must be qualified; and the occurrence of overload, clipping or dropped samples must be checked. A controlled laboratory tone, independently observed where practical, can test parts of that model. If a receiver drops samples and writes a continuous-looking file, matching the final file digest on every replay establishes only that the already truncated sequence is stable. The missing interval remains absent. A native sample counter or documented overflow indicator may expose the omission, but if no such record exists the investigator should not invent a loss duration.

A useful cross-check is to alter one fact at a time. Keep the file bytes constant but change the signedness field and verify that the decoded

Copyright 2026, James M. Atkinson

sample comparison rejects the mismatch. Preserve the correct manifest but invert a selected bit, and verify that the protected file digest changes. Feed an authorised reference signal under a different gain setting and examine whether the calibrated output changes in the predicted manner. Introduce a deliberate buffer loss, then confirm that the downstream graph marks the gap instead of creating fictitious zero samples. Each test challenges a particular premise. In the final report, write every conclusion with its conditions: given the nominated bytes, the stated interpretation, the executed recipe and the calibration evidence, this value was obtained. The assumptions are not a nuisance attached after the result; they are part of the result's meaning.

Dr. James M. Atkinson, Moderator: I thank Richard Wesley Hamming for identifying the evidence boundary. With respectful passage of the token, I invite John von Neumann to examine the next distinct technical layer. The historical specialists are participating in a fictional modern educational discussion, not an actual recorded meeting.

Copyright 2026, James M. Atkinson

John von Neumann, Fifth Principal Contributor: Dr. Atkinson, there is a temptation to describe the receiver as a single programme, but a modern SDR is a system of interacting machines. Analogue components condition the electromagnetic field before digitisation, programmable logic may filter or decimate samples, driver software transfers buffers, a host processor computes spectral estimates, and an operator interface selects what is displayed. Each component possesses a configuration and, often, a history-dependent state. A reproducibility argument that begins only when the host application receives bytes may be sufficient for reproducing an offline calculation; it is not sufficient to establish that a past observation was made under the stated RF conditions. We must draw the system boundary explicitly.

I propose a provenance graph in which every substantial evidence object and computational transformation is a node. The raw sample file, protected acquisition metadata, calibration certificate, firmware and FPGA identities, driver, processing code, numerical libraries and analysis recipe are referenced by verifiable identifiers. Directed edges show which versions and inputs produced each derivative. This is not a mystical diagram: it must be backed by actual stored objects and recorded operations. A hash of one node protects a specified byte sequence from unnoticed change under stated custody assumptions, while a signed manifest may connect nodes if its signing keys and controls are trustworthy. The graph itself should preserve previous versions so that a later correction does not erase the history of the analysis.

The graph needs to state which transformations are pure and which are stateful. A pure numerical transform on a declared vector and parameters is

Copyright 2026, James M. Atkinson

comparatively straightforward to reproduce. A block processor that adapts its noise estimate over time has hidden state unless its starting state and processing history are recorded. A receiver that changes gain automatically is not processing the same physical quantity throughout the capture unless the gain changes and settling periods are identified. An FPGA that applies a decimation filter with an unknown initial state may produce a brief boundary transient that no downstream replay can reproduce from the exported samples alone. The report must distinguish what was observed from what cannot be reconstructed without unavailable state.

Timing is another hidden connection between subsystems. The nominal sample rate printed by the host does not by itself establish the ADC aperture times. Host clock timestamps may describe transfer completion rather than acquisition. If the sample counter advances across a dropout while the file writer omits bytes, subsequent processing must retain an explicit gap. Interpolated values may be useful for certain exploratory displays but cannot become evidence of a received signal during the missing interval. In an independent replay the gap mask is an input with the same importance as the sample data. A system that discards it cannot truthfully reproduce the scientific meaning of its time axis.

Consider three forms of replication. In the first, the same executable and inputs are run twice on identical hardware, yielding exactly the same bytes. That demonstrates a constrained form of determinism. In the second, an independent implementation of the stated algorithm processes the fixed source data and agrees within an appropriate numerical tolerance. This gives stronger protection against common implementation errors, though the two implementations may share assumptions. In the third, a calibrated

Copyright 2026, James M. Atkinson

experimental setup creates a new authorised RF stimulus and the receiver system produces a result consistent within measurement uncertainty. This tests acquisition and physical interpretation, not identity of the original historical samples. A defensible monograph should keep all three tests distinguishable.

The acceptance programme should include a calculation whose output is independently predicted. At a nominal complex sample rate of 2,000,000 samples per second and an FFT length of 4,096, the nominal bin spacing is approximately 488.28125 hertz. A script that changes the rate metadata to 1,920,000 while leaving the complex samples fixed produces a nominal spacing of 468.75 hertz. The transform's complex coefficients may be identical while the physical frequency labels differ. This hypothetical example can be checked without requiring any knowledge of a real emitter. A test harness should therefore compare not merely arrays but also units, axis definitions and reference-plane calibration. Where the source was not actually clocked at its nominal rate, further uncertainty must be included.

I would not demand bitwise equality where the scientific claim does not require it. An order-of-operations difference in floating-point accumulation can change the least significant digits of an average. If the same detector's score is far from a threshold, such variation may be immaterial. If the score lies near the threshold, a tiny difference can reverse the reported result, and that instability is material. The proper acceptance criterion is a predetermined tolerance connected to measurement uncertainty and decision risk, not a tolerance invented after viewing the outputs. For critical outcomes, report the numeric score, threshold, uncertainty and classification from both systems. If they disagree, retain the disagreement

Copyright 2026, James M. Atkinson

as evidence that the purported conclusion is not stable under the tested conditions.

We should distinguish systematic faults from random variation. A mismatched calibration constant can bias every estimate in one direction while leaving repeatability excellent. A changed FFT window alters leakage and effective noise bandwidth in ways that may affect short bursts or nearby tones. A threshold selected retrospectively to make an observed event look significant invalidates simple prospective false-alarm interpretations, even if that threshold can be replayed exactly. The test of a processing pipeline is therefore not only whether the calculations repeat; it also asks whether the chosen procedure was fixed independently of the outcome and whether the calibration and statistical assumptions remain sound. The reviewer should have access to both the development record and the final decision rule.

The most instructive experiment is blind. A second laboratory receives a protected copy of the IQ dataset, the processing contract, a declared software environment and a list of expected output types, but not the original analyst's final classifications. It produces intermediate numeric products and a decision record; a custodian compares them against the reference using thresholds agreed in advance. Next the custodian gives several intentionally altered configurations, including an IQ swap, an outdated filter coefficient, an omitted gap mask and a changed display palette. The system should identify substantive changes without treating a harmless colour difference as a numerical failure. This tests the discrimination of the verification procedure, not just the compliance of participants.

Copyright 2026, James M. Atkinson

Finally, governance must be visible in the evidence trail. An analyst may be fully entitled to process an authorised defensive capture without being entitled to retain decoded private communications indefinitely. Reproducibility can be achieved through minimally necessary inputs, secure access and well-documented protected test vectors. The custody ledger must identify the legal authority, access history and transformations but should avoid unnecessary reproduction of communications content. Scientific reproducibility is a demanding standard precisely because it forces institutions to describe what was done, what was preserved, what could not be repeated and why. I return the token to the moderator with a recommendation: validate each link in the computational chain and refuse to let a polished final image substitute for those links.

George Edward Pelham Box, Peer Question: Professor von Neumann, your provenance graph may be exact and still encode a model that is only approximately appropriate. A receiver's noise may not be stationary, its clipping indicator may miss brief nonlinear events, and a windowed spectral estimator can report a stable line where the input actually varies between short observation periods. If two laboratories use the same flawed noise model, they may reproduce a statistically misleading threshold while believing that numerical agreement constitutes an independent verification. What would you place in the acceptance report to distinguish a successfully reproduced model from evidence that the model describes the acquisition circumstances? I also ask about correlation between overlapping FFT segments. Could a programme create hundreds of nearly identical plotted frames from one short observation and then report hundreds of independent confirmations? Finally, explain how an analyst should revise a

Copyright 2026, James M. Atkinson

detection rule after discovering model inadequacy without retroactively assigning its new false-alarm properties to the original exploratory search.

John von Neumann, Response: Professor Box, the model must be treated as a proposition under examination, not as a ceremonial credential. The acceptance dossier should state the noise and signal assumptions used by the detector, what observations were used to choose parameters, how often those assumptions were checked, and which conditions would invalidate them. A computational replay can establish that both laboratories applied the same estimated noise variance and threshold. It cannot, merely by agreement, establish that the background was stationary or that the selected distribution described the actual observations. That requires a separate model-checking exercise on appropriate independent data. The report should not use the word verified without specifying whether it means verified calculation or supported physical model.

An overlapping FFT estimator illustrates the problem well. Suppose a 4,096-sample window advances 1,024 samples at each frame. Consecutive frames then share 3,072 samples, or 75 percent of the samples in each window. The numerical result may be useful for display continuity or improved temporal sampling of a spectral estimate, but those frames are not independent experiments. Counting them as independent confirmations can produce overconfident significance statements. The actual dependence depends on the window and signal process; a simple count of frames is not an effective sample size without further analysis. A sound pipeline records the window length, hop, window coefficients, averaging rule, frame count and exclusion of invalid intervals, and it keeps the inferential analysis separate from the graphical convenience of overlapping views.

Copyright 2026, James M. Atkinson

I would require a controlled residual analysis. Apply the detector to background-only records from the actual class of environment where it will be used, inspect variation over time and frequency, and compare observed false alarms against the prospective expectation. Use synthetic perturbations to test clipping, clock spurs, gain changes and nonstationary interference. Reserve at least part of the evaluation data outside the selection process. Where the background changes materially, the report should say that the originally specified false-alarm calibration is not established for those conditions. If the apparatus includes an adaptive estimator, its adaptation and reset policy are part of the computational graph. The numeric values may repeat faithfully while the statistical reasoning requires revision.

When a detection rule is revised, preserve the original rule, outputs and exploratory history. The new rule receives a version and is evaluated prospectively on new or appropriately reserved data. One may recalculate the old record as a transparent derivative and explain how conclusions change, but it is invalid to assign a post-selection prospective error rate to an already inspected search. A good archive enables later investigators to see both the computation that generated a suspicion and the separate experiment that tested it. I would regard this division as an essential feature of independent scientific reproduction. It prevents the authority of a repeatable programme from being mistaken for authority over the statistical premises that programme happened to employ.

Walter Andrew Shewhart, Peer Question: Professor von Neumann, I would ask how the institution should manage a receiver pipeline whose environment changes gradually rather than through an obvious software

Copyright 2026, James M. Atkinson

release. A calibration coefficient may be updated after a service visit, a numerical library may change when the operating system updates, and a filter may acquire a slightly different response as the analogue hardware ages. The monitoring team may continue to see familiar waterfalls and assume that the system remains stable. What control measurements and change records would distinguish ordinary variation from a change that invalidates comparability with historic observations? I am also concerned with the practical moment of release. Which reference checks should block acceptance when a revision crosses a predeclared limit, and which discrepancies may be documented as harmless without quietly relaxing the standard? Please address the case of a receiver that passes a routine tone check yet responds incorrectly to a brief broadband pulse, since a stable mean value may disguise a serious transient fault.

John von Neumann, Response: Dr. Shewhart, a maintained receiver pipeline should have both configuration control and periodic physical performance control. A change ledger names software dependencies, executable artefacts, firmware and FPGA images, calibration constants, hardware servicing, sampling-clock references and the identity of the operator or automated deployment process. The ledger is not merely an inventory: each relevant change triggers a predefined regression suite. A library upgrade might require renewed numerical comparison of known test vectors; a change of analogue filter or gain calls for RF calibration checks; an alteration to capture buffering requires a gap-detection test. The test selected must correspond to the part of the chain that could have changed.

I would distinguish reference controls for steady-state and transient response. A continuous tone at a known nominal frequency can detect

Copyright 2026, James M. Atkinson

certain scaling or frequency-axis errors, but it may not exercise an overload-recovery path, an impulse response or short-burst capture behaviour. A step, a brief pulse or a controlled multitone signal can challenge those mechanisms in a lawful laboratory. An independent monitor should confirm the applied stimulus where meaningful, and test records should state the operating gain, bandwidth and clock conditions. Calibration cannot simply be presumed stable because a single displayed line stays in place. Measurements near the detector's operational limits deserve explicit controls rather than an attractive chart.

Before release, declare limits derived from the actual required measurement performance. The laboratory should identify which failures block the build and which bounded discrepancies are acceptable under a defensible uncertainty budget. A changed numerical output that remains within tolerance may be recorded as numerical equivalence; if the tolerance was not fixed before the test, acceptance is not yet established. A failed transient check should not be overridden because the average tone check passed. Nor should an operator hide a material difference behind a favourable selection of display scale. A programme may be released with a stated restricted scope if the evidence supports that restriction and relevant authorities accept it, but the restriction must travel with the data and any report relying on the programme.

Long-term comparability requires preserved versions of the reference experiments, not just a running success indicator. A later examiner should be able to see whether an historical measurement used calibration coefficient A rather than coefficient B, and which numerical library and sample decoder were operative at the time. New analysis may be performed

Copyright 2026, James M. Atkinson

on the original data under a new pipeline, but it must be labelled as a derivative. That separation allows the institution to investigate drift without falsifying history. The strongest form of process control is not never observing a change; it is detecting a change, understanding its consequence and preventing unqualified comparison until the new conditions have been validated.

Dr. James M. Atkinson, Moderator: The five principal contributions and seven answered ordinary peer questions have separated bitwise file equality, software execution and calibrated RF inference. I now pass the token through four reciprocal examinations of four different named respondents. Each reply shall address its immediately preceding question, without claiming that repeatability alone authenticates a physical source.

Alan Mathison Turing, Cross-Peer Question to Grace Brewster Murray Hopper: Admiral Hopper, your operational dossier contains source revisions, executable digests and device identities, yet I should like to know whether it records the actual computational route taken during an adaptive decision. Imagine two installations loading nominally the same classifier but using different CPU vectorisation instructions. Both pass a reference tone and present essentially identical waterfalls. During a rare buffer discontinuity, however, a fallback branch executes on one machine and not the other, producing a different threshold decision. Would you treat the two pipelines as independently reproduced if their usual-case outputs matched? How would you capture the path through conditionals, state changes and exception handlers without logging every sensitive sample twice? I also ask what should happen when the same software release dynamically selects between two FFT backends. A simple version number does not resolve which

Copyright 2026, James M. Atkinson

backend was invoked. Please explain how you would audit the operative branch and prove that the evidence record is not merely a list of intended settings.

Grace Brewster Murray Hopper, Cross-Peer Answer to Alan Mathison Turing: Mr. Turing, I would not call the pipeline independently reproduced for that exceptional case merely because the ordinary case passed. The claimed equivalence must be scoped to conditions actually exercised. Where the branch is relevant to a reportable detection, record the transition condition, branch or backend identifier, numerical input and output summaries sufficient to examine the decision, and the configuration hash or signed code version that governs the branch. This can be done without copying protected communications content into every diagnostic log. The analyst may preserve a protected reference to the original sample interval, a fixed numerical checksum over an intermediate array, a record of the state-transition event, and the exact parameter values used. The technical log should distinguish data needed to reproduce the algorithm from personal content not needed for the authorised purpose.

A dynamic dispatch mechanism must be made explicit. If the application chooses an FFT implementation according to CPU architecture or available accelerator, the actual selected backend and library build should be logged. The acceptance suite must test the numerical equivalence of each supported branch under the desired tolerances. It is insufficient to claim that the backends implement the same mathematical Fourier transform; their scaling, ordering, precision, rounding and exceptional-value behaviour may differ. If one code path has never been validated on the relevant input class, the report should say so. The fact that a fallback is rarely entered does not

Copyright 2026, James M. Atkinson

convert an unknown into a proven condition. A rare path may be precisely where missing samples or overload produce a serious evidential error.

I would also record state transitions independently of the final plot. A filter reset, an overflow marker, a change in gain, a threshold adaptation and a change of FFT backend can each alter the meaning of subsequent outputs. A compact event log with monotonically ordered identifiers and links to source sample offsets may provide adequate reconstruction, provided its own reliability was tested. It should record absence or failure of logging as a condition, not silently assume that no recorded event means no event occurred. A later examiner must be able to discover that the programme's diagnostic channel had been disabled. The controls protecting these logs are part of the evidential chain; a self-reported event log generated by an untrusted programme is not independent attestation of its own correctness.

To test the system, force the normal and exceptional branches with controlled synthetic IQ data and induced buffer conditions. The independent examiner should predict which path will run, verify the emitted identifier, compare intermediate arrays and check the final decision. Repeat the test on both processor architectures and record every discrepancy. If a decision disagrees under a permissible numerical tolerance because its score lies near threshold, the correct classification may be indeterminate rather than a forced equivalence. Corrected builds receive new identifiers and must be rerun. I would consider the pipeline reproduced only to the level supported by these experiments. One tested configuration cannot grant blanket assurance to unexecuted code paths, particularly where those paths alter evidence exclusion or threshold decisions.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, let us suppose our source IQ bytes are hashed and unchanged, but a later investigator discovers that the original manifest declared the wrong full-scale reference. A new derivative corrects the voltage scaling, and the spectral power values shift in an entirely predictable way. The new calculation produces different numerical arrays yet is arguably a more accurate interpretation of the historical record. How should an evidence system maintain both versions without describing the correction as a tampering event? What kinds of checksum and semantic checks would distinguish byte continuity from a correction to the interpretation contract? I also wish to ask whether a small numerical error bound is adequate when the processing graph includes a nonlinear detector that turns a slight difference into a new event label. Please distinguish a benign conversion from loss of information and give a suitable acceptance test that an external examiner could reproduce without needing to trust the original programmer.

Richard Wesley Hamming, Cross-Peer Answer to Grace Brewster Murray Hopper: Admiral Hopper, the evidence system should preserve the original sample bytes and their original reference digest, the historic manifest and its own integrity record, and the revised manifest with a dated explanation of the scaling correction. A newly generated derivative carries a new object identifier, revised processing recipe and digests of its actual bytes. The old result remains discoverable and labelled as superseded or qualified; it is not erased. If the raw samples remain unchanged, that fact may be established independently of the changed voltage interpretation. An analyst can therefore say that byte continuity was maintained while a documented

Copyright 2026, James M. Atkinson

correction altered the physical scale. The distinction avoids both false allegations of tampering and false claims that nothing substantive changed.

I would have the verification suite compare sample arrays at the stage where conversion takes place. If integer codes are unchanged and only a linear voltage-per-code factor is corrected, a reference vector containing positive, negative and boundary values can show that the transformation obeys the new scale. If earlier processing clipped, quantised or resampled the data, the revised scale cannot recover values already discarded. The report should not pretend that a mathematically reversible unit conversion restores missing analogue information. It is essential to identify the reference plane for the claimed voltage and to verify that the hardware's calibrated gain actually supports it. The numerical conversion is testable on stored bytes; the analogue calibration may require separate instrument evidence.

Checksum equality has no general semantic implication. A protected digest verifies bytes over its declared scope. It cannot say whether a voltage factor is correct, whether the sample rate was calibrated, or whether I and Q were reversed during acquisition. A metadata-contract validator can catch contradictions between fields and a known equipment specification, but even a syntactically valid manifest may contain a false value. Negative controls should alter the scale, signedness and byte order independently while leaving raw bytes fixed, and confirm that the appropriate stage comparison detects each change. A clean programme should also reject a manifest whose version or required fields it cannot interpret. Quietly supplying default values is convenient in consumer software but hazardous in a forensic measurement chain.

Copyright 2026, James M. Atkinson

As to the detector, a small numerical difference is not necessarily a small inferential difference. If the original power score barely exceeded a threshold, a corrected scaling may reverse the reported event flag. The acceptance test therefore needs both a numerical tolerance for the stage values and a separate criterion for decision agreement, including a specified region of uncertainty near the threshold. Compare the old and new score, threshold, measurement uncertainty and decision, and disclose any changed conclusions. A false-alarm rate selected or calibrated for the old units cannot simply be carried forward to a different physical scale without checking the detector model. An independent examiner should be able to reconstruct each calculation and understand why the improved one differs. That is responsible correction, not a defect in preservation.

Richard Wesley Hamming, Cross-Peer Question to John von Neumann: Professor von Neumann, I ask about the provenance graph when it contains many linked artefacts but no independent check of the actual acquisition hardware. A system may retain every software binary and digest, yet a frequency offset in the sampling clock could cause all subsequent FFT frequency labels to be biased. Another system might reproduce the identical bias with impeccable computational fidelity because it uses the same incorrect rate metadata. How should the graph distinguish the experimental claim that a physical signal occupied a particular radio frequency from the computational claim that a fixed array maps to a particular nominal bin? Must the original calibration and reference measurements become first-class evidence objects rather than administrative attachments? I also ask how one should handle a revised uncertainty model: if an engineer later discovers that the reference-clock stability had been overstated, can the

Copyright 2026, James M. Atkinson

original calculations remain reproducible while the historical interpretation changes? The archive must surely allow that distinction without claiming to have measured the past a second time.

John von Neumann, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, calibration and reference observations must indeed be first-class nodes in the provenance graph. A claim about nominal bin location is determined by the stored sample array, transform length and declared sample rate, but a claim about actual radio frequency also depends on the accuracy of the acquisition clock and frequency reference, the receiver's tuning state and the conversion chain. Their documentary support cannot be relegated to a filename called 'calibration' without identifying which instrument was tested, when, under what conditions and with what stated uncertainty. The graph should connect the particular capture epoch to the applicable calibration evidence and indicate any assumptions needed to transfer that calibration to the field measurement.

If the nominal sample rate is wrong, an independently repeated FFT may still produce identical complex coefficients. The frequency axis constructed from the wrong metadata will be consistently wrong as well. That is precisely why an experiment using a known physical reference stimulus belongs beside the offline replay. A second-host calculation tests the processing of fixed bytes; a calibrated stimulus and an independent monitor test elements of the physical acquisition model. If the original capture cannot be repeated, one may test similar hardware to inform uncertainty, but that does not amount to recreating the historical electromagnetic event. The report should distinguish the provenance and relevance of any later measurement from the specific evidence acquired at the earlier time.

Copyright 2026, James M. Atkinson

A revised uncertainty model can be incorporated without overwriting the historic result. Retain the original calibration statement and the original calculation, then publish a new interpretive derivative explaining why the prior clock uncertainty was understated. The new version should include its assumptions, updated uncertainty calculations and effect on each reported frequency or timing claim. A statement that a historic line was observed at a precisely asserted frequency may need to be weakened to a broader interval. The fact that the original numerical processing remains bitwise reproducible does not immunise the physical conclusion against later corrections. Science gains credibility when it can revise interpretations while preserving its observation record intact.

For acceptance, I would define separate evidence gates: integrity of the original bytes; consistency of representation and processing; calibration and clock traceability; and sufficiency of the inference for the authorised reporting purpose. A failure at the physical gate cannot be cancelled by passing the computational gate. Conversely, a changed software library need not negate a physical observation if an independent algorithm reproduces the pertinent measurement within justified tolerance. The graph should expose both dependencies to the reviewer. Its value lies not in making every connection unquestionable but in allowing the investigator to identify exactly which connection supports a contested proposition and which connection remains uncertain.

John von Neumann, Cross-Peer Question to Edsger Wybe Dijkstra: Dr. Dijkstra, we have considered exact byte identity, numerical tolerance, software configuration and calibrated experiments, but a final methodological danger remains. A laboratory may implement every check

Copyright 2026, James M. Atkinson

you propose and still report one undifferentiated word, 'reproduced', on the cover of its report. In particular, a black-box comparison may establish matching output over a fixed suite without exposing the state transitions that gave rise to it. How should a formal assurance statement separate the existence of the original source file, the computational equivalence of its interpretations, the stability of detection decisions and the validity of an emitter inference? I also ask what evidence would lead you to refuse an unqualified conclusion even if all visible tests had passed. A thoughtful reviewer must know whether successful testing is sufficient merely for a bounded engineering statement or for a much stronger assertion about an event beyond the receiver. Please specify the narrowest honest vocabulary the institution should employ.

Edsger Wybe Dijkstra, Cross-Peer Answer to John von Neumann: Professor von Neumann, I would forbid the unqualified word because it conceals the predicate. We should instead write 'the nominated bytes were identical to the protected reference', 'the specified decoding produced equal complex sample values', 'the named processing stages agreed within declared tolerances', or 'the independent laboratory obtained a consistent measurement of the authorised reference stimulus within stated uncertainty'. These are testable statements with different premises. A detection classification should be described separately, with its score, decision boundary and sensitivity to numerical variation. An emitter attribution involves additional physical and contextual evidence and must not be inferred from a matching waterfall. Precision in language is a form of engineering control when the words govern legal and operational decisions.

Copyright 2026, James M. Atkinson

The assurance record should include the input object's identity and hash scope, the complete decoding contract, the graph version and executable environment, the comparison metrics at consequential stages, and the test inventory including deliberately failing controls. It should identify which cases were not run and why. If a black-box element cannot expose sufficient internal state, the permitted claim may be limited to externally observed equivalence on the tested vectors. The inability to inspect its logic is not necessarily a reason to discard every result, but it is a reason to refuse an assertion that the internal implementation was independently verified. A conscientious researcher does not extend a finite experiment to universal certainty through an adjective.

A report also requires a record of the experiment's prior decisions. The acceptance tolerance should be published before the blind comparison. The classifier threshold and statistical model should not be retroactively chosen after seeing the event. If the team changed the processing recipe during debugging, it should preserve the older run and assign a new identifier to the repaired one. A failing near-threshold case cannot be made to disappear by silently changing rounding policy or excluding the interval. The result may legitimately be indeterminate; that is a scientific outcome rather than an embarrassment. Unqualified conclusions should be withheld when a material decision depends on an unverified branch, a disputed clock, an unexplained sample gap or a calibration outside its established validity.

Finally, my assurance vocabulary would separate computation from observation and observation from inference. The first describes actions performed on bytes; the second concerns a physical event observed through instruments; the third connects that observation with a proposition

Copyright 2026, James M. Atkinson

about an external source. A programme can be perfectly deterministic while the observation is corrupted; an observation can be reliable while a downstream classifier is mistaken; and a correct classifier can identify a waveform family without identifying its owner. Each transformation between those propositions calls for evidence. The strongest roundtable conclusion is not that modern software can guarantee the truth, but that a well-designed record permits a later independent examiner to locate the exact boundary between proven continuity, validated calculation and residual doubt.

QUESTION 095. TECHNICAL SOURCE NOTES. This contemporary dialogue is a fictional scholarly reconstruction and does not represent quotations or an historical exchange among its deceased experts. Selected technical background references: National Institute of Standards and Technology, NIST SP 800-86, Guide to Integrating Forensic Techniques into Incident Response (2006), https://csrc.nist.gov/pubs/sp/800/86/final, a general digital-evidence process guide rather than RF measurement validation; Signal Metadata Format, SigMF Specification Version 1.2.6, https://sigmf.org/, providing metadata fields and a structure for recorded samples but not guaranteeing correctness of physical capture; SciPy v1.18.0 signal.welch documentation, https://docs.scipy.org/doc/scipy/reference/generated/scipy.signal.welch.html, documenting power spectral density conventions and Welch processing parameters. Engineering claims about calibration, actual firmware behaviour, legal authority and proprietary numeric implementations require separate instrument-specific source checks.

Copyright 2026, James M. Atkinson

QUESTION 095. TEN WORKED CHECKS. Each variable is defined within its example. All numbers are hypothetical and must not be presented as measured radio-frequency evidence. These checks verify limited arithmetic relations, not full software or measurement validity.

EXAMPLE 1. Hypothetical FFT bin spacing: for a nominal complex sample rate F_s = 2,000,000 samples/s and N = 4,096 FFT points, $\Delta f = F_s/N$ = 2,000,000/4,096 = 488.28125 Hz. This is an axis calculation, not a verified ADC clock calibration.

EXAMPLE 2. Changed metadata only: if the same complex samples are labelled F_s = 1,920,000 samples/s with N = 4,096, Δf = 1,920,000/4,096 = 468.75 Hz. Identical FFT coefficients can therefore receive different nominal frequency labels.

EXAMPLE 3. Overlap of windowed frames: with frame length N = 4,096 samples and hop H = 1,024 samples, overlap N−H = 3,072 samples and fractional overlap (N−H)/N = 3,072/4,096 = 0.75 = 75%. The two frames are not statistically independent by virtue of being stored separately.

EXAMPLE 4. Capture duration: for S = 16,384 consecutive valid complex samples at F_s = 2,000,000 samples/s, duration $T = S/F_s$ = 16,384/2,000,000 = 0.008192 s = 8.192 ms. Missing samples require a distinct gap record.

EXAMPLE 5. Power-ratio conversion: a power ratio R = 2 corresponds to G = 10 log10(R) = approximately 3.0103 dB, not 6.0206 dB. Voltage and power gain conversions must not be conflated.

EXAMPLE 6. Density integration over a nominal flat band: $P = S_p B$, where $S_p = 1\times10^{-10}$ V^2/Hz and B = 1,000 Hz gives $P = 1\times10^{-7}$ V^2; the approximation

Copyright 2026, James M. Atkinson

assumes constant density over the band and appropriate reference impedance/measurement conventions.

EXAMPLE 7. Raw-file size: for N_s = 1,000,000 complex samples stored as interleaved 16-bit I and 16-bit Q, bytes per sample = 2 + 2 = 4 and total size = $N_s \times 4$ = 4,000,000 bytes before any headers.

EXAMPLE 8. Raw throughput: at F_s = 2,000,000 complex samples/s and 4 bytes/complex sample, throughput = $F_s \times 4$ = 8,000,000 bytes/s, excluding framing, overhead and recording duplicates.

EXAMPLE 9. Power SNR: if signal power P_s = 1,000 arbitrary matched units and noise power P_n = 100 of the same units, the ratio is P_s/P_n = 10, giving SNR = 10 log10(10) = 10 dB, contingent on matched measurement bandwidth.

EXAMPLE 10. Clock-rate offset: a nominal F_s = 2,000,000 samples/s with an actual relative rate deviation $\varepsilon = 1\times10^{-6}$ implies absolute rate difference $F_s\,\varepsilon$ = 2 samples/s. This is a sample-count drift illustration, not a measured timebase uncertainty.

EDITORIAL QUALIFICATION. All deceased-expert speech in this modern fictional symposium was composed for the textbook and is not archival testimony. Byte-level continuity, numerical repeatability, acquisition authenticity, emitter attribution and legal permissibility are separate propositions. Stage A verifies specified structural requirements only; source-to-claim correspondence, historical suitability, mathematical and electronic-engineering correctness, broader semantic novelty and full continuous publication proof remain outstanding. Sample content must be minimised and preserved only with appropriate authority.

QUESTION 096

Copyright 2026, James M. Atkinson

Why must exploratory threshold adjustment be separated from confirmatory RF tests?

Dr. James M. Atkinson, Moderator: Professor Neyman, a receiver operator can examine a broad waterfall, adjust a threshold until several intriguing patches become visible, then report that the same display offers statistically significant evidence of discrete transmissions. Yet the choice of threshold may depend upon the very fluctuations the operator seeks to evaluate. I invite you to separate exploratory discovery from prospective confirmation, explain the effect of multiple time-frequency comparisons and correlated windows, and propose a lawful calibration experiment in which software-defined receivers are evaluated on genuinely independent test records. Please distinguish the physical acquisition chain from the statistical decision rule, and be especially careful not to convert the visual appearance of a signal into an unsupported claim identifying its source. This is a fictional scholarly debate written for the present textbook.

Copyright 2026, James M. Atkinson

Jerzy Neyman, Principal Contributor: Dr. Atkinson, the central confusion arises when one treats a rule selected after inspection as though it had been prescribed independently of the observations. A statistical test requires a defined question, a test statistic, an acceptance or rejection region, a background model and a decision rule whose performance is to be evaluated. If a receiver analyst looks at a recording, experiments with a succession of thresholds and chooses the one that makes a particular peak appear exceptional, the resulting decision is conditioned on a selection process. The reported nominal probability calculated for one fixed threshold does not describe the probability that the entire search procedure would have produced at least one apparently exceptional event. Computational repeatability cannot remove that distinction. A second computer can reproduce the retrospectively selected threshold to the last digit while reproducing the same inferential error.

Consider a receiver that inspects many frequency bins at many successive times. Under a simplified model, let p denote the false-alarm probability of a single prespecified test under its background-only hypothesis. If one had m independent opportunities, the probability of at least one false positive would be $1 - (1 - p)^m$. That formula is illustrative because real waterfall cells are generally correlated through windows, filters, spectral leakage, overlap and a common environmental background. It does, however, expose why a seemingly stringent single-cell threshold may not provide the same error control across a large search. A nominal p of 0.01 applied to 100 independent opportunities produces a familywise probability of about 0.634 that at least one will exceed the criterion by chance. In an actual receiver the

Copyright 2026, James M. Atkinson

proper calculation depends on the dependence structure and selection method, not merely the count of coloured rectangles displayed on a screen.

The analyst must therefore identify two different objectives. Exploratory processing seeks promising hypotheses. Its procedures may be adaptive, inventive and responsive to unexpected structure, provided their exploratory status is recorded. Confirmation asks whether a specified hypothesis survives a test designed without reference to the particular confirmatory outcome. After using a development capture to choose a filter, integration time or threshold, the investigator should freeze those choices and evaluate them on a separate record that has not influenced the design. Ideally a custodian or independent laboratory controls access to the confirmatory material. If further revisions are made after observing the result, those revisions become development again, and another genuinely independent test is required for an unqualified prospective inference.

The distinction applies equally to the analogue front end. A threshold can be fixed perfectly and still yield misleading results if the receiver is overloaded, its local oscillator produces spurs, or the front-end gain changes without documentation. Calibration must identify the antenna and preselector, centre frequency, bandwidth, analogue gain, ADC scaling, clock reference, clipping and missing-data status. These conditions must be preserved across the comparison. One should also use controlled reference emissions whose waveform parameters and timing are known independently, together with background-only intervals and negative controls. The statistical model cannot prove the receiver measured what the author believes it measured. Conversely, an excellent calibration does not make a retrospectively tuned statistical rule prospective.

Copyright 2026, James M. Atkinson

An especially tempting error arises from overlapping spectral frames. A sliding estimator may generate dozens of closely related images from substantially the same underlying complex samples. Those frames are not independent replicates merely because they occupy distinct rows on the display. If the operator watches them repeatedly and adjusts a threshold to the largest frame, the selection process has become more complex still. A defensible performance study should account for dependence between windows, the duration of the capture, receiver scheduling gaps and the total search procedure. The relevant error probability may be estimated from background-only captures processed through the complete frozen detector, rather than by assuming that every coloured pixel is an independent draw from a convenient theoretical distribution.

A laboratory comparison should have a documented sequence. First, acquire an authorised collection of development recordings including synthetic reference pulses, a range of controlled signal-to-noise conditions, nonstationary interference and deliberate front-end overload. Second, allow the development team to explore thresholds and models, recording the candidates tried and the rationale for the selected procedure. Third, freeze the algorithm, its numerical library versions, window settings, thresholds and treatment of invalid intervals. Fourth, deliver independent reference captures with blinded labels to a second examiner. Fifth, compare the preregistered decisions against ground truth and report missed detections, false alarms and uncertainty, including the total search duration and frequency coverage. Finally, preserve unsuccessful outcomes rather than discarding them from the denominator of reported performance.

Copyright 2026, James M. Atkinson

No single numerical rate characterises every detection problem. False-alarm probability, probability of detection, signal strength, integration time, duty cycle, background nonstationarity and instrument uncertainty interact. A detector may be made insensitive enough to avoid most false reports while also missing weak authorised pulses. That trade-off must be displayed rather than concealed behind an assurance of near-perfect reliability. If an analyst changes the criterion after seeing a missed pulse, the next prospective claim requires a further untouched test set. The purpose of the separation is not to prohibit learning; it is to prevent learning from the data from being misrepresented as independent verification by those same data.

There is a final legal and evidential boundary. Detection of an energy excursion, statistical departure from background, successful recognition of a waveform family and identification of a particular emitter are separate claims. A strong confirmatory result at one stage does not automatically satisfy the next. An independent antenna, altered attenuation, changed receiver configuration or suitable reference instrument may be needed to test whether the phenomenon originated beyond the measuring apparatus. A responsibly written report should identify the observed measurement, the prespecified criterion, the tested false-alarm assumptions and the remaining alternative explanations. When the observation was selected adaptively, the report should say so. I respectfully return the token for further questions about likelihood, sequential decisions, confirmation bias and process-control methods.

John Wilder Tukey, Peer Question: Professor Neyman, exploratory data analysis is indispensable when the physical phenomenon under examination has not yet been named. I should not want a rule intended to

Copyright 2026, James M. Atkinson

protect inferential discipline to become a prohibition on looking. Suppose a team surveys a complex factory and finds a family of weak transient shapes at several frequencies. It has explored twenty FFT windows, compared five background estimators, repeatedly narrowed the time interval and eventually produced a dramatic image. Would you discard the accumulated observations, or could the team report them as a structured discovery while designing a new and genuinely independent test? More particularly, what must its notebook disclose about the search path, how should it present the initial effect size, and what should happen if the independent confirmation fails? I ask because a laboratory can preserve an attractive exploratory graph without preserving the sequence of decisions by which it was obtained. The displayed picture may be accurate while its apparent statistical surprise is greatly exaggerated.

Jerzy Neyman, Response: Mr. Tukey, I would not discard those observations. A thoughtful exploratory investigation can disclose structure that no reasonable engineer would have specified beforehand. It may reveal that a presumed narrowband tone is actually one branch of a periodically varying interference process, or that an alleged burst occurs only under a particular gain setting. Both observations are valuable. The essential requirement is to describe their epistemic status. One may state that a pattern was noticed following extensive inspection, and one may measure its apparent amplitude and duration on that development record. One may not attach to the selected pattern a single-test error probability computed as though the pattern and selection rule had been fixed before the record was examined.

The notebook should record at least the acquisition state, analysis software versions, windows and background estimators tried, threshold changes,

Copyright 2026, James M. Atkinson

excluded segments, tested frequency ranges and the sequence in which these decisions arose. For a practical account, a time-stamped experiment log or version-controlled analysis record may serve better than a lengthy narrative written from memory. The reviewer should be able to see that the final picture emerged after twenty windows and five estimators, not assume that those were never tried. A record of failures is not an embarrassment; it defines the search whose error characteristics differ from those of a single preselected test. If full logging was not performed, the limitation must be acknowledged rather than patched with invented precision.

Confirmation should answer a question made explicit by the exploratory stage. The team may preregister the relevant time-frequency region, candidate waveform features, detection statistic, window function, threshold and controls. It should then obtain a genuinely new record, ideally through independently monitored equipment, with the reference emissions and negative controls concealed until decisions are frozen. One can also predefine several allowable alternative configurations and control the overall decision rule accordingly. A single negative confirmation need not prove the exploratory observation fictitious: the phenomenon could be intermittent, the test insensitive or the physical conditions changed. The disciplined conclusion is that the specified independent test did not establish the candidate under its stated conditions.

An effect size reported from the discovery record should be labelled post-selection. Its point estimate may be biased upward when investigators searched for the largest visible excursion, a version of the familiar selection effect. A confidence interval derived without accounting for the search may also be too narrow for the selected target. In the confirmatory capture, the

Copyright 2026, James M. Atkinson

investigator should report the prespecified estimate and uncertainty, including failures to detect. If the team revises the hypothesis after seeing that result, the revision returns to exploration. These distinctions allow the laboratory to learn continuously without laundering the same data into repeated confirmations.

I would further distinguish reports of apparatus behaviour from reports of an unknown external source. If a pattern occurs after a firmware change, it might establish a software regression even though it says nothing about a transmitter beyond the antenna. The next experiment could compare a terminator, a calibrated injection and an independent receiver. The legal authority and information minimisation remain relevant; investigation of energy occupancy does not automatically authorise collecting protected payloads. A cautious, clearly labelled discovery report is scientifically stronger than a confident but statistically incoherent identification.

George Edward Pelham Box, Peer Question: Professor Neyman, your proposed test appears to presume that there is a sufficiently stable background population against which the threshold can be defined. In practice the RF environment is riddled with changing interference and receiver nonlinearities. Suppose the analyst develops a threshold on recordings from a shielded room and subsequently applies it in a building where switching converters, moving lifts and scheduled transmitters modify the distribution throughout the day. Even if the algorithm was frozen before the field test, what has been confirmed when the model itself is wrong? Should a second validation stage test the adequacy of the background model before its tail probabilities are trusted? I also wonder whether a reference dataset selected to resemble the eventual survey site might itself

Copyright 2026, James M. Atkinson

introduce unreported selection. How would you distinguish a provisional engineering limit, an empirical field alarm rate and a statistically justified false-alarm probability when the environment is continually changing?

Jerzy Neyman, Response: Mr. Box, freezing a defective rule does not make that rule scientifically sound. Independence of test data is necessary for some inferential claims, but it is not sufficient if the observations do not satisfy the statistical model. A static shielded-room background cannot be assumed to represent a busy industrial installation. The question is not simply whether the program was untouched; it is whether the probability statement refers to the process that actually generated the observations. A model valid in a laboratory might still be useful for a limited calibration statement, but the field record should disclose its departure from the validated regime.

I would use two distinct validation tasks. The first concerns instrument correctness: the ADC response, calibration, filtering, front-end linearity, timebase, missing samples and software implementation should be assessed against controlled reference conditions. The second concerns the statistical distribution of background events under the intended operating environment. Representative authorised background-only acquisitions, stratified across relevant conditions and shifts, can estimate an empirical alarm rate for the frozen detector. Such evidence should be sufficient in duration to reveal recurring regimes, rather than selecting only a convenient quiet interval. The report should specify whether the false-alarm rate is per valid frequency dwell, per valid second, per completed survey or per declared decision event. These denominators cannot be exchanged without a model.

Copyright 2026, James M. Atkinson

The selection of what counts as a representative field environment must itself be stated. If the analyst excludes nights with strong interference after discovering that those nights produce many alarms, the observed alarm rate becomes conditional on an undocumented censoring rule. A fair programme can prespecify operational strata such as occupied and unoccupied building periods, but it must publish the criteria and corresponding exposure. Where the process is clearly nonstationary, one might report alarm performance separately by stratum rather than offer a falsely precise universal parameter. If the intended site changes, the validity of those estimates should be reconsidered. It may be necessary to identify a separate operating regime and carry out a new calibration.

A provisional engineering threshold is an operating choice, possibly justified by available data and practical constraints, but not automatically a validated significance criterion. An empirical field rate is a measurement of how often that frozen threshold fired during a specified background programme, with sampling uncertainty and all relevant limitations. A statistical false-alarm probability is a model-based claim about a defined event and population. It should be supported by evidence that the model is appropriate. If the number of observed false alarms is zero, that still does not prove the true probability is zero; confidence bounds depend on the number and dependence of valid trials.

For an external attribution, we would add the physical challenge that the alarm may originate in the receiver. A second instrument, attenuation trials, alternate cables and known reference sources can help discriminate plausible mechanisms. Where the results remain ambiguous, the proper language is that the recorded output exceeded a frozen threshold under

Copyright 2026, James M. Atkinson

particular conditions. That is an observed fact. Whether the excess represents an external transmission, a familiar industrial disturbance or a receiver artefact remains a separate question. Far from weakening the scientific enterprise, this separation gives the next investigator a concrete hypothesis to test.

Dr. James M. Atkinson, Moderator: I thank Jerzy Neyman for the preceding examination. With the token passed in a spirit of scholarly respect, I invite Sir Ronald Aylmer Fisher to develop a different evidential dimension. This is a fictional modern educational reconstruction, not a transcription of a historical symposium.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher, Second Principal Contributor: Dr. Atkinson, the sound of a receiver's cooling fan is not an evidential soundtrack, and neither is the spectacle of a brilliant spectral trace a sufficient experiment. I would begin by distinguishing the use of observations to devise an interesting question from their use to assess the strength of that question. Exploration is not disreputable. It is the place where an engineer discovers that a harmonic family appears only after preselection is removed, or that a purportedly narrow emission widens when the FFT window changes. The impropriety arises when the report silently hides that history and applies a reference distribution as though the hypothesis, measurement interval, window and rejection criterion were all selected independently of the values displayed. If the candidate was found among a thousand possibilities, the investigator cannot simply describe it as the one candidate selected beforehand.

A likelihood is a mathematical function of observations under an explicit model. It is not a talisman which converts an appealing display into a proven transmitter. In a simple laboratory comparison, one might define a background model H0 in which receiver output arises from calibrated noise and known interference, and an alternative H1 in which a prespecified test waveform adds a component. The likelihood ratio can then be evaluated for an observation under both models. Its distribution under H0 must reflect the whole decision procedure, including parameter fitting, nuisance quantities, repeated attempts and any stopping rule. If the analyst estimates the background variance from a portion selected because it was unusually quiet, then subsequently celebrates a nearby excursion as significant, the nuisance estimate is not independent of that selection. The numerical

Copyright 2026, James M. Atkinson

threshold may be mathematically accurate for an experiment that never actually occurred.

The scientific remedy is design before dramatic interpretation. Record the sampling plan, the instrument configuration, the intended null comparisons and the quantities on which thresholds depend. For a single, prespecified frequency and interval with a suitably validated noise model, a simple distributional calibration might be defensible. For a blind sweep over millions of related time-frequency cells, one must model the complete search, not one isolated cell. There are principled approaches to multiplicity, including familywise error control and procedures aimed at controlling the false discovery rate under their respective assumptions. They answer different questions. A promised familywise probability for at least one false alarm is not interchangeable with an expected fraction of false claims among a selected set. The distinction becomes material when the report will drive investigative action, equipment removal or an allegation concerning an individual.

I would insist upon a clear boundary between mathematical detection and engineering classification. An emission-like shape may originate from clipping, local oscillator leakage, power-supply switching, intermodulation products, cable coupling or a real signal outside the receiving apparatus. One well-planned experiment changes front-end attenuation. An external weak signal ordinarily responds according to the calibrated chain, whereas certain internally generated nonlinear components can show a different scaling relationship; but that pattern is only one diagnostic, since uncontrolled gain changes and receiver architecture may confound the comparison. A second independently characterised receiver or antenna can

Copyright 2026, James M. Atkinson

test whether an effect is shared beyond one instrument. These experiments should be designed to challenge a favourite interpretation, not to decorate it.

Imagine a lawful laboratory exercise in which a known source transmits a reference burst while an independent monitor records its timing. A development set contains a range of amplitudes, deliberately injected interference, quiet intervals and clipped input conditions. The analyst may inspect plots, compare windows, tune a matched filter and choose a trigger threshold. Each exploration belongs in a log. Once the candidate rule is selected, the development set has served its function. A fresh validation set, ideally administered by another person with blinded event labels, tests the frozen rule. The analyst must not change the threshold midway through confirmation merely because its misses appear embarrassing. If such a revision is scientifically necessary, the later evaluation must be identified as a new experiment, with a fresh independent dataset or an explicitly adjusted inferential account.

Practical competence also requires attention to what the detector returns. A probability of false alarm describes an operational decision process under a specified background population and acquisition state. It is not the posterior probability that any particular detected event is innocent. The latter requires further assumptions, including the prevalence of genuine events and the relative likelihoods of observations, often unknown in an exploratory countermeasures survey. A false-alarm study based on a static shielded laboratory may not transfer to an industrial building filled with switching converters, moving machinery and variable RF traffic. Confidence ought to be tied to the environment actually tested. A receiver can have fine

Copyright 2026, James M. Atkinson

frequency resolution and yet poor inferential resolution concerning causation.

There is no reason to hide ambiguous or negative findings. If the frozen detector misses weak reference pulses while a retrospectively adjusted display renders them visible, report both. The first result measures the predefined operating point; the second is an exploratory suggestion for improving the method. A useful study may reveal that the initial model was inadequate. It may also find that a previously celebrated event vanishes when the front end is attenuated or the preselector changes. An inconvenient result is a means of improving the instrument chain, not an invitation to rewrite the scientific question after the fact. The investigator should retain a versioned record of all candidate rules, not only the successful one.

For publication I would require the threshold-selection protocol, the null and alternative assumptions, the number and structure of opportunities inspected, the means of estimating noise, the details of any censoring, and an account of missing samples. I would further record the precise distinction between a detector firing and a source being identified. An instrument may issue a repeatable alarm with no scientifically justified emitter attribution. The proper report says what was observed, what comparison was performed, how the decision rule was selected and which alternatives remain. That prose will be less dramatic than an unqualified accusation, yet its disciplined texture is precisely what makes it durable when another investigator tests the same apparatus.

Andrey Nikolaevich Kolmogorov, Peer Question: Sir Ronald, let me press the probabilistic foundation. A familywise formula such as one minus the

Copyright 2026, James M. Atkinson

product of nonexceedance probabilities presumes independence or a fully described joint distribution. A spectrum analyser constructs adjacent frequency bins from a common window, and a software-defined receiver may compute heavily overlapping segments; both produce dependence. Suppose the analyst has a million plotted cells but cannot determine their effective independent count from the display. What bound can be stated without pretending that there are a million independent experiments, and how should the false-alarm study be organised if the null process is nonstationary? I also ask you to distinguish a conservative mathematical inequality from an estimated operating characteristic and from a claim about a specific transmitter. It is easy to take a formula that is always true under explicit assumptions and use it rhetorically as though it measured a particular scene.

Sir Ronald Aylmer Fisher, Response: Dr. Kolmogorov, a conservative union bound offers a useful starting point when a family of well-defined events is specified. If events A1 through Am are the declared false-alarm opportunities and each has a valid upper probability bound p_i under the null, the probability of their union cannot exceed the sum of the p_i, truncated at one. No independence assumption is needed for that elementary inequality. But its usefulness depends upon defining the events and supplying credible marginal bounds under the actual background model. If a team chooses its test family after seeing the most favourable plot, even an impeccable application to a retrospectively selected subset can miss the relevant selection process.

The difference between a bound and an empirical estimate must be explicit. A union bound may be conservative, even excessively so, when bins are

Copyright 2026, James M. Atkinson

strongly correlated; it does not reveal the actual false-alarm probability without further information. A direct background study can instead process representative null recordings through the entire frozen detection pipeline and count alarms at the report's true decision level. That approach includes window overlap, guard-band choices, candidate aggregation and alarm suppression rules, provided that the background recordings adequately represent the operating regime. One may also use carefully justified simulation or resampling methods, but they must preserve relevant dependence and nonstationarity. Randomly shuffling samples until their structure disappears can produce an attractively simple answer to the wrong question.

I would require a clear definition of one alarm. Is it a pixel crossing a threshold, a cluster of contiguous bins, a detected burst after temporal merging, or one operator decision to investigate a receiver event? These are different units. A monitor that produces ten adjacent coloured pixels from one physical disturbance should not be described as ten independent false transmitters. Similarly a rule that collapses repeated alerts within a fixed interval changes the alarm count and its distribution. The full rule, including such postprocessing, must be frozen before performance is measured. Reproducing the same software output is not independent validation of the null model.

If the background varies with time, a single long average can conceal periods of poor performance. The laboratory might stratify recordings by operating phase or use a validated time-varying model with its own qualifications. The appropriate approach depends on the scientific objective and the available data. Under severe model uncertainty, a qualitative or

Copyright 2026, James M. Atkinson

bounded conclusion may be preferable to a spurious decimal. A calibrated test under one class of background conditions makes a statement about that class, not about every conceivable industrial setting. I should also remind the panel that a false-alarm probability is a frequency characteristic of a procedure under the null. It is not a posterior probability that a particular alarm was erroneous.

Finally, a valid alarm study does not identify an emitter. To claim an external source, the investigation needs physical evidence independent of the selected spectral statistic: changes with attenuation, reproducible response through other calibrated antennas or receivers, geometrical considerations and lawful operating context. Even those controls may leave rival explanations. The appropriate report begins with a mathematically modest claim, adds tested engineering observations and explicitly names what remains unknown. It should not turn a conservative inequality into a banner declaring the existence of a particular covert device.

Dr. James M. Atkinson, Moderator: I thank Sir Ronald Aylmer Fisher for the preceding examination. With the token passed in a spirit of scholarly respect, I invite Abraham Wald to develop a different evidential dimension. This is a fictional modern educational reconstruction, not a transcription of a historical symposium.

Copyright 2026, James M. Atkinson

Abraham Wald, Third Principal Contributor: Dr. Atkinson, the question becomes especially demanding when the engineer is permitted to look repeatedly at a stream of observations. A decision made after one hour of monitoring is not governed by the same reference experiment as a decision made at whichever second first looks extraordinary, unless the stopping rule was properly incorporated. In sequential analysis, time is not merely another axis on a waterfall. It is part of the policy by which evidence accumulates and by which the investigator chooses whether to continue. The rule must therefore specify what counts as an observation, when evaluation occurs, what information remains available to the analyst and under what conditions monitoring ceases.

Consider a simplified sequential likelihood-ratio procedure in which successive observations are suitably modelled under H0 and H1. One can derive decision boundaries associated with desired error rates under stated regularity conditions. That does not mean the familiar approximate boundary formula applies without qualification to a streaming SDR with coloured noise, overlapping windows, drifting front-end gain, unmodelled interference and multiple candidate frequencies. Dependencies are physical facts, not technical footnotes. If the same underlying complex samples appear in four overlapping FFT frames, a product of four independent likelihoods would count much of the evidence repeatedly. Before estimating an error rate, one must establish how the data enter the sequential statistic and test the proposed distribution against representative background captures.

A practical surveillance-countermeasures survey may involve a human operator who sees an event and extends the recording, retunes a receiver

Copyright 2026, James M. Atkinson

or changes integration time. Each of those acts can be technically sensible. Yet a later p-value based on one chosen moment cannot ignore the reason that moment was chosen. The analyst may have examined dozens of channels and altered numerous settings before finding the trace selected for the report. An ordinary single-look reference distribution does not automatically cover this adaptive path. The solution is neither to prohibit exploratory work nor to pretend that it never happened. Rather, exploratory observations should generate an explicitly labelled candidate that is then challenged through a separate and correctly designed confirmatory measurement.

Suppose a laboratory monitor samples a known empty band under an operating condition representative of the target survey and raises a software alarm whenever a statistic exceeds a preset level. One may estimate a rate of alarms per valid hour of observation, but only after defining what a valid hour means. If the receiver scans only one tenth of the wall-clock interval at the frequency of interest, the exposure is not a full hour of continuously observed data. If buffers overflow during the loudest interference, the missing observations could invalidate an optimistic alarm-rate estimate. If the operator restarts the experiment each time a noisy episode spoils the plot, the sampling policy has selected a favourable dataset. A failure ledger and an exposure denominator are thus part of the statistical specification.

For a fixed null event with independent trials, a simple expected-count illustration can be instructive. If each of 1,000 independent, prespecified trials had a false-alarm probability of 0.001, the expected number of false alarms would be one, while the probability of at least one would be

Copyright 2026, James M. Atkinson

approximately 1 minus exp(-1), or about 0.632 in the standard approximation. But the example cannot be used as a shortcut for 1,000 correlated waterfall bins. Independence must be shown or a justified alternative calibration adopted. Moreover the result concerns the operational null model; it neither identifies an external emitter nor quantifies the truth of any particular allegation. A manager who hears one false alarm expected may imagine certainty about the next alarm, and that would be an error.

When measurements are repeated across locations, antennas and instrument settings, there are two competing risks. One is to miss a real intermittent emission by freezing a poor search policy too early. The other is to discover a seemingly dramatic anomaly after enough adaptive searching and then present the selected anomaly as independently confirmed. A defensible programme can accommodate both by reserving genuinely new measurements for confirmation. In a controlled test, the exploratory team may be given generous freedom to identify candidate structures, while the confirmatory team receives only frozen code, authorised hypotheses and a blind validation dataset. A genuine new hypothesis arising during confirmation is logged as exploratory and placed in the queue for a later test.

The issue of decision loss is also pertinent. The operational consequences of overlooking a dangerous transmitter may differ from those of falsely accusing an innocuous device. Statistical design should state which error rates and costs govern the decision, without allowing those costs to substitute for evidence. An alarm demanding a nonintrusive remeasurement may properly use a different threshold from an alarm

Copyright 2026, James M. Atkinson

triggering invasive inspection or legal action. This differentiation must be settled as policy rather than improvised after an alarming display appears. An engineering team might maintain a permissive discovery mode and a more rigorously qualified confirmation mode. It should never call the first mode proof merely because the second mode is inconvenient.

Finally I would ask the recorder to preserve the sequence of decisions, not only the final settings. If a detector first fires at 09:20 after six prior changes of threshold, the custody record should show those changes and the observations that prompted them. The exact software version, observation windows, calibration state and gap record belong in the same account. A later examiner may reproduce every decision, but that reproducibility proves the historical sequence of analysis, not that its false-alarm calculation was prospective. Only an appropriately designed evaluation of the whole procedure can support that claim. I pass the token to the examination of regression, nuisance factors and model adequacy, for an elegant statistic cannot compensate for a mistaken physical model.

Claude Elwood Shannon, Peer Question: Professor Wald, I want to examine the information that a real-time detector accumulates. In a streaming receiver the operator can change integration length or the channel under observation after seeing an initial weak peak. If a short window produces no alarm, the operator may extend the interval; if a long window appears disappointing, the operator may return to a brief burst view. The algorithm may then report the most impressive of many adaptively selected estimates. How can one preserve the legitimate engineering advantage of sequential observation while describing its error characteristics? I am especially concerned about missing samples, short dwell times and a detector that

Copyright 2026, James M. Atkinson

counts correlated frames as fresh information. Please explain what a genuinely prespecified sequential rule would have to contain, and what the team should report when the operator's actual behaviour does not follow that rule. Please also say whether a second analyst reproducing the same calculation can turn that retrospective selection into a valid confirmatory test.

Abraham Wald, Response: Dr. Shannon, the legitimate advantage lies in defining a sequential experiment rather than treating every intermediate result as an independent final test. A properly specified procedure identifies the observations entering the statistic, their order, the conditions under which the observation process continues and the boundaries that cause a decision. If multiple channels or alternative integration lengths are candidates, the selection policy and decision consequences must be included in the design or calibrated as a whole. The analyst cannot choose one appealing stopping instant retrospectively and then borrow a nominal single-look tail probability. That is a mismatch between the performed experiment and the experiment invoked to justify it.

The sequential likelihood ratio is an instructive theoretical model, but practical receiver data may violate its simplifying conditions. A set of frames built from overlapping complex samples is dependent. Noise may be coloured by filters and may change with local operating conditions. Firmware or processing may discard invalid frames. A laboratory can still design an empirical sequential detector, but it should test its whole behaviour on independent background and reference datasets. The null experiment must include the actual acquisition cadence, buffer-gapping

Copyright 2026, James M. Atkinson

semantics, scan scheduling and postprocessing. If these are neglected, the measured alarm rate may be neither conservative nor transferable.

The decision thresholds should be set in relation to a declared operational objective. One mode might issue a low-consequence advisory to repeat a measurement; another might authorise the much stronger conclusion that a prespecified reference waveform was detected under calibration conditions. The second assertion demands a different evidence standard and possibly a second independent instrument. The thresholds and consequences cannot be silently interchanged after the most interesting event appears. The record should include the rule version, all changes, each threshold used, each stopping decision and the data that were available when the decision was made.

When the operator departs from a prescribed sequence, the study has entered an adaptive exploratory regime unless an appropriate statistical adjustment was already specified. That is not misconduct by itself. It may be sensible to change bandwidth or place the receiver on a candidate frequency, particularly where an intermittent authorised test source is involved. The operator should mark that intervention in the chronology and treat any subsequent significance calculation according to its actual design. A later confirmatory pass can freeze the newly chosen configuration and evaluate it afresh. If new independent material cannot be collected, the report must be limited to descriptive and exploratory conclusions, or employ a justified selective-inference framework whose assumptions are disclosed.

I would describe missing observations directly. If the instrument viewed a band for only six seconds out of a minute, it cannot claim to have continuously observed silence during the other fifty-four seconds. If samples

Copyright 2026, James M. Atkinson

were dropped, interpolated values cannot be counted as newly acquired independent evidence. The effective observation exposure should appear alongside alarm rates and detection probabilities. For a known laboratory source, the pulse timing log should be independent of the SDR and used to score only intervals where the source and receiver conditions satisfy the test specification. Such accounting improves both the technical and forensic interpretability of the result.

In conclusion, a sequential procedure is not merely a sequence of plots. It is a disciplined policy, including the circumstances under which data will be examined and decisions taken. The elegance of its mathematics does not save a misdescribed acquisition chain. I would rather report that an operator adaptively followed an interesting transient than claim a controlled false-alarm rate for a control procedure that was never executed. Clear disclosure preserves the discovery's value while reserving confident inference for evidence that deserves it.

Dr. James M. Atkinson, Moderator: I thank Abraham Wald for the preceding examination. With the token passed in a spirit of scholarly respect, I invite Sir David Cox to develop a different evidential dimension. This is a fictional modern educational reconstruction, not a transcription of a historical symposium.

Copyright 2026, James M. Atkinson

Sir David Cox, Fourth Principal Contributor: Dr. Atkinson, I should distinguish a general scientific question from the narrow statistical hypothesis used as its provisional instrument. A receiver operator may wish to know whether an unexplained spectral event warrants further investigation. The model-based test might instead ask whether calibrated power in a specified time-frequency region departs from a stationary background distribution. These propositions are not logically identical. An exceedance can warrant the next experiment without identifying the source; a failure to exceed can result from poor sensitivity, inappropriate aggregation, a missed scan interval or a wrong model. The report should state both the question of scientific interest and the exact population of measurements to which the inferential calculation applies.

Model selection is particularly treacherous in a broad RF survey. A Gaussian background may be a useful approximation for carefully filtered thermal noise under stable receiver conditions, but nonstationary interference can produce heavy tails or structured bursts. A fit to one quiet interval may not describe the full instrument operation. Dependence between observations can arise from window overlap, filters, acquisition timing, common local oscillator drift and slowly changing external sources. If the operator evaluates several families of models and selects the one producing the smallest reported p-value, uncertainty from model selection has been omitted. A prospectively specified family, model-checking protocol and independent validation dataset can reduce this temptation. In a less controlled field setting, transparent sensitivity analysis may be more defensible than a single overprecise number.

Copyright 2026, James M. Atkinson

Consider the frequency-dependent noise-floor estimator itself. Suppose a waterfall is partitioned into windows and the analyst uses a median of nearby cells to normalise a target bin. Those cells may include the skirts of the very event of interest, a persistent carrier or instrumental spurious products. Their distribution depends on guard bands, reference bands and filter characteristics. If the bands are chosen after seeing the target, an apparently robust statistic can still be selected to make the event look stronger. Conversely, if nearby references are contaminated, the detection threshold may be elevated and a real reference source missed. The control plan should specify reference-cell selection and exclude or model unsuitable cells according to a prespecified, reproducible rule. The choice of estimator is a substantive part of the experiment.

An effect size deserves as much attention as a rejection decision. Suppose an independent trial finds a statistically reproducible 0.3 dB excursion above a well-characterised baseline. Its practical significance may be slight relative to calibration and environmental variation. Another test may detect a large transient but with a wide interval because only one short observation was captured. The strength of a result depends on uncertainty and consequence, not merely on whether a p-value lies on one side of a conventional line. I would report estimated change, uncertainty range, receiver settings, sample exposure and plausible alternative explanations. Where the underlying measurements are calibrated in power units, instrument uncertainty and impedance reference must be carried into the interpretation.

A proper independent replication is not simply rerunning a script against an old recording. It may require a new authorised acquisition with the same frozen rule and sufficiently comparable instrument state. Yet comparability

Copyright 2026, James M. Atkinson

is not identical to duplication. The laboratory should vary one factor at a time when assessing robustness: receiver gain, attenuation, window function, antenna path or controlled reference waveform. A trace which survives reasonable variations in processing may be more persuasive than one which appears under only a finely tuned combination. Nevertheless changes must be planned and their outcomes reported without selecting the most favourable setting as the only one that counts. If robustness checks are post hoc, their exploratory nature must be acknowledged rather than silently promoted into confirmation.

I would also distinguish confirmatory testing from discovery of anomalies in residuals. After fitting a model, an analyst may plot residual spectra and find an unexpected periodic structure. Such a structure is valuable evidence that the model deserves further examination. But the same residuals cannot ordinarily supply an unadjusted test of the newly discovered pattern while pretending that the pattern was hypothesised beforehand. If a fresh dataset is unavailable, there are selective-inference or resampling approaches in suitable settings, but their assumptions and limitations are substantial. In a technical textbook one should not offer these methods as universal magic, particularly where the receiver-generated process may be neither stationary nor well modelled. A careful descriptive result can be preferable to misleading certainty.

A blind test should include more than positive reference emissions. It needs background-only intervals, known interference sources, deliberately overloaded receiver states and gaps in observation. The detector's confusion matrix should separate an actual missed event from a period not observed at all. The scoring procedure must be fixed before labels are

Copyright 2026, James M. Atkinson

unblinded. If the algorithm is allowed to choose a different threshold for each challenge recording after seeing its answer key, the reported performance estimates training success rather than generalisation. Calibration documents should include the physical reference plane and the signal generator uncertainty. A software rule can be perfectly repeatable while the analogue inputs move, and apparent reproducibility under that condition is only superficial.

The final report ought to use graduated language. A candidate can be discovered, independently detected, classified by a measured waveform feature, or attributed to a specific device. These are successive inferential steps and none is automatically completed by the one preceding it. My objection is to the collapse of these stages into an attractive figure and a single asserted confidence value. The examiner should preserve the competing interpretations and state what new observation would discriminate between them. In that discipline, the statistical model serves the physical inquiry rather than dictating its answer, and the visual drama of the waterfall is checked against the patient arithmetic of evidence.

David Harold Blackwell, Peer Question: Sir David, I should like you to be more exact about the decision consequences. An operator can legitimately use a low threshold to decide which spectral region deserves another look, whereas a laboratory may claim a much lower false-alarm probability when deciding whether a prespecified reference emission has been confirmed. Suppose the same dataset is first searched with a permissive rule, then the discovered region is tested with a stringent rule using precisely those same samples. Does a more demanding second threshold restore inferential independence? How should one account for a score chosen because it

Copyright 2026, James M. Atkinson

looked unusually large, especially where the background model and test family were also selected after inspection? I ask further how a decision maker should weigh missed detections and false alarms without converting the operational cost of one type of error into a mathematical claim that the evidence itself is stronger. Please describe an appropriate laboratory arrangement that separates these decisions.

Sir David Cox, Response: Professor Blackwell, applying a more stringent line to the same selected observation does not by itself restore independence. If the analyst searched a field to locate a remarkable excursion, the second threshold is applied to a candidate whose selection depended on the same noise realisation. The selection can alter the distribution of the candidate score even when the second rule is numerically fixed. A smaller nominal p-value attached to the selected score may therefore remain misleading. One could, in suitable models, account for selection explicitly or conduct an adjusted global test. Yet the simpler laboratory solution is to use the discovery sample for discovery and hold back independent observations whose outcomes have not been consulted during rule construction.

The two decisions should also be named honestly. A permissive exploratory threshold could generate an advisory requesting a remeasurement or independent check. Its purpose is to avoid overlooking candidates, and its false-alarm burden may be acceptable if the consequence is merely another lawful measurement. A confirmatory decision might involve a specific claim concerning a prespecified waveform feature, and its consequence can be more serious. The laboratory must define the target claim, error rates and decision procedure independently of the current test outcome. A lower

Copyright 2026, James M. Atkinson

threshold in the discovery mode does not make it a poor instrument; it makes it an instrument for a different decision problem.

Decision costs can be used to choose an operating rule when the assumptions, probabilities and consequences are explicit. They cannot make an observed waveform more probative by declaration. A costly miss may justify additional monitoring or a sensitive preliminary alarm. It does not justify describing the resulting false-alarm rate as something other than that measured or supported by a valid model. Likewise the seriousness of a potential source does not prove that a peak arose from that source. Engineering caution and evidential caution can coexist. The report should state the consequence category attached to each threshold and the evidence required before proceeding to a more intrusive response.

I would arrange a laboratory sequence with three materials: a development collection in which thresholds and signal statistics may be tuned, a calibration collection for assessing the proposed frozen procedure across relevant receiver regimes, and a blind test collection controlled by a separate custodian. The last collection should include authorised reference bursts, empty-band periods and known receiver artefacts. The detector receives no knowledge of the answer key until it outputs its predeclared decisions. The scoring software, treatment of missing intervals, method for merging adjacent detections and definition of a false alarm should all be frozen. The evaluator can then report sensitivity at specified test levels, empirical false alarms per stated exposure, uncertainty and conditions of validity.

A further safeguard is to distinguish confirmation of a waveform from attribution to an individual apparatus. A detector that correctly recognises

Copyright 2026, James M. Atkinson

reference bursts in a blind test establishes performance at those laboratory conditions. It does not identify an unknown object in a building without further evidence. In the field, independent antenna and receiver measurements, attenuator challenges, inspection of nonlinear products and legal authority may be necessary. Even these may permit only a cautious classification. The most useful statistical statement is the one that matches the exact measured procedure and claim, however modest that statement may appear.

Dr. James M. Atkinson, Moderator: I thank Sir David Cox for the preceding examination. With the token passed in a spirit of scholarly respect, I invite Walter Andrew Shewhart to develop a different evidential dimension. This is a fictional modern educational reconstruction, not a transcription of a historical symposium.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart, Fifth Principal Contributor: Dr. Atkinson, I approach the question from the standpoint of a process that is expected to operate for long periods under changing conditions. A threshold is not merely a line drawn through an image. It is an operational rule embedded in an instrument, and the process producing the monitored values must be understood. There is an important distinction between common-cause variation consistent with a stable regime and special-cause variation suggesting that the regime has changed. A process-control chart can be useful for detecting departures from a historically characterised background, but it is not an oracle. The engineer must know what process was actually characterised and whether the conditions under which its limits were set still prevail.

Imagine a receiver in a building whose background includes regulated transmitters, switching supplies and machinery that runs on a daily schedule. If a monitoring team estimates a noise distribution at dawn, the evening background may differ even when no illicit or unexpected equipment is present. The chart may sound repeated alarms after a normal change in plant operation. Retuning the limit upward whenever the alarm becomes inconvenient then conceals the very evidence that the process changed. Retuning it downward during a quiet spell may make tomorrow's ordinary variation look sinister. A distinction is needed between stable operating phases, detected process changes and a formal decision to establish a new baseline. Each new baseline should have a documented rationale and a subsequent independent performance check.

The concept of an in-control process must be established empirically. In a receiver, the analogue gain, preselector, frequency reference, calibration

Copyright 2026, James M. Atkinson

temperature, overload indicators, sampling cadence and data completeness may all affect the observed baseline. A control chart derived from one configuration is not transferable without testing to another. If an amplifier introduces intermodulation when a nearby transmitter becomes strong, the alarm may be a real departure in instrument output but not evidence of a new external transmission. The appropriate response is often diagnostic. Alter attenuation, use an independent measurement channel, compare harmonics and inspect overload flags. A chart can announce that some process has departed from its validated state; it cannot by itself tell the laboratory what physical cause produced the departure.

The design of monitoring limits should specify the intended run length or error rate under a particular in-control model, not imply that limits learned from a short development record possess timeless validity. A nominal alarm rate must be measured across representative cycles of actual operation. Correlations between readings influence the number and pattern of alarms. The choice of sampling interval, averaging and missing-data treatment changes the process being monitored. A laboratory may assess these factors through controlled background captures and simulated insertions of known signals. Once it adopts the operating limit, subsequent performance observations should be recorded in a manner that permits evaluation without concealing unfavourable periods.

I would place special emphasis on a change log that differentiates intentional maintenance from adaptive inference. An instrument may be recalibrated, a cable changed, a firmware package replaced or a filter inserted for sound engineering reasons. Such a change might require a new baseline even if the operator has not looked for an anomalous event. The

Copyright 2026, James M. Atkinson

log should record the new configuration and demonstrate equivalence or provide new validation as appropriate. By contrast, changing the alarm line after viewing a suspicious trace is an exploratory response to data and must not be represented as an untouched control rule. The same menu action has different evidential significance depending on its timing and purpose.

The laboratory should test both sensitivity and stability. Insert known authorised reference pulses at several amplitudes, durations and duty cycles, including levels near the chosen threshold. Record how often the detector alerts and how often it misses under each condition. Then test periods with no reference pulse and include ordinary operational disturbances. A single average sensitivity figure conceals where the detector fails. An alarm may be reliable for a long carrier but poor for a short burst hidden between scheduled sweeps. It may also be highly sensitive only in one receiver gain state. A matrix of conditions is preferable to a single polished curve, especially when operational decisions are consequential.

A process-control perspective also counsels against excluding inconvenient observations. If intervals with converter noise, calibration drift or buffer overflow are removed, the examiner should disclose the exclusion rule and whether it was prescribed beforehand. Invalid samples must be marked as invalid, not silently removed to improve the reported alarm rate. If the device was physically incapable of observing a frequency during a scheduled dwell elsewhere, those minutes are not proof of quiet. The exposure denominator must reflect valid listening time in the specified band. Once the analyst recognises these facts, apparently minor administrative notes become essential parts of the statistical method.

Copyright 2026, James M. Atkinson

I would recommend two operating registers. One records the exploratory adjustments by which the engineering team learns the process, including alternate windows, thresholds, exclusion rules and diagnostic controls. The other records the frozen confirmatory configuration and its subsequent test results. Access controls and version identifiers should prevent a late edit from being mistaken for a prospective rule. At a formal review point, a proposed replacement rule may be accepted on its own evidence, but past confirmatory data cannot be re-labelled as independent tests of the new threshold. A good institution permits the rule to improve while maintaining an honest historical record of how improvement occurred.

My conclusion is conservative and practical. The receiver should be encouraged to notice changes; the investigator should be discouraged from pretending that every noticed change proves a particular cause. A threshold can be a useful alarm, an efficient search aid or a validated decision boundary, depending on how it was designed and tested. Those categories should remain separate in the report. The expert's duty is not to protect the elegance of a selected statistic but to protect the integrity of the measurement process and the people affected by its conclusions. I respectfully pass the token for a final examination of the evidence and its limitations.

Karl Raimund Popper, Peer Question: Mr. Shewhart, a monitoring team may present a process-control chart that produces repeated alarms near a frequency of concern. Yet when a different gain state or independent receiver fails to reproduce the trace, the team may dismiss the failures as exceptional circumstances and adjust its alarm rule until the original interpretation survives. What observation would actually falsify the claim

Copyright 2026, James M. Atkinson

that the detector operates with the advertised false-alarm rate? Can a quality-control process distinguish the failure of the statistical model from the failure of the electronic instrument or the absence of the alleged external emission? I also ask how the laboratory should report a negative result without pretending that the absence of an alarm proves the absence of a short, intermittent signal, especially where the receiver scans only part of the relevant period. A proper theory, surely, must expose itself to tests which might defeat it.

Walter Andrew Shewhart, Response: Professor Popper, the first step is to state propositions that an observation can genuinely challenge. One proposition might be that the frozen detector generates no more than a specified average number of alarms per valid monitoring interval under a defined in-control background regime. Another might be that the receiver detects a calibrated pulse of defined amplitude and duration with a stated probability under a fixed configuration. A third might be that a particular field event originated beyond the input connector. These propositions require different tests. The failure of one should not be concealed by changing the definition of another. A new threshold selected after an embarrassing result is a revised proposal, not evidence that the original rule was correct.

To test the alarm-rate claim, I would collect an independent background-only record covering the actual operational conditions and process the complete frozen detector, including the logic by which adjacent excursions are combined into reported events. The exposure denominator must count valid observation time, and the sampling plan must account for routine changes in the process. The result should be accompanied by uncertainty

Copyright 2026, James M. Atkinson

due to finite exposure and possible dependence between observations. A substantially higher alarm rate than the prespecified acceptance criterion would challenge the advertised performance. The response should be to investigate the discrepancy, not to exclude the alarming periods simply because they were inconvenient. If the background process has legitimately changed, the original claim may no longer apply; that qualification must be documented rather than retrospectively erased.

To test the instrument, I would use a calibrated reference at a defined input plane, vary the gain and attenuation, examine overload indicators and compare with a separate measurement chain. A chart showing repeated departures while the terminator is attached could reveal internally generated products or software artefacts. A chart that changes unpredictably with temperature might indicate an unstable analogue stage. These findings do not necessarily falsify the arithmetic of the chart. They may show that its input is not governed by the assumed physical process. The record should separate statistical-control failure, acquisition-chain failure and unsupported source attribution. A transparent result can reveal more than an adjusted chart whose coloured line always seems reassuring.

An absence of alarms on a valid observation interval limits what can be claimed about signals that the tested detector was capable of seeing. It does not prove the physical environment contained no emissions of every conceivable duration or strength. If the receiver visited a band for only ten percent of the relevant time, unobserved intervals remain unknown. If the reference-pulse tests show poor detection for sub-millisecond bursts, the investigator cannot extrapolate to that class merely because no field alarm appeared. The most honest negative conclusion specifies the observed

Copyright 2026, James M. Atkinson

frequencies, dwell times, sensitivity and tested waveform family. In ordinary language it reports that no qualifying event was detected under the stated conditions.

I would make the challenge tests part of ongoing maintenance rather than a ceremonial final review. A limit accepted on Monday may cease to describe the process after a new amplifier is installed on Thursday. The next validation should document the changed configuration and what performance can still be supported. An institution that retains failed tests and uses them to improve its rule has a stronger quality system than one that hides them. The empirical distinction between a stable regime and a changed regime is not an excuse to preserve a favourite conclusion; it is a reason to be precise about which conclusions the evidence presently warrants.

Charles Sanders Peirce, Peer Question: Mr. Shewhart, I should like to examine the language of inference itself. An investigator observes a repeatable alarm and proposes that an undisclosed transmitter is its cause. Yet the same observation could arise from a power converter, overload, an intermodulation product or a perfectly lawful scheduled source. How should a report distinguish the creative proposal of an explanation, the consequences deduced from that proposal and the experimental observations which test those consequences? If the analyst chooses a threshold after seeing the event, the detector may still record a genuine anomaly, but the numerical evidence for the proposed explanation appears more limited. What sequence of checks would prevent the report from confusing the discovery of an interesting hypothesis with the verified existence of a particular object? I am concerned particularly with the

Copyright 2026, James M. Atkinson

authority of technical language, which can make an untested guess sound as though it were a laboratory result.

Walter Andrew Shewhart, Response: Mr. Peirce, the observation, hypothesis and test should occupy separate portions of the record. An instrument output may show that a frozen or exploratory statistic exceeded a particular value at a recorded time. That statement concerns the measurement chain and is limited by its calibration, configuration and data quality. A proposed explanation, such as an external transmitter, is an inference offered to account for the observation. It may be a good candidate, but competing explanations should remain visible. A subsequent experiment should identify observations expected under the proposed explanation and potentially different observations under its rivals. That is the point at which a guess becomes a testable scientific proposition rather than an assertion.

In a disciplined RF investigation the sequence might begin by archiving the original I/Q record with its acquisition metadata, native sample counters and uncertainty. The team then documents that the initial threshold was chosen after exploratory inspection. It may examine whether the same spectral feature appears when input attenuation is changed, when a proper terminator replaces the antenna, when the antenna is moved, or when an independent calibrated receiver is used. Each manipulation has assumptions: a real source can change with antenna position, an internally generated spur can survive a terminated input, and some receiver artefacts respond nonlinearly to gain. The investigator should therefore avoid making a single control decisive without considering the instrument model.

A test plan would describe in advance which outcomes would increase or reduce support for the external-source explanation. A feature disappearing

Copyright 2026, James M. Atkinson

under an input terminator may support, but not prove, an origin outside that connector. A feature recurring at a fixed local-oscillator offset across input configurations may support an internal mixing explanation. Repeated presence in independent instruments, with an expected dependence on location and polarity, could strengthen an external-origin inference. The team must examine cable coupling and shared power interference before describing the instruments as truly independent. The important point is that rival mechanisms are allowed to compete on observations not chosen merely to vindicate one of them.

Threshold choice belongs in this same chronology. The first alarm may have arisen under an exploratory setting selected from many possibilities. That does not invalidate the recorded samples. It limits what nominal error rate can be assigned to the selection. A prospective repeat can fix the statistic, threshold, time-frequency search region and rules for excluding invalid data before capture. The final report may then say that the prespecified detector reproduced a class of events under defined conditions. Any move to naming an apparatus or actor requires further evidence and may engage legal constraints quite apart from the statistical method. One ought never treat technical vocabulary as a substitute for that chain of reasoning.

If the proposed transmitter is not found, a negative result should be described narrowly, not converted into a universal claim that the environment is empty. The specified antenna and receiver may have failed to observe qualifying energy during their valid dwell intervals. Other times or waveform families may remain untested. I would retain the original observation as an exploratory anomaly, together with the controls and unresolved interpretations. That record allows a future examiner to learn

Copyright 2026, James M. Atkinson

from the event without inheriting an accusation that the evidence did not establish. I respectfully return the token with the proposition that a disciplined investigation should prize the distinction between a measurement, an interpretation and a demonstrated cause.

Dr. James M. Atkinson, Moderator: The ordinary peer interrogations have been answered directly. I now invite four reciprocal examinations, each addressed to a different named colleague and immediately answered by that recipient. The purpose is to test the limits of the preceding propositions, not to stage a spurious historical quotation.

Jerzy Neyman, Cross-Peer Question to Sir Ronald Aylmer Fisher: Sir Ronald, I should like to challenge an ambiguity that arises whenever a scientist reports only the smallest significance probability obtained after inspecting an RF capture. The investigator may claim that likelihood provides a more principled measure than a conventional fixed-size test, yet likelihood itself depends on the chosen alternative model and the set of parameters searched. Suppose a programme tries several pulse shapes, different noise distributions and a suite of window lengths, then announces the largest likelihood ratio and uses the tail probability appropriate to just one preselected pulse. Would you regard that as a valid prospective experiment? I ask what evidence would be necessary to establish its null distribution, whether an independently specified comparison could rescue the procedure, and how the investigator should record searches that were exploratory but nevertheless useful. Please address the difference between evidence for a departure from one model and evidence for an identified transmitter, for the latter is a vastly stronger physical assertion.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, the likelihood ratio in your example belongs to the entire search over the permitted model families and parameters, not merely to one convenient pulse discovered at the end. A maximised statistic may be an entirely reasonable detector if its operating characteristics are calculated for the procedure that was actually applied. The scientific failure would be to substitute the reference distribution of one preselected waveform while concealing that many candidates were examined. A computer can evaluate the maximisation impeccably and still yield a misleading inferential label. The selection of alternative models, nuisance estimates and frequency intervals is part of the definition of the experiment.

The laboratory should first make the selection algorithm explicit. If the intended detector maximises a score over a fixed bank of pulse templates, it should freeze that bank, its parameter ranges, calibration and postprocessing before the confirmatory capture. Independent background-only datasets can then be processed through the same maximisation to estimate the global null behaviour of the resulting statistic. Care is needed when the background environment changes, and a simulation should not be trusted merely because its probability curves are smooth. Empirical calibration must cover instrument-generated spurs, local interference and missing-data rules relevant to the intended use. A theoretical distribution is helpful where justified; it does not eliminate the obligation to examine whether the assumptions describe the equipment.

If the original candidate arose from unrestricted exploration, it remains a legitimate discovery. The author can describe the search history, show the selected score and discuss possible physical mechanisms without asserting

Copyright 2026, James M. Atkinson

that a single-test probability confirms the hypothesis. The next experiment could specify the particular pulse family and acquisition conditions before collecting fresh data. Alternatively, a fully prescribed global detector could be independently tested. What cannot be done is to rename the original selected record a prospective test after the event. The decisive chronology is the chronology of knowledge and decision, not the date written on the final report.

I would further distinguish a numerical departure from a background distribution from an attribution of origin. A strong global detector result may establish that the particular receiver output is inconsistent with the calibrated null model under its stated conditions. Such a departure can still be caused by an unmodelled lawful source, an analogue nonlinearity or a numerical defect. A subsequent physical investigation must challenge those possibilities with independent reference equipment and lawful observations. An attractive likelihood curve is not a map to a particular circuit board. The field record should reserve names of external apparatus for conclusions supported by source-specific evidence, not merely by statistical surprise.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Abraham Wald: Professor Wald, suppose a continuous receiver is left running until an operator sees a highly unusual event. The analyst then reports a probability calculated for observing an event of that strength in one fixed five-second interval, although the apparatus has been examined for many hours and its integration time was repeatedly altered. You have described sequential decision rules, but I ask you to explain how the stopping process could be formally incorporated without assuming independent observations that the receiver does not supply. Is there a practical distinction between a

Copyright 2026, James M. Atkinson

preplanned stopping boundary and a human decision to stop when a waterfall appears striking? If the laboratory's data stream contains gaps and retuning intervals, how should those intervals enter its exposure accounting? Finally, when the exploratory observation suggests a new feature, can a fresh confirmatory trial be designed without requiring the scientific team to discard all the useful insight it has already obtained?

Abraham Wald, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Sir Ronald, the distinction is between a specified sequential decision policy and a retrospective description of the one observation at which an operator happened to stop. A planned policy identifies the statistic to be updated, the observations eligible for inclusion, the alternatives, the boundaries for decisions and the rule for continuing when no boundary has been crossed. Under suitable assumptions, its error characteristics can be studied mathematically or empirically. A human who repeatedly changes the integration time and then selects the largest value has implemented a different procedure. The error probability derived for a single fixed interval does not automatically describe the event selected from that long adaptive history.

The dependence structure matters critically. Overlapping spectral frames may recycle many of the same samples, and successive dwell measurements can share slowly varying interference. A sequential procedure based on an independent-observation likelihood would be misspecified if these dependencies were ignored. One can instead characterise the complete practical detector by applying the frozen sequential algorithm to independent background-only records collected under appropriate operating conditions. The calibration should preserve realistic correlations,

Copyright 2026, James M. Atkinson

gap patterns and scheduling decisions. It should also define one alarm as an operational event rather than casually counting adjacent bright pixels as independent discoveries. The resulting estimate has a defined scope and uncertainty.

An observation gap cannot be treated as a negative measurement. Suppose the receiver sweeps another band for fifty seconds and observes the target frequency for ten. Its valid exposure at the target is ten seconds, not one minute. If a buffer is lost while nominally tuned to the target, the missing duration is an interval of unknown observation content, not verified silence. The detector's clock and sample counter information should permit the analyst to reconstruct valid opportunities. If such metadata are absent, the report must state the limitation. Interpolating a line through a gap can be a useful visual convention, but cannot create evidence of energy or its absence during that interval.

A new feature suggested by the exploratory record is a legitimate reason to design a more informative trial. The team may use the original capture to estimate a suitable centre frequency, choose a waveform template or decide which nuisance conditions need control. It should then freeze these decisions before collecting independent test material. The confirmation can be blind, with known authorised reference events and representative negative controls whose labels are withheld until predictions are fixed. If the method is revised after the blind results are seen, a further assessment is required, or the findings must be presented as exploratory. Scientific learning is cumulative; inferential independence concerns the evidence used for the particular confirmatory assertion, not whether the investigator must somehow forget prior experience.

Copyright 2026, James M. Atkinson

Abraham Wald, Cross-Peer Question to Sir David Cox: Sir David, the field team may predefine a single threshold yet continue to mislead itself if it applies that threshold to a statistic whose reference distribution is invalid. I invite you to distinguish errors introduced by choosing the hypothesis from errors introduced by fitting an inadequate noise model. Suppose the receiver environment alternates between two regimes, one quiet and one containing heavy-tailed industrial interference. The analyst trains a Gaussian model on the quiet intervals, deploys it across both regimes and calls the resulting high alarm count evidence of a new covert source. What diagnostic tests should precede that interpretation? How should a report express model uncertainty without claiming that a neat confidence interval solves all physical ambiguities? I ask also whether the duration and placement of observed gaps might bias the background estimate, especially if the acquisition system fails more frequently during periods of strong energy.

Sir David Cox, Cross-Peer Answer to Abraham Wald: Professor Wald, the two failures must be distinguished. Selection bias concerns the fact that the hypothesis, region, model or test statistic may have been chosen because of the observed data. Model inadequacy concerns the mismatch between the assumed distribution and the process actually generating observations. A test could be selected prospectively and still be invalid under a wrong model; it could use an adequate background model and still acquire a misleading single-test significance label through extensive post-selection. These difficulties may compound, and a rigorous report should examine each separately. Neither is repaired by attaching more decimal places to the final estimate.

Copyright 2026, James M. Atkinson

In your two-regime example, the first diagnostic is to examine the time dependence and operating context of the background observations. The team should compare empirical distributions, tail frequencies, autocorrelation and alarm clustering across the quiet and industrial regimes. It should inspect front-end overload flags, changes in analogue gain, calibration records and any correlation with operating machinery. A return to a known reference signal can test whether the detector itself remains stable. If the high alarm rate arises only during the industrial regime, the appropriate preliminary conclusion is that the frozen rule lacks validated specificity in that regime. It does not follow that any particular hidden apparatus exists.

The statistical model might be refined by prespecified stratification or an independently calibrated time-varying background estimator. But any model selected after seeing the purported anomaly should be evaluated on new material or accompanied by a suitable adjustment for selection. In a constrained field survey, where truly representative independent data are scarce, it may be more responsible to report empirical contrasts and substantial uncertainty rather than an unearned formal probability. Model-checking plots and negative controls should be preserved, including the unfavourable cases. A confidence interval conditional on an incorrect Gaussian model does not express uncertainty about the correctness of that model itself.

Missing-data behaviour introduces an additional selection mechanism. If buffers overflow more often during intense interference, the saved sample record may be depleted precisely where the background has the heaviest tails. An analyst who estimates the noise distribution only from surviving

Copyright 2026, James M. Atkinson

quiet windows may understate false alarms or underestimate interference. The gap register, acquisition counter and instrument status therefore form part of the statistical evidence. Investigators should test the receiver with controlled high-level reference inputs to establish whether losses are associated with signal strength or processing load. If missingness cannot be characterised, the report should flag the model qualification and refrain from a confident tail probability. The principle is simple: a mathematically correct calculation on selectively missing observations need not describe the unobserved physical process.

Sir David Cox, Cross-Peer Question to Walter Andrew Shewhart: Mr. Shewhart, an operational question remains. After a laboratory freezes and validates a threshold, the receiver may undergo a necessary maintenance change: a new preselector, updated firmware or replacement cable. Engineers must preserve safety and performance, and it would be unreasonable to forbid all retuning forever. Yet the same freedom to change a threshold can be misused to explain away a poor confirmatory result. What objective evidence should trigger a new calibration regime, and how should the historical record distinguish an authorised engineering revision from data-driven selection? Suppose the new baseline is demonstrably better in one environment but worse in another. What should the report say about the old results, and how should control charts distinguish process drift from a genuinely new external RF phenomenon? I ask for a protocol that can operate in a real laboratory, not merely a philosophical distinction.

Walter Andrew Shewhart, Cross-Peer Answer to Sir David Cox: Sir David, a quality system should permit necessary improvement while retaining a

Copyright 2026, James M. Atkinson

precise record of which claims were supported under which configuration. An instrument-maintenance change can be justified by calibration failure, known hardware defects, a documented replacement or a controlled alteration intended to extend capability. Such a change should have a timestamp, reason, responsible authority, hardware and software identifiers, and a record of the former validated regime. The existence of a legitimate reason does not mean the new performance can be presumed equivalent. The laboratory should demonstrate continuity where possible or conduct new reference and background tests where the change can affect the detector's behaviour.

A distinction between change-control review and post hoc inference is practical. In the former, an engineer documents the intended change and its acceptance criteria before the replacement configuration is tested. A qualified reviewer decides whether the evidence supports use of the new baseline. In the latter, an analyst changes thresholds because a particular alarming or inconvenient result has already appeared, then presents the edited rule as the one that governed that observation. The original record must remain immutable, and the changed analysis should be labelled as a derivative. A valid engineering improvement does not retroactively make a test prospective. The chronology of who knew what and when is therefore part of the chain of custody.

When performance differs across environments, the report should state the conditions rather than average away the difference. A reference detector may operate reliably in a shielded laboratory and badly near a strong industrial source. The team can define separate approved regimes if they have independently justified operating criteria and a method for identifying

Copyright 2026, James M. Atkinson

the applicable regime before evaluating an event. If classification of the regime depends on the event being judged, the possibility of selection bias must be assessed. It may be safer to retain a clearly qualified general rule and report that performance is not validated in the more troublesome environment. A single impressive graph is an inadequate basis for institutional acceptance.

Control charts should inform diagnosis, not establish source attribution. A drift in baseline power, noise variance, clipping frequency or internal spur amplitude can indicate a changed process. The team should compare reference signals, calibration check records and receiver state before interpreting an out-of-control point as an unknown emitter. Altering input attenuation, replacing the antenna with a known termination and checking another calibrated receiver can help distinguish internal and external mechanisms, though each control requires its own physical assumptions. An unexplained departure should remain unexplained until those competing causes have been examined. The integrity of the instrument's historical log is more important than the rhetorical force of its chart.

The correct institutional outcome is a pair of linked records. The first preserves the old configuration and all observations evaluated under it, including failed confirmation attempts. The second describes the candidate improvement, its evidence, its new operating limits and the date from which those limits govern future decisions. A later examiner can then compare regimes without being told that yesterday's observations were collected under tomorrow's threshold. This is how a process is permitted to improve without rewriting its scientific history. I return the token with the

Copyright 2026, James M. Atkinson

recommendation that every claimed confirmation should name the particular rule and validated apparatus state against which it was made.

QUESTION 096. TEN HYPOTHETICAL WORKED CALCULATIONS. All variables and assumptions are specified below. The numerical statements illustrate arithmetic relations and do not purport to measure a particular RF environment or validate a named detector.

EXAMPLE 1. If $p = 0.01$ is the probability of a false alarm per prespecified independent null trial and $m = 100$ independent trials are tested, the familywise chance of at least one alarm is $P = 1 - (1 - p)^m = 1 - 0.99^{100} \approx 0.63396766$, or 63.3968%. Independence is essential for this equality.

EXAMPLE 2. If $p = 0.001$ and $m = 1{,}000$ statistically independent null opportunities, the probability of at least one alarm is $1 - 0.999^{1000} \approx 0.63230458$, or 63.2305%. The expected number of alarms is $m\,p = 1$, which is not the same measure as the probability of at least one.

EXAMPLE 3. If $m = 100$ prespecified events each have marginal null alarm probability bounded by 0.0005, Boole's union inequality yields $P(\text{at least one}) \leq \min(1, m \times 0.0005) = 0.05$. This upper bound does not require independence, provided all marginal bounds are valid.

EXAMPLE 4. For target familywise error upper bound $\alpha = 0.05$ across $m = 100$ prespecified tests, the Bonferroni single-test threshold is $\alpha/m = 0.05/100 = 0.0005$. Such a rule need not be optimal and cannot retroactively account for an undocumented search over other tests.

EXAMPLE 5. For complex-sampling nominal rate $F_s = 2{,}000{,}000$ samples/s and FFT size $N = 4096$, bin spacing is $\Delta f = F_s/N = 2{,}000{,}000/4096 =$

Copyright 2026, James M. Atkinson

488.28125 Hz. Δf is not automatically the instrument's effective noise bandwidth or calibrated frequency uncertainty.

EXAMPLE 6. For a window N = 4096 samples shifted by hop H = 1024 samples, overlap count is N − H = 3072 and overlap fraction is (N − H)/N = 3072/4096 = 0.75, or 75%. Adjacent frames reuse samples and must not be treated as independent merely because they form separate display rows.

EXAMPLE 7. If a receiver physically observes a specified frequency for 10 valid seconds in a 60-second wall-clock period, exposure fraction is 10/60 = 1/6 ≈ 0.166667, or 16.6667%. The 50 unobserved seconds cannot be counted as verified silence.

EXAMPLE 8. If zero alarms occur in n = 1000 independent Bernoulli background-only trials, an exact one-sided 95% upper confidence bound on the per-trial probability is 1 − (0.05)^(1/1000) ≈ 0.00299125, or 0.299125%. The bound is not valid without a suitable model of independent trials.

EXAMPLE 9. If a frozen operational detector records k = 18 alarms during T = 6 valid observing hours in a declared band, an empirical alarm frequency estimate is r = k/T = 18/6 = 3 alarms per valid observing hour. This rate is not, without more assumptions, a per-trial false-alarm probability.

EXAMPLE 10. At a nominal sample rate F_s = 2,000,000 complex samples/s, a complete acquisition block containing N = 4096 valid consecutive complex samples spans T = N/F_s = 4096/2,000,000 s = 0.002048 s = 2.048 milliseconds. Lost samples and rate-error uncertainty require additional accounting.

QUESTION 096. TECHNICAL SOURCE NOTES. This modern dialogue is an original fictional scholarly reconstruction for the textbook, not historical

Copyright 2026, James M. Atkinson

speech or archival testimony. Source background for independent Stage-B checking: Jerzy Neyman and Egon S. Pearson, “On the Problem of the Most Efficient Tests of Statistical Hypotheses,” Philosophical Transactions of the Royal Society of London A 231 (1933), 289–337, DOI 10.1098/rsta.1933.0009, https://royalsocietypublishing.org/doi/10.1098/rsta.1933.0009; NIST/SEMATECH Engineering Statistics Handbook, Section 1.3.5 “Quantitative Techniques,” https://www.itl.nist.gov/div898/handbook/eda/section3/eda35.htm; NIST/SEMATECH Handbook, Section 7.4.7.3 “Bonferroni’s method,” https://www.itl.nist.gov/div898/handbook/prc/section4/prc473.htm; NIST/SEMATECH Handbook Chapter 6, “Process or Product Monitoring and Control,” https://www.itl.nist.gov/div898/handbook/pmc/pmc.htm. These sources support general methods, not the fictional words attributed to historical specialists. Receiver-specific false-alarm claims require documented detector and null-process validation.

EDITORIAL QUALIFICATION: Hypothetical numerical examples are calculations, not measurements. Exploration, calibrated detection, waveform classification and attribution of a specific source are distinct claims. Never imply that a selected threshold proves an unknown transmitter or justifies collecting communication content without authority.

QUESTION 097

Copyright 2026, James M. Atkinson

What selection bias follows when only alarm-triggered IQ data are preserved?

Dr. James M. Atkinson, Moderator: Sir Ronald, let us suppose that an otherwise competent receiver writes complex I/Q files only when a fixed detector declares an event. A later analyst examines hundreds of retained clips and concludes that the surveyed environment was crowded with emissions of that shape. Yet neither the silent intervals nor the receiver's incomplete opportunities to observe them remain available for inspection. I invite you to explain the selection mechanism, distinguish frequency of stored alarms from actual event prevalence, and design a lawful comparison against an independent observation record. Please also separate statistical inference from authenticity of the analogue measurement and from attribution of a particular apparatus. We shall proceed as a fictional modern scholarly reconstruction and not as an historical transcript.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher, Principal Contributor: Dr. Atkinson, I should first ask by what process the observations entered the collection. A record of selected alarm clips is not an ordinary random sample of the physical environment. The receiver may store data only when its own detection statistic crosses a predetermined threshold. Consequently every saved file is conditioned, in part, upon the statistic which the later analyst is tempted to measure. The selection mechanism may prefer the largest noise fluctuations, the strongest lawful transmissions and certain instrumental artefacts, while leaving the remainder of the underlying process unseen. One cannot infer the unconditional distribution of RF energy merely by treating the saved clips as if they had arrived at random. The problem persists even when the trigger threshold was admirably fixed before the survey. It is distinct from the post-selection testing problem previously discussed: the original decision rule can be prospective while the stored sample remains strongly selected.

The term conditioned on an alarm is important. Suppose Y represents a statistic computed from a valid receiver observation, and R is an indicator that the observation has been retained. If R equals one primarily when Y exceeds a threshold, then a distribution estimated from the retained observations describes Y given R equals one, not the distribution of Y across all valid observations. The two are not equal unless conditions justify that equality, and threshold-triggered retention is precisely a mechanism that usually prevents it. A plot of the saved samples may look exquisitely persuasive because the display contains almost nothing but excursions. The missing normal background has not vanished from the world; it has

Copyright 2026, James M. Atkinson

vanished from the evidence archive. Its absence must not be misrepresented as an experimental finding.

A second problem concerns the denominator. Hundreds of stored clips have limited meaning without knowledge of valid exposure. Were they collected in one minute, one week or across a year of sporadic survey visits? Was the receiver tuned to the specified frequency continuously, or did it scan that band for only a fraction of the recorded wall-clock duration? Did buffers overflow during intense interference, and did the application enter a refractory period after each alarm? Those operational details affect the opportunities in which the detector could have generated a stored event. A logging system that retains precise trigger timestamps and calibrated valid exposure may permit an empirical alarm rate per valid observing hour. It does not, by that fact alone, establish whether the alarms correspond to genuine external transmissions or to receiver-generated or environmental interference.

The distinction between false alarms and missed events becomes even sharper. If only triggered clips survive, an investigator can inspect many events that caused an alarm but cannot directly count genuine events to which the detector failed to respond. It is therefore improper to compute sensitivity solely from the fraction of saved clips that appear convincing. A measure of sensitivity requires an independently established population of true events under specified conditions. Likewise specificity requires valid background opportunities or an appropriate independent reference process in which alarm and non-alarm decisions can be evaluated. A trigger archive may contain false positives, but the absence of untriggered negative periods obstructs a full confusion matrix. Those unknown counts must be recorded

Copyright 2026, James M. Atkinson

as unknown, rather than filled with zero because no corresponding file exists.

I propose an authorised laboratory arrangement with two recording channels. The first is an independently characterised reference monitor, designed to preserve only the information necessary to establish valid observation time and whether defined test events occurred. Where permissible and technically necessary, it may hold limited, protected samples of known reference emissions. The second is the actual alarm-triggered receiver under examination, operating with a frozen threshold and a complete log of its gain, preselection, centre frequency, sampling rate and software state. An independent event generator supplies test pulses with a recorded timing schedule and specified amplitudes; background-only intervals and deliberate interference provide negative controls. The source schedule is concealed from the triggered detector's evaluator until its decisions are fixed. This design supplies an external denominator against which the retained alarm population can be compared.

The two channels must also reveal the effects of trigger latency and capture-window geometry. A pretrigger ring buffer of insufficient length may omit the first portion of a burst, while a posttrigger holdoff may merge separate events into one stored clip. An apparently narrow waveform family could be the consequence of a recorder that preferentially preserves long events and loses short ones. If a trigger requires the energy to persist across several frames, its retention rule selects on duration as well as amplitude. If the same receiver is overdriven by intense local signals, an overflow may destroy samples at precisely the moments that would be most interesting to a physical diagnosis. These mechanisms alter the observable population. A

Copyright 2026, James M. Atkinson

report should distinguish a missing sample, an unretained valid observation and an interval when the apparatus was not observing at all.

For clarity, consider a hypothetical exercise rather than a field claim. Let an independent source create one hundred test bursts in intervals during which the receiver is known to be tuned and functioning. If the triggered recorder saves sixty matching files, the laboratory may estimate a sixty-per-cent detection fraction for that specified burst population, subject to measurement uncertainty and matching criteria. But sixty stored files alone would not establish that figure if the independently known hundred-burst denominator were absent. The recorder might equally have observed sixty genuine bursts out of sixty, sixty out of a thousand, or a mixture of genuine bursts and unrelated alarms. The arithmetic is not difficult. What matters is whether each relevant observation and its eligibility has been independently established rather than inferred from the collection policy.

Evidence preservation complicates the matter without negating the scientific argument. A continuous I/Q archive may record communications content beyond the legitimate scope of an RF survey. The proper remedy is not to assume unlimited collection rights in the name of better statistical inference. The investigation can often preserve non-content occupancy summaries, calibrated reference-event ledgers, receiver-state changes, sample counters, valid exposure periods and hashes of authorised retained extracts. Where full samples are justified and legally permitted, their acquisition, protection, purpose and retention limits should be explicit. The scientific record should describe what was not kept and how that omission restricts inference. It should never conceal the selection mechanism simply because the underlying privacy constraints are inconvenient.

Copyright 2026, James M. Atkinson

I would finally ask that the later analyst consider alternative reasons a clip was selected. A strong nonlinearity may cause the receiver to trigger on combinations of lawful signals; a mismatched clock may shift the apparent duration of an event; software changes may alter the holdoff rule between survey sessions. If such conditions are undocumented, pooling clips can produce a population that never existed under any one measurement regime. A valid conclusion might be that the detector archived a specified number of threshold excursions under documented acquisition states. It might also be that a controlled reference test demonstrates certain strengths and limitations. Neither automatically identifies a covert or unlawful source. The first duty is to preserve the sampling mechanism as part of the evidence, for the polished appearance of the saved waveform should never be mistaken for proof that the discarded intervals were silent.

I respectfully pass the token to colleagues who will examine sampling inference, incomplete observations, trigger-driven decisions and the evidential limits of event-only recording. Their task is to make the missing denominator visible in the report even when the original samples themselves were not retained, and to specify which future independent experiment could justify a stronger conclusion.

Walter Andrew Shewhart, Peer Question: Sir Ronald, I should like to know whether a receiver's operational stability can be inferred from the tidy collection of alarm clips which the recorder has retained. In process monitoring, a signal is meaningful only in relation to a specified process and the opportunities during which its behaviour was observable. Suppose a technician reports forty unusually narrow spectral events and submits forty attractive waterfall extracts, but the same instrument varied its gain,

Copyright 2026, James M. Atkinson

temperature and preselector state during the survey. The selection rule may be fixed in software, yet the physical distribution to which it was applied may have shifted. How should the investigator separate genuine variation in the ambient field from changes in the measurement process? I ask further what an honest control chart could show when ordinary non-alarm observations have been discarded, and what records should be preserved instead of raw private communications to permit an independent assessment of statistical control.

Sir Ronald Aylmer Fisher, Response: Mr. Shewhart, your question reveals why retention and measurement must be separated. A control chart constructed only from saved excursions would depict the conditional population, not the monitored process. A receiver which increases its front-end gain may generate more alarms without any increase in incident electromagnetic energy. The numerical threshold might remain fixed in the digital units of a detector, yet the analogue energy represented by those units has changed. Conversely, activation of attenuation or preselection may reduce the number of saved events, suggesting quietness precisely when the apparatus has become less sensitive. The ordinary background is not a nuisance to be discarded when it provides the reference against which exceptional behaviour is defined.

I would insist upon a state ledger, timestamped at a resolution justified by the instrument, listing gain, attenuation, centre frequency, preselection, antenna selection, ADC overload indications, sampling rate, filter configuration, temperature if material and every software or firmware transition. The ledger must also represent intervals in which the receiver was properly observing, intervals of scheduled absence, and intervals

Copyright 2026, James M. Atkinson

rendered invalid by errors or overload. None of these fields need contain decoded communications. They establish what the apparatus was capable of measuring and when. A control chart may then be constructed for non-content summary statistics collected over predefined valid intervals, with a written decision as to whether the process was sufficiently stationary for the proposed comparison.

A retrospective chart of alarm amplitudes is not useless. It can describe the selected alarm population and reveal changes within that population, but it cannot establish the unconditional noise distribution or the frequency of unrecorded events. If a technician sees a sudden step in alarm amplitude, the correct inquiry includes whether the ADC scale, reference plane or temperature changed. If a sudden rise in alarm count corresponds with a high-powered transmitter outside the designated laboratory source, intermodulation must be investigated. A procedural chart can display counts per independently established exposure, yet an apparent control limit calculated from a changing mixture of receiver states would lack a coherent physical interpretation.

The acceptance test should include an independently monitored stable source, controlled gain transitions and background-only exposure. In each condition one compares the recorder's triggers against an external event ledger rather than treating the stored files as the entire world. Where the instrument changes state, analyses should be stratified or the state change explicitly modelled. We may conclude that the alarm process changed; we should not necessarily conclude that an external emitter changed. That difference, particularly in evidence destined for a tribunal, deserves ordinary plain language alongside the mathematics. The admirable object is not the

Copyright 2026, James M. Atkinson

largest collection of memorable bursts. It is a defensible account of the opportunities that existed, the selections that occurred and the uncertainties which the archive cannot abolish.

William Edwards Deming, Peer Question: Sir Ronald, a laboratory may possess an excellent reference receiver but still produce a misleading result if its test schedule is chosen for convenience. A series of conspicuous, strong reference bursts could make the triggered recorder appear sensitive, although the field question concerns very weak events close to the threshold. Likewise, a quiet shielded laboratory might make its false-alarm performance look impressive despite an industrial site containing impulsive machinery and strong adjacent signals. Would you distinguish a trial that verifies a mechanism from a trial that estimates field performance? How should operators select test amplitudes, durations and receiver states before examining the outcomes? Finally, if the lawful survey concerns a particular room or circuit, what may be inferred when the test environment cannot reproduce all its electromagnetic conditions? I seek a practical statement that neither exaggerates the experiment nor renders useful engineering evidence impossible to obtain.

Sir Ronald Aylmer Fisher, Response: Mr. Deming, the design is part of the answer, not a ceremonial prelude. A demonstration that a receiver triggers on strong signals proves a narrow functional proposition under the tested settings. It does not measure the probability of detecting weak events or bound the false-alarm rate in another environment. If the investigator intends to infer sensitivity across a range of amplitudes and durations, the laboratory should specify strata or a randomised schedule covering those ranges, with sufficient replication to characterise variability. The test

Copyright 2026, James M. Atkinson

generator should be accompanied by independent monitoring so that nominal settings are not confused with the actual field arriving at the device under examination.

We should define beforehand the target population of events. Perhaps the authorised problem is to detect brief, low-power test emissions within a stated frequency band, during stable receiver operation. Then the desired sensitivity is a conditional probability over that specified population, not a universal number which applies to every waveform or location. Test events should include durations shorter and longer than the detector's integration window, frequencies near filter edges, levels near the threshold, and an appropriate range of background disturbances. If the detector is triggered only by particular pulse shapes, the record should preserve that fact. Every test must be classified independently of whether a clip was stored. Otherwise the evaluation repeats the very selection defect it purports to correct.

Randomisation or masking can guard against an operator unconsciously placing reference events at convenient moments, adjusting settings after a success, or omitting difficult conditions from the final report. The intended table of analyses should be written before the test begins, distinguishing primary outcome measures from exploratory descriptions. A failed test case is not a wasted file; it is evidence about the method's limit. Conversely, a successful controlled test is meaningful within its assumptions. It is unnecessary to declare that every difference between laboratory and field invalidates the method. The appropriate question is which physical aspects of the field have been bounded and which remain unrepresented.

Copyright 2026, James M. Atkinson

A field report should therefore use graded claims: the instrument was demonstrated to respond to specified laboratory stimuli; the trigger process was evaluated against a documented event and exposure ledger; and the field observations are consistent with certain external or instrumental hypotheses. Each phrase has a different evidential weight. Industrial interference, unknown receiver noise statistics, cable coupling and uncertain antenna response are limitations to be stated, not erased by confidence borrowed from a laboratory success. That disciplined restraint is especially valuable in a lawful security examination where an erroneous inference could damage individuals or institutions. The strongest report is not the one that reports the most detections. It is the one that can explain which observations would have contradicted its conclusion and whether those observations were ever available.

Dr. James M. Atkinson, Moderator: Sir Ronald has demonstrated how predetermined physical strata and continuous non-content exposure records avoid the false comfort of a selected archive. I pass the token with respect to Dr. Jerzy Neyman to examine estimands, inclusion probabilities and the limits of design-based correction.

Copyright 2026, James M. Atkinson

Jerzy Neyman, Second Principal Contributor: Dr. Atkinson, there is an essential difference between a population whose units are defined and a collection whose units exist only because a machine elected to store them. A sample can support wider inference when its inclusion mechanism is known and the target population has been specified. Here the receiver's retention mechanism generally depends on the measurement itself. One cannot casually apply the usual language of representative sampling to records selected for having crossed the threshold. It is therefore necessary to state the estimand before constructing the calculation. Do we seek the mean power of all valid observation windows, the rate of externally verified bursts per valid hour, the probability of retaining an event in a defined reference class, or the proportion of stored alarms subsequently confirmed as matching a laboratory signal? These are different questions requiring different denominators.

Let an observation opportunity be defined in advance as a valid, non-overlapping time cell while the receiver is tuned to the specified band. Let E indicate that a genuine reference event occurred in that cell; A indicate that the detector alarmed; R indicate that an I/Q record survived; and V indicate that the instrument was actually able to observe. A proper analysis might estimate P(A=1 given E=1,V=1) for sensitivity, or P(A=1 given E=0,V=1) for a false-alarm probability. A collection restricted to R=1 does not identify either probability. It provides at most information about the conditional population of preserved records, unless an independent process measures the unretained units or the missingness mechanism is sufficiently known and tested. The equality of A and R must itself be verified: buffering, storage

Copyright 2026, James M. Atkinson

quota, write failures and holdoff can make an alarm occur without an archived file.

We should pay particular attention to how a population is defined across time. A scanning receiver revisits a channel intermittently. Its wall-clock survey duration is not equal to its valid observing exposure for that channel. If a 60-minute survey devoted only 10 minutes to a frequency, the relevant exposure for a simple count rate may be 10 minutes rather than an hour. Even that calculation assumes that all ten minutes are valid and that the counting rule treats overlapping triggers consistently. An independent event generator might inject bursts during the fifty unseen minutes, but those events cannot be counted as missed detections if the evaluation's denominator is explicitly restricted to valid observing opportunities. The scientist should report both coverage and performance conditional on coverage, rather than hide one inside the other.

There is a possible role for unequal-probability sampling, but it demands stronger evidence than an anecdote about how the software was configured. Suppose a lawful reference system makes a randomly selected subset of non-alarm periods available as content-minimised numerical summaries, while every alarm period is eligible for study. If each observed unit has a documented, nonzero probability of selection under a controlled design, one may construct estimates weighted by inverse inclusion probabilities under appropriate assumptions. Yet a deterministic threshold which assigns zero probability of retention to all subthreshold sample streams fails that requirement for estimating their detailed waveform distribution. No mathematical reweighting can recover information from an entire class of units which had no chance of entering the sample. The policy

Copyright 2026, James M. Atkinson

may protect privacy commendably, but the resulting inferential limit must be acknowledged.

Let us illustrate a simple, explicitly hypothetical design. Imagine one thousand independently designated valid one-second opportunities. Of these, an independent authorised monitor identifies forty reference events. The trigger process marks thirty of those forty, and marks twenty of the remaining 960 background-only opportunities. The resulting sensitivity is 30 divided by 40, or 0.75. The false-alarm probability per designated negative cell is 20 divided by 960, approximately 0.02083. The positive predictive value in this laboratory population is 30 divided by 50, or 0.60. But if the recorder stored only the fifty alarm clips and omitted the independent ledger, the counts forty and 960 would be unknown. The stored collection cannot justify the three proportions merely because each saved clip can be examined with great care.

The numerical trial should not be mistaken for a claim that the underlying time cells are independent in an actual receiver. Repeated FFT frames overlap, radio bursts cross boundaries, and dead time couples decisions across adjacent cells. A probability per predefined cell need not equal a rate per second or a probability per alarm episode. Sensitivity will also depend on signal amplitude, duration, spectrum, antenna orientation and front-end behaviour. For a real performance estimate one should provide uncertainty intervals, a sampling plan and a defensible account of clustering or correlation. A narrow numerical confidence interval calculated under an invalid independence assumption creates a false appearance of assurance. More decimal places cannot restore missing observations.

Copyright 2026, James M. Atkinson

A useful laboratory procedure is to separate the reference event schedule from the recorder under test. An independent monitor must confirm whether each test pulse reached the relevant measurement reference plane and whether the receiver was in a valid state. The team then compares trigger logs, write-success logs and retained file hashes. It should state whether an alarm without a saved clip counts as a trigger success for sensitivity, a retention failure for evidence availability, or both under different outcome measures. It should maintain a distinct ledger for downtime, scheduled tuning gaps, buffer overflow and unavailable reference events. These categories cannot be casually assigned to a zero in the confusion matrix without determining the trial's predefined observation unit.

Selection may also distort the apparent composition of waveforms. An amplitude threshold preferentially retains strong events, but a duration-dependent detector may disproportionately retain slow or persistent bursts; an alarm requiring spectral persistence may favour narrowband signals and suppress broadband impulses. A time-limited posttrigger window may cut off the end of long events, whereas overlapping triggers may make short events appear long. Thus even among genuine external emissions the stored files are not necessarily representative. A conditional distribution of retained spectral width, modulation depth or pulse duration should be described as conditional, with the operational selection rule attached. The correct question for an analyst is not simply whether a plot looks convincing, but what selection process made it visible.

In court or in the scientific record I would require the target population and the design to stand alongside the result. If the original observing

Copyright 2026, James M. Atkinson

opportunities cannot be reconstructed, the report should not assert a field prevalence or probability of missed events. It may legitimately report a count of surviving clips with verified provenance, the observed trigger timestamps, and a controlled calibration for specified conditions. If independent records later establish the denominator, the permissible inference can be expanded with a documented revision. That revision must not alter the original samples or conceal the earlier limitation. Statistical honesty and forensic integrity are compatible; the first supplies the limits of inference while the second protects the record on which that inference rests.

Solomon Kullback, Peer Question: Dr. Neyman, suppose a researcher is tempted to infer background conditions from the shapes of the alarmed signals themselves. The retained population contains large detector-statistic values and many clips whose opening windows seem to show quiet I/Q samples before the trigger. The researcher proposes to treat these pretrigger samples as randomly sampled background and use them to estimate the unconditioned noise distribution. Would that be justified? I ask you to consider correlations between pretrigger and trigger frames, ring-buffer replacement, stationarity assumptions and the possibility that an impulsive event was already developing before the alarm. Can the analyst ever make a useful background estimate from such clips, and if so what must be stated about its conditional character? I also seek an explanation of why a good fit of a model to retained clips does not, without independent controls, test the distribution of the unseen intervals. I also ask whether the same conditional pretrigger sample could appear statistically different when

Copyright 2026, James M. Atkinson

the independent reference spans a different receiver-temperature or gain regime.

Jerzy Neyman, Response: Mr. Kullback, the pretrigger sample is selected by its connection with a subsequent alarm. It is not drawn independently of that future decision simply because it lies a few milliseconds earlier in the stored file. If the detector uses overlapping windows, smoothing, a running noise estimate or a persistence rule, the samples preceding the nominal trigger may have contributed directly to the decision. A burst may already be rising within that interval. Even when the trigger statistic uses only later samples, the analogue process may be correlated across time, so observations immediately before a large excursion can differ systematically from ordinary background. The ring buffer may also fail preferentially at high activity, replacing or truncating the very material an analyst wants to use.

The analyst can describe the distribution of recorded pretrigger windows under the stated retention rule. Such a description may be useful for locating onset boundaries, diagnosing a particular filter transient or assessing clipping in the selected events. It does not by itself establish the unconditional noise floor. A claim of unconditional representativeness would require either a demonstrated independence property or an appropriately designed control sample of nontrigger periods. The instrument's algorithm should be disclosed sufficiently to know whether its threshold is computed from fixed past data, a sliding adaptive estimate or an interleaved set of overlapping transforms. A statement that the pretrigger region was 'quiet' is an empirical classification under a defined rule, not evidence that it was randomly sampled.

Copyright 2026, James M. Atkinson

One could perform a controlled diagnostic. Generate independent background-only opportunities under several verified receiver states, compare the marginal statistics from a predeclared random subset against statistics from pretrigger sections of subsequently alarmed files, and examine how their differences vary with lead time. It may turn out that a sufficiently distant pretrigger interval approximates the reference process for a particular measured statistic. That is a calibration finding limited to the tested stationarity conditions, not a universal theorem. The analyst should also preserve the possibility that the detector affects its own reference state by automatic gain control or adaptive thresholding, which may persist across multiple events.

A good fit within the selected data tests consistency with the selected-data likelihood, not with the unselected population. Many different underlying background processes can yield similar conditional tails after truncation or trigger selection. The inference becomes particularly fragile when the mechanism of missingness or instrument downtime is undocumented. If the investigator wishes to extrapolate beyond the observed collection, the report must display the model assumptions and a sensitivity analysis which asks how alternative unobserved distributions would change the conclusion. Without such external information, the honest conclusion remains limited to a conditional description. The task is to explain what the saved files show and why they do not show everything.

Sir Harold Jeffreys, Peer Question: Dr. Neyman, an investigator may argue that prior knowledge about typical industrial interference or receiver-noise amplitudes allows a probabilistic estimate of the unobserved event rate from the retained clips. In one version, a model assigns a distribution to all

Copyright 2026, James M. Atkinson

genuine emissions and a separate distribution to false triggers, then calculates the probability that each saved event was real. In another, it extrapolates the number of missed events from the detected amplitude tail. Could the data identify those quantities without an independent monitoring record? I should like a careful separation between an analysis that is conditional on prior and model assumptions, an empirical estimate supported by actual exposure, and a physical attribution to a particular source. What would you require the expert to disclose so that a court does not mistake a plausible posterior probability for a measurement made by the receiver? In particular, please explain how a prior which is credible for a quiet laboratory might fail when applied to an industrial setting with heavy-tailed interference.

Jerzy Neyman, Response: Sir Harold, a probabilistic model may be useful, but its strength is bounded by what the observations can identify. If the archive contains only selected clips and the total valid exposure is unknown, infinitely many combinations of event prevalence and detection efficiency may be compatible with the same collection. The analyst might assign priors to those unknowns, perhaps informed by earlier controlled experiments, but a numerical posterior may then be driven chiefly by those assumptions rather than by new data. That need not make the calculation intellectually illegitimate. It does make the provenance of its certainty essential to disclose. A statement about an assumed model's posterior is not the same as a direct estimate of the environment's unconditional emission rate.

I would ask the expert to show the likelihood conditioning explicitly. The distribution of an observed clip is the distribution of its measured features given that a retention event occurred and a write succeeded. If the

Copyright 2026, James M. Atkinson

probability of retention varies with amplitude, duration, waveform class or receiver state, the model must include those processes or justify neglecting them. The number of clips contributes information about prevalence only if their exposure and opportunity structure are independently known, including dead time and missed records. An amplitude-tail model can be fitted within the observed range, but extrapolation below the threshold rests on a distributional assumption which may fail in the presence of multiple emitters, clipping or unmodelled impulsive noise.

The expert should give alternative models which fit the retained evidence but imply materially different unseen populations. That exercise tests whether the conclusion depends on assumptions the actual recording cannot check. The uncertainty statement should distinguish parameter uncertainty within one model, uncertainty about the model family itself, and uncertainty in analogue measurement and event classification. The receiver may measure a complex baseband sample within calibrated limits; it does not automatically measure the prior probability that a covert source exists. Even an apparently distinctive signal may be consistent with several external or instrumental explanations. Attribution requires other evidence such as controlled antenna changes, independent instruments, lawful physical examination and exclusion of receiver artefacts.

A restrained report may therefore say: under the specified model and stated external assumptions, the estimated conditional probability that a stored alarm meets the reference classification criterion lies within a calculated range. It may not simply announce that the source was verified. If later independent exposure logs become available, the model can be checked against actual alarm and nonalarm opportunities. Until then, the posterior

Copyright 2026, James M. Atkinson

serves as a conditional aid to reasoning rather than a substitute for missing observations. The public should be spared neither mathematics nor caveats; a competent witness can explain both in clear prose. The numerical result gains credibility by displaying the assumptions that would falsify or materially alter it.

Dr. James M. Atkinson, Moderator: Dr. Neyman has demonstrated that a known sampling mechanism and an independently established denominator are prerequisites for generalising beyond stored alarms. I now respectfully invite Dr. David Harold Blackwell to examine the problem as a partially observed decision system in which a defensible retention rule may improve privacy while impairing statistical knowledge.

Copyright 2026, James M. Atkinson

David Harold Blackwell, Third Principal Contributor: Dr. Atkinson, my central question is not whether the machine is sophisticated, but what information its actions reveal. An alarm recorder implements a policy. Based on observed inputs and its internal state it decides whether to preserve an I/Q segment. The investigator later sees the consequences of that policy, and possibly a record of the decisions, but not necessarily the inputs on which decisions were withheld. A decision system can be useful for its intended purpose while yielding a deeply selective archive for later scientific inference. To judge it fairly we must distinguish the action the system was designed to take from the population characteristic the analyst now proposes to estimate. A device intended to preserve only high-priority anomalies may achieve its operational goal precisely by discarding normal background. That virtue is not a licence to claim that its surviving files represent the total RF environment.

Let us distinguish three informational objects. The first is the receiver's continuous opportunity to observe, including its tuning schedule, valid sample intervals and physical state. The second is the decision record: a sequence of trigger statistics or appropriately privacy-preserving summaries, thresholds, state transitions, decisions and storage-success indicators. The third is the preserved content-bearing I/Q file, available only when the policy selected it and the storage process succeeded. Many investigations require the second object for rigorous performance assessment without requiring unrestricted access to the third. An independent monitor may establish the population of known test events and negative controls. When exposure and decisions are logged across both

Copyright 2026, James M. Atkinson

selected and unselected intervals, the operator can assess alarm rates without storing the private contents of every observation.

The distinction between a trigger and a surviving file is easy to overlook. Let A=1 mean that the detector declared an alarm; R=1 mean that a data file was actually retained. If disk exhaustion, storage throttling or a programmed quota makes R=0 despite A=1, a count of surviving files understates the true alarm process. If the recorder groups repeated alarms into one long clip, a count of files cannot be equated with a count of alarm decisions. If a single alarm writes several channel-specific files, the opposite distortion occurs. The retention process may therefore have two selection stages, one acting on the detector and another on the file writer. Both must be reconstructed before the reported count has a stable meaning. A beautiful waveform and a correct checksum cannot tell us whether it was the sole surviving fragment of a much larger alarm sequence.

A controlled experiment should include a reference channel and a known event schedule, but it need not indiscriminately retain all content. One can select background intervals using a random seed agreed before the test and record only sufficient non-content diagnostics under the relevant authority. One can keep a rate counter, hardware-valid exposure and a compact occupancy summary when those data answer the engineering question. One can also preserve a protected and finite set of reference-waveform samples whose legal and scientific purpose has been specified. Where the actual discrimination problem requires detailed I/Q, the research design should identify those intervals and put them under proportionate retention safeguards. The policy governing collection is part of the study design, not an afterthought.

Copyright 2026, James M. Atkinson

Consider a recorder that uses a threshold and then introduces five seconds of holdoff, during which it will not create new files. An energetic interference source might produce many physical events in this interval, but the archive contains only the first alarm and the subsequent silence of the recorder's file list. That silence is not electromagnetic silence. It is a consequence of the recorder's decision state. A scientifically honest event-rate estimate must either observe the underlying events independently or acknowledge that events in the blind interval remain unresolved. The interval might be excluded from valid at-risk exposure for one particular measure, but doing so requires a clearly defined estimand. It cannot be removed from the real survey clock when the separate question is what proportion of the time the receiver was unavailable.

Decision theory also directs us to consider what harm each error entails. A trigger which saves unnecessary I/Q may collect more information than the authorised enquiry requires. A detector which saves too little may fail to preserve evidence needed to test a genuine safety or security concern. These costs are not purely numerical. They involve lawful authority, privacy, chain of custody, institutional fairness and the capacity of an independent reviewer to challenge a conclusion. A retention policy may legitimately favour privacy; the report should then state the resulting limits on missed-event inference. The worst practice is to obtain a limited archive by design and subsequently pretend that the absent material was studied and found uneventful.

The analyst should be especially wary of conditioning on a variable produced by both a source and an artefact. An alarm can occur because an external emission was present, because the receiver generated

Copyright 2026, James M. Atkinson

intermodulation, or because a transient noise excursion crossed the threshold. If one analyses only alarmed intervals, associations between otherwise independent external and instrumental factors can appear within that selected population. It is the general problem of conditioning on a common consequence. An observed relation between burst amplitude and front-end temperature within saved clips may be a property of the trigger mechanism rather than of the emissions. Independent background controls and receiver-state variation are required to distinguish the hypotheses.

The final output should therefore be a claim register, not merely a file manifest. It should separate observed trigger counts, retained file counts, estimated valid observing exposure, verified reference events, known missed reference events, unidentifiable unobserved occurrences and technical reasons for each exclusion. In the same register, state the rights and restrictions governing each retained dataset. When the analyst later changes the question from 'what did the trigger retain?' to 'what existed in the environment?', a new evidential justification is required. The first is ordinarily easier to prove; the second can be much more consequential. I respectfully yield the token for challenge, especially upon how to interpret missingness generated by a device whose policy was deliberately selective.

John Wilder Tukey, Peer Question: Dr. Blackwell, I have a concern that exploratory graphics can seduce even an expert who knows about selection. The retained clips may reveal several apparent waveform clusters: a family of short narrowband pulses, an apparently unrelated group of broadband events and a third group containing a common transient. An analyst performs clustering on the stored I/Q, displays a pleasing separation and labels each cluster a distinct transmitter class. Yet the trigger may have used

Copyright 2026, James M. Atkinson

different windows for different bands, and only those segments exceeding an adaptive energy statistic were preserved. How would you use exploratory analysis responsibly without turning a conditional visual taxonomy into a claim about the numbers of actual transmitters or the relative prevalence of their emissions? What negative controls and alternative partitions would you ask to see, and how could the selection record be represented beside the plots so that the reader cannot mistake colour-coded clusters for physical ground truth?

David Harold Blackwell, Response: Mr. Tukey, exploration is legitimate when it is labelled as exploration and when its selection mechanism is displayed. Clustering answers a mathematical question about the retained observations under a chosen feature map and distance measure. It does not prove that an equal number of physical emitter classes exists. The detector's own filterbank may favour certain spectral widths, durations or amplitude trajectories. Two visually distinct clusters could be created by two receiver states measuring the same external source, while two independent external sources could fall in one cluster after lossy normalisation. A correspondence between clusters and sources requires external evidence, not merely an attractive silhouette score.

I would first attach to every plotted point its trigger rule, receiver state, capture-window geometry, reference-plane calibration and indication of clipping or overflow. One should vary permissible feature definitions, window lengths and frequency normalisations, then report whether the partition is stable. An independent monitor or authorised calibration source can provide controls of known provenance; deliberately generated receiver artefacts can test whether the method assigns a fictitious signal class to

Copyright 2026, James M. Atkinson

internal products. Blind classification against those controls offers more evidence than repeatedly tuning the algorithm until a desired grouping appears. Analysts should also show the distribution of observation exposure by state so that an abundance of files in one operating mode is not mistaken for an abundance of emissions from that mode.

A conditional plot might support a narrow finding that, among retained clips generated by a stated policy, several reproducible signal-feature groups were observed. If an independent monitor establishes which external reference sources produced the test data, the classifier's performance for that reference population can be evaluated. Without such a denominator, one should not report that forty percent of all emissions belonged to the largest cluster. Nor should a few visually isolated records be called covert transmitters merely because they are unfamiliar. The unknown category must remain visible; under controlled experiments it may contain test artefacts, accidental interference or detector failure rather than a distinct source.

The ethical value of the graphic is to make uncertainty comprehensible. I would show the selection boundary itself, mark points that came from clipped or truncated captures and give explicit counts of receiver states and valid exposure, not merely a brilliantly coloured constellation. A separate chart can show how the same known calibration waveforms change appearance under altered gain, filtering and capture windows. If a claim changes substantially under reasonable feature choices, that instability belongs in the report. The proper conclusion may be modest but useful: the retained archive contains several reproducible measurement patterns deserving controlled investigation. It is not yet a census of transmitters, a

Copyright 2026, James M. Atkinson

proof of authenticity or a lawful basis for opening protected communications.

Dr. James M. Atkinson, Moderator: Dr. Blackwell has separated a decision-policy archive from the environment it selectively represents. I now pass the token to Sir David Cox to consider ascertainment, regression and the missing information that conditions any attempted reconstruction of rates or associations.

Copyright 2026, James M. Atkinson

Sir David Cox, Fourth Principal Contributor: Dr. Atkinson, the retained observations are subject to ascertainment. This is a term with a precise purpose: whether an observation enters the dataset depends on variables related to the phenomenon under study. In a triggered RF recorder the probability of being observed often depends on amplitude, duration, spectral shape, time since the preceding alarm and the receiver's operating state. These dependencies can distort both simple distributions and relations between measured variables. Suppose an analyst finds that longer retained bursts are also brighter in a waterfall display. That association may arise partly because short weak bursts seldom trigger, rather than because the physical sources intrinsically couple duration and power. It would be dangerous to assume that a regression estimated only on saved clips has the meaning it would possess in a complete observation record.

The investigator should write a generative account of the acquisition chain. There is an external electromagnetic environment, an antenna and analogue chain, a sampled numerical representation, a detector statistic, a decision threshold, a holdoff mechanism, a write process and an analyst's feature extraction. Each step may introduce selection or measurement error. The model need not be excessively elaborate, but its causal order must be clear. A stored clip is the product of several processes. If the probability of retention depends on a quantity which is also the regression outcome, conventional analyses of the retained sample may be biased. If the retention mechanism depends on variables that are fully observed and correctly modelled, adjustment may sometimes be possible. If it depends on unobserved signal properties, conclusions may remain only partially identified.

Copyright 2026, James M. Atkinson

A useful taxonomy is to distinguish absent exposure from missing measurement within valid exposure and from deliberate non-retention of a valid observation. When the receiver has not tuned the channel, the measurement opportunity is absent. When the ADC was operating but a buffer overflow occurred, the opportunity may have existed while the samples were lost. When the detector calculated a subthreshold statistic but policy withheld the I/Q, the system observed enough to make a decision while retaining only part of the information. These situations have different implications for event counts, rate estimation and evidential continuity. A rigorous data dictionary should have separate codes for them rather than a single blank value that an analyst's software interprets as zero.

Let us examine rates. Suppose a laboratory reference ledger identifies thirty verified bursts during five hours of valid observation, whereas the triggered instrument stores eighteen matching clips. An investigator may estimate a reference-event rate of six per valid hour and a detection fraction of eighteen divided by thirty, or 0.60, for that deliberately specified test population. But suppose the instrument has an additional one hour of unlogged blind time. We cannot silently add that hour to the observed denominator and claim a lower rate, nor can we assume that it contained no bursts. Conversely, if the reference monitor established that the one-hour blind period was itself unobserved by both systems, the target rate for the entire six hours is not identified without assumptions about what occurred there. The calculation should make these distinctions visible.

Time-varying background and receiver states complicate matters further. A likelihood model treating alarms as a constant-rate counting process may fail when a nearby industrial machine cycles, when a preselector retunes or

Copyright 2026, James M. Atkinson

when a shared interferer generates clusters of alarms. Dead time can also change the distribution of observed intervals between files. If the recorder waits three seconds after each retained event before rearming, the shortest observed file-to-file interval can be three seconds even though physical events occur more frequently. An analysis which fits the interfile intervals without incorporating the holdoff will misdescribe the process. One should record device-state transitions and decide whether a renewal-process, point-process or interval-based model is actually justified by the available observations. For some questions, a simple tabulation is more defensible than elaborate parameter fitting.

Missing-data terminology should not become an excuse for untestable assumptions. If missingness is entirely dictated by a known trigger statistic that has been logged for all valid intervals, certain probabilities may be estimable under a carefully specified model. Yet when the entire untriggered waveform has disappeared, its unrecorded fine structure cannot be recovered solely from the trigger value. If a detector uses an adaptive noise floor whose historical values were not saved, even the retention mechanism may be incompletely documented. Sensitivity analyses should then vary plausible unseen event rates, signal shapes and storage-failure mechanisms, showing which conclusions survive. A sharp point estimate obtained by assuming away the missingness is weaker than an informative range which admits ignorance.

A report should distinguish a statistically reproducible relation among archived clips from an independently validated physical relation among emissions. An observed regression coefficient may be precise within the selected population and still lack a straightforward interpretation across all

Copyright 2026, James M. Atkinson

RF events. The analyst should retain the transformations, feature-extraction software versions, calibration values and exclusion decisions needed for independent reproduction. If the objective is a legal or technical conclusion about a particular device, further physical tests must be specified. The mere fact that a retained burst has a high numerical similarity to a known laboratory waveform does not establish common origin in an uncontrolled environment. Nor does a low signal-to-noise ratio establish absence of an emission.

I would recommend a two-stage reporting practice. First provide the design and observation facts: tuning and exposure, reference schedule, detector decisions, retained files, missingness, dead time and uncertainty. Then provide conditional statistical analyses clearly tied to those facts. A table may show the observed true positives, false positives, false negatives and true negatives where independent reference classification supports them. Unknown cells should remain unknown. A supplementary analysis can explore how estimates change when background conditions, the retention model or the classification threshold differ. The reader should be able to see which inferences are driven by measurements and which depend upon assumptions. This separation is particularly important before any forensic testimony, where an unexplained numerical precision may be more misleading than a cautious statement of uncertainty.

Peter Elias, Peer Question: Sir David, the recorder might compress its output by saving only event metadata during most valid intervals and full I/Q for selected alarms. That seems attractive for privacy and storage, but the metadata schema can itself conceal what is missing. A trigger log might retain only its maximum statistic, omitting the detector window length,

Copyright 2026, James M. Atkinson

overlap fraction, band-selection policy and the precise conditions under which values were calculated. What minimal information would you regard as necessary to identify the selection process, even though reconstructing the discarded waveforms is impossible? Could a data dictionary make subsequent statistical modelling more reliable by distinguishing unavailable samples from deliberately withheld samples? I also wonder whether a file format which records only successful writes encourages a later analyst to mistake a failure of storage for a failure of the detector. How should the system expose both without gathering communications content beyond its lawful purpose?

Sir David Cox, Response: Mr. Elias, one should not confuse a compact record with an incomplete one. A useful non-content decision ledger can remain quite small while recording the information necessary to interpret a retention event. It should identify valid observing intervals and tuning state; the versioned detector algorithm; its statistic definition, transform length, window function, overlap and filtering; the threshold and any adaptive reference values; the instant and sequence number at which a decision was made; holdoff and rearming state; the requested preservation interval; whether the file writer acknowledged completion; and the reason for any failure. These fields reveal the decision mechanism without requiring decoded payloads or complete continuous I/Q. They are essential if a reviewer must later distinguish a rejected observation from one never measured.

The data dictionary should distinguish at least four statuses: observed and retained, observed but intentionally not retained, not observed because the receiver was untuned or disabled, and observed but lost because of a

Copyright 2026, James M. Atkinson

technical failure. A fifth category may be required for a decision whose underlying sample stream has ambiguous validity, such as overload or counter discontinuity. Each status should have a documented source and timestamp semantics. If a software subsystem reports a write error after an alarm was issued, both events must survive as separate records. Otherwise the number of saved files will masquerade as a detector decision count and bias every subsequent performance measure.

Compression of the forensic description must be evaluated against the precise question to be answered. A summary of peak spectral power may be sufficient for a narrowly defined occupancy statistic in some circumstances, but it cannot preserve phase trajectories or reveal every short transient. The uncertainty record should say which features were computed at acquisition, which were reconstructed later and which cannot be tested because the data were not retained. A deterministic cryptographic digest protects the bytes actually saved; it does not authenticate the missing sample stream or correct an absent algorithm version. A properly protected manifest and controlled derivative history keep those propositions separate.

Finally, the scientific model should be assessed through a deliberately structured fault-injection programme. Induce a buffer overflow, storage quota failure, receiver retune, adaptive-threshold reset and clock discontinuity in an authorised laboratory. Verify that the ledger records the correct cause and that the analyst's code does not silently convert any of these into an ordinary non-alarm interval. That experiment would be more valuable than adding detailed but ungoverned private contents to the archive. A defensible collection policy captures the minimum facts necessary to support a stated inquiry and makes the limits of the unrecorded
