remainder explicit. No statistical technique can replace such candour after the acquisition has ended.

Dr. James M. Atkinson, Moderator: Sir David has explained how a selective archive can alter observed associations even when its internal numerical calculations are perfectly repeatable. I now invite Dr. Abraham Wald to examine detection policies acting through time, especially intervals suppressed by holdoff, repeated alarms and decisions taken under constrained evidence retention.

Copyright 2026, James M. Atkinson

Abraham Wald, Fifth Principal Contributor: Dr. Atkinson, a sequential decision system must be understood as a process rather than a pile of isolated success stories. At each observation opportunity the receiver possesses a state based on previous samples, previous alarms and the rules under which it is permitted to continue or refrain from recording. A threshold may be fixed, yet the effective chance of a file appearing can depend on how many times the device has recently alarmed, whether a buffer remains available, and whether the trigger statistic accumulates evidence across successive frames. The resulting retained clips are conditioned on a history of decisions. We must therefore resist the temptation to treat each saved file as an independent, identically distributed draw from the environment.

The distinction between a detector alarm and the file writer's rearm state is central. Imagine a trigger which initiates a 100-millisecond capture and refuses further alarms during that capture. If physical bursts occur in rapid succession, the retained record may contain one long file or one file with multiple events, yet the trigger counter might remain at one. Alternatively a system may extend its capture on every alarm, merging multiple bursts into a single episode. The number of files per hour is not the number of emissions per hour, and it is not even necessarily the number of threshold crossings per hour. Any likelihood calculation must identify its event unit. If the unit is a file, the model concerns the file-generation mechanism. If the unit is an independently verified physical burst, the model must include missed and merged events.

We can formulate a carefully delimited test using independent, authorised reference pulses. Consider an observation period with a known sequence of

Copyright 2026, James M. Atkinson

event times and a separate ledger of valid receiver state. The recorder's policy is frozen before the sequence begins. It issues alarm decisions, enters holdoff states, and writes files with reported success or failure. A reviewer compares physical events against alarms, alarms against retention requests, and retention requests against completed files. Each comparison yields a different rate and a different failure mode. We should not combine the stages into an undifferentiated statement that 'the recorder captured eighty per cent of events' unless the definition of captured has been agreed and the handling of overlapping events is explicit.

The sequential nature of the decision introduces dependencies into any uncertainty calculation. If a strong event changes automatic gain, the response to a later weak event may differ from its response in isolation. If a running background estimator is contaminated by a burst, it may raise the threshold temporarily and suppress neighbouring events. If the operator changes bands following an alarm, subsequent observations are no longer sampled under the original fixed schedule. There is no objection to an adaptive policy when its purpose is lawful and properly specified, but analysis must condition on its states. A naive binomial confidence interval for independent alarms will generally be unjustified if decisions are clustered by shared noise, overlapping transforms or recorder holdoff.

One may use controlled randomisation to examine these effects without collecting unrestricted communication content. The independent reference schedule can vary interburst spacing, amplitude and duration while the recorder under test remains blind to the schedule. It is important to include events arriving during the declared holdoff period and to decide in advance whether these are classified as expected non-detections under the policy or

Copyright 2026, James M. Atkinson

are counted against a broader operational coverage criterion. Both summaries can be useful, but they answer different questions. A receiver which intentionally ignores all but the first event in a cluster may perform exactly as designed and still be unsuitable for estimating how many physical events the cluster contained.

For example, suppose twenty known reference events occur during valid receiver observation, and twelve elicit detector alarms. Of those twelve, ten lead to files which pass byte-integrity checks. The alarm sensitivity for that defined test population is twelve twentieths, or 0.60. The proportion of alarm decisions yielding surviving files is ten twelfths, about 0.8333. The proportion of known events yielding surviving files is ten twentieths, or 0.50, assuming each file is matched uniquely to an event. It would be a serious reporting error to call the ten saved files evidence of a fifty-per-cent field event prevalence. These numbers describe controlled performance measures whose denominators come from an independent reference record, not from the stored alarm files themselves.

We must also account for the cost of unnecessary recording. The policy may impose a legal or institutional limit on the data that may be kept, particularly where I/Q samples could contain protected communications. In that case a design which reduces full sample retention can be entirely appropriate. The experimenter may preserve summary counters, calibrated occupancy statistics, decision states and limited authorised reference segments rather than entire streams. The scientific consequence is that some questions cannot later be answered. That limitation is not evidence of dishonesty; it is the legitimate boundary of the experiment. Dishonesty enters if a

Copyright 2026, James M. Atkinson

subsequent report conceals the boundary and asserts that the unretained data proved the absence of an emission.

A practical acceptance record should list the reference-event definition, exposure intervals, event matching tolerance, trigger state, holdoff policy, write success, file hash and treatment of merged or truncated clips. A reviewer should be able to rerun the detector against retained authorised reference data, where available, and explain why the resulting decisions agree or disagree with the original decisions. When content is lawfully unavailable, the reviewer may still test the software on a controlled surrogate sequence. The report must say which validation used the actual survey data, which used laboratory substitutes and which cannot be reproduced because observations were never retained.

Finally, a sequential procedure must distinguish the statement that an alarm occurred from the statement that an external source existed. The latter requires a physical account of the antenna, analogue chain, clock, noise, interference and alternative mechanisms. An alarm is a system action in response to measured statistics; it is not a verdict. The display may provide a useful trail for an authorised engineer, but the security of that trail depends on measured reference conditions and on accurate disclosure of what the recorder failed to see or was prohibited from keeping. I pass the token to my colleagues for a final interrogation of the data-custody and statistical distinctions.

Grace Brewster Murray Hopper, Peer Question: Dr. Wald, my concern lies in the machine-readable account of the selection policy. Engineers sometimes preserve a configuration file containing the threshold and write a series of alarm clips, but fail to preserve the actual compiled program, firmware

Copyright 2026, James M. Atkinson

revision, buffer semantics or error logs from the field session. Later they replay the clips with a newer algorithm and declare that the receiver must have alarmed for the same reasons. Would you distinguish reproducibility of a later numerical transformation from reconstruction of the original acquisition decision? What would a minimally sufficient event ledger contain, and how should it handle changes in software during the survey? If privacy rules prevent saving continuous I/Q, how can an independent examiner still audit trigger counts, valid exposure, write failures and intentional non-retention without being supplied with communications content unrelated to the authorised enquiry? The record must also distinguish a decision made in firmware from a derivative decision made later in the host software.

Abraham Wald, Response: Admiral Hopper, a replay with new software is a new experiment unless the original policy and its state can be reconstructed faithfully. A saved waveform may produce the same spectral statistic under two implementations, yet those implementations may differ in the order of filtering, floating-point rounding, window alignment, adaptive-threshold update or file-write timing. The event ledger must identify the actual acquisition chain, including instrument model and relevant hardware state, software and firmware identities, configuration digest, clock provenance, decision thresholds, buffer and holdoff rules, and status codes for both detector and writer. If an upgrade occurs halfway through the survey, it creates a new observation stratum unless equivalence has been demonstrated under an appropriate test.

The ledger should preserve the distinction between an observation opportunity and a storage action. A record can identify a valid receiver

Copyright 2026, James M. Atkinson

interval, a detector statistic or privacy-preserving threshold-crossing summary, an alarm decision, the requested retention interval and the outcome of the storage request. It can indicate deliberately suppressed files separately from failures caused by quota exhaustion or transport error. Each event should carry an acquisition-side monotone identifier and a timestamp whose source and uncertainty are documented. A file hash can authenticate the bytes of a saved extract relative to its reference digest, but it cannot authenticate an unrecorded interval or prove that the original algorithm was correctly implemented. Those distinctions allow an audit without a complete continuous I/Q archive.

An independent reviewer should be able to construct three counts: how many valid opportunities were monitored under each state, how many alarms the detector declared, and how many corresponding files survived with intact custody records. A separate reference monitor, operating within its own lawful scope, may then establish the number of genuine test events and background-only opportunities. Only with that information may the analyst compute sensitivity or a per-cell false-alarm fraction for the specified test population. Where such a reference does not exist, the unknown cells remain blank. A reconstructed statement of 'zero missed events' would be no more valid than claiming a storage system never lost data because its directory contains no files labelled lost.

The software package should support independent negative controls. Inject a known signal that should alarm, one which should not, a sequence which exceeds the file writer's throughput, a clock discontinuity and a trigger during holdoff. Confirm that the recorded event states correspond to the known conditions. The independent examiner should also be able to parse

Copyright 2026, James M. Atkinson

old manifests without silently applying revised defaults. Provenance is not merely a list of version names; it is a history of which executable rules created each observation and which later transformations were applied. When the reporting question moves from operational behaviour to a legal or physical attribution, the expert must obtain additional evidence rather than enlarge the meaning of a machine-generated alarm.

Dr. James M. Atkinson, Moderator: The five principal contributions now stand before the panel. I invite the principal experts to pass the token among one another for reciprocal examination, ensuring that each challenge is answered by the named colleague and that methodological differences remain visible rather than prematurely reconciled.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Jerzy Neyman: Dr. Neyman, your example of a thousand predefined observation opportunities with an independent event ledger is persuasive, yet I would question the consequences of dividing a continuous RF stream into nominally equal cells. A burst crossing a boundary may be counted in two adjacent opportunities; a long interferer may contaminate many cells; and an overlapped short-time Fourier transform may generate multiple detections from one physical occurrence. How would you define the population before observing the sample so that an apparent confusion matrix does not depend arbitrarily on the chosen time-cell width? What would change if the outcome sought were an event arrival rate rather than a per-cell false-alarm probability? I ask also whether a random sample of background intervals, selected with independently recorded probabilities, can repair some inferential limitations without requiring continuous preservation of potentially protected

Copyright 2026, James M. Atkinson

communication content. At what point does aggregation destroy the very denominator it was intended to secure?

Jerzy Neyman, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Sir Ronald, the unit must follow the estimand. If the question concerns whether a defined interval contained a detectable reference emission, a predeclared time cell may be suitable, provided the handling of boundary events is specified. An event crossing the edge should be assigned by a predetermined rule, perhaps according to independently established onset time, rather than counted twice merely because two processing frames overlapped. If the question is a physical burst arrival rate, the experiment instead requires a definition of an event episode, a separation rule and procedures for merging or splitting near-simultaneous occurrences. Neither formulation is universally superior, and one cannot move between them without additional assumptions.

A confusion matrix may be formed for the chosen set of valid cells or events when an independent reference identifies both positive and negative opportunities and when the detector's decisions can be matched to those opportunities. Overlapping FFT frames are computational units, not necessarily independent experimental units. One may process many overlapping frames to make a single event decision, but the count of such frames must not automatically become the denominator for an independent-binomial probability. Clustering, dead time and changing background conditions must be reflected in the experimental design and uncertainty calculation. A sensible protocol reports the decision unit as carefully as the sample rate or threshold.

Copyright 2026, James M. Atkinson

Random sampling of background opportunities can indeed improve inference within the limits of its design. If the system records selection probabilities and preserves authorised non-content summaries for a randomly selected subset of non-alarm periods, one may estimate specified background characteristics using suitable weighting or design-based methods. But a random summary of peak energy cannot recover the detailed I/Q phase of unselected periods. Nor does it establish the number of true reference events unless their status is independently determined or inferred under a defensible model. A sampling plan should state which variables were available for every unit and which appeared only for the sampled units. The promise of a representative sample must be connected to a particular variable and population, not offered as a general certificate for every possible later enquiry.

Aggregation destroys a denominator when it collapses distinctions necessary for matching exposures, source states or detector decisions. A daily alarm total without valid tuning time cannot support a per-channel rate; a file count without an alarm-decision count cannot assess retention success; and a positive-clip archive without reference negatives cannot identify specificity. The best record keeps small, privacy-preserving counts at the proper physical and temporal granularity, with missingness codes and receiver-state epochs. Thus the statistical design and the evidence-retention policy should be drafted together. Their common purpose is to make the warranted inference possible while declining to preserve material which the lawful enquiry does not require.

Jerzy Neyman, Cross-Peer Question to David Harold Blackwell: Dr. Blackwell, I would press you on the fairness of evaluating a deliberate decision policy

Copyright 2026, James M. Atkinson

against a statistical goal it was not built to satisfy. A recorder might be designed to preserve only exceptional RF excursions because storage and privacy obligations prohibit continuous I/Q retention. An analyst subsequently asks for an estimate of the proportion of weak short bursts that were missed. Plainly that target cannot be reconstructed from the positive archive alone. But can we design a two-tier policy under which the machine retains minimal, appropriately protected performance metadata from non-alarm intervals while reserving full waveform evidence for specially authorised events? What safeguards would prevent the supposedly non-content metadata from becoming an alternative vehicle for intrusive surveillance? And how would you explain to an engineer why a mathematically optimal trigger policy for operational detection may still be suboptimal for unbiased retrospective estimation?

David Harold Blackwell, Cross-Peer Answer to Jerzy Neyman: Dr. Neyman, a policy's value depends on the decision problem it was designed to solve. If the objective is to alert an authorised operator to a limited class of signal anomalies while minimising storage, an alarm-only archive may be entirely rational. It can still be unfit for a later estimate of unseen event prevalence. The distinction is not a criticism of the original design; it is a reminder that the design's action rule determines what evidence survives. An engineer should not infer from operational success that every scientifically interesting characteristic of the environment was measured, preserved or identifiable.

A two-tier arrangement can be appropriate. One tier maintains compact records of receiver state, valid exposure, threshold decisions, algorithm versions, holdoff periods and storage outcomes. The other contains strictly controlled I/Q excerpts for events whose retention is lawful and necessary.

Copyright 2026, James M. Atkinson

An independent reference-event monitor or predetermined random sampling programme can supply additional non-content measures for calibration. To ensure that the summary tier does not itself become an intrusive surveillance apparatus, the organisation must define authorised purposes, restrict frequency and temporal granularity to what those purposes require, impose access controls and retention limits, and avoid recording decoded payloads or unnecessary identifiers. Technical minimisation and legal authorisation must both be examined, since even metadata may be sensitive in particular contexts.

One can evaluate both decision utility and inferential utility. Decision utility asks whether a policy triggers when it should, refrains when it should, and operates within costs and lawful boundaries. Inferential utility asks whether the preserved observations identify the population characteristics needed for a stated later question. Those objectives may conflict. A policy may benefit operational performance by holding off repeated alarms, but this holdoff suppresses file counts and complicates estimates of physical event arrivals. A policy may minimise data collection by withholding subthreshold I/Q, while preventing retrospective reconstruction of subthreshold waveform structure. The evaluation should make the tradeoff explicit rather than call one design intrinsically superior.

For this investigation I would specify the permitted claims in advance. An alarm log supports a statement about detector actions under documented exposure; a reference comparison can support a bounded sensitivity estimate; retained clips can support analysis of the preserved waveforms; and independent physical controls are required before a particular source is attributed. Every step adds evidence and also new assumptions. A

Copyright 2026, James M. Atkinson

transparent report can praise a privacy-preserving policy while declining to calculate quantities the policy leaves unidentified. That is not a retreat from scientific rigor. It is its application to a decision system operating under actual institutional constraints.

David Harold Blackwell, Cross-Peer Question to Sir David Cox: Sir David, your account of ascertainment raises an awkward causal possibility. Suppose receiver gain changes, the background interference changes, and the probability of a clip being retained depends on both. Among the retained clips, an analyst observes an apparent association between the gain setting and a signal feature, even though the true external signal population may not have changed. Would you explain how conditioning on the file-retention event can generate such an association, and how one might distinguish it from a real change in the observed RF environment? I should also like you to consider what can be learned when only coarse threshold counters survive from the unretained periods, perhaps because privacy constraints rightly prohibit keeping complete I/Q. Where is a sensitivity analysis informative, and where must the answer be that the association is not identifiable without new evidence? Could the record disclose precisely which adjustment variables were observed before retention and which became visible only after a file was selected?

Sir David Cox, Cross-Peer Answer to David Harold Blackwell: Dr. Blackwell, the apparent association may arise through the process by which the records enter the study. Imagine, for simplicity, that both receiver gain and the instantaneous amplitude of an independent noise fluctuation affect whether a file is saved. Conditioning on saved files means selecting cases for which their combined effects were sufficiently large to cross the trigger

Copyright 2026, James M. Atkinson

boundary. Within that selected population, a lower gain may require a larger noise fluctuation for a clip to appear, whereas a higher gain may permit smaller fluctuations to be retained. The retained observations can therefore exhibit a relation between gain and noise amplitude which is largely generated by the selection boundary. It would be mistaken to treat that relation as evidence that the external physical source changed its emitted power with the operator's gain setting.

To distinguish selection from physical change, the analyst should examine independent measures of receiver state and externally controlled reference signals. A laboratory may apply the same calibrated stimulus at several gain settings and observe how the recorder's selection region changes. If an independent monitor records the background without the same selection rule, its non-content statistics can help distinguish a genuine change in ambient conditions from a filtering effect. A state-stratified study of valid exposure may allow the analyst to estimate alarm rates conditional on each state. Yet the detailed distribution of unretained waveforms may remain unidentifiable if their properties were neither logged nor sampled under an independent design.

Coarse counters can still be valuable. They may establish how often the detector declared an alarm in each specified interval, whether the receiver was in holdoff, and how many valid opportunities were available. They cannot reveal the full phase or modulation structure of suppressed samples. A sensitivity analysis should vary the assumed distribution of unobserved signal features, plausible instrument nonlinearities and the mapping from physical events to saved files. If the desired conclusion remains stable over a credible range of models, that stability is useful evidence about robustness.

Copyright 2026, James M. Atkinson

But such an analysis must not be used to declare that the models have been empirically distinguished when they have not.

In some cases the responsible answer is partial identification: the evidence establishes a bound or a conditional relation, not a unique population parameter. We may report the range of event rates compatible with measured exposure and specified maximum dead time, or say that the clip population contains a repeatable association under the documented threshold. A precise unconditional prevalence requires additional independent observation. The limitation should be stated in the language of the technical witness: the receiver did not retain data sufficient to decide between the alternatives. This is preferable to presenting a regression coefficient with narrow confidence limits while omitting the fact that every observation was selected by the very mechanism under examination.

Sir David Cox, Cross-Peer Question to Abraham Wald: Dr. Wald, let us finish with a recorder whose operating policy is sequential. After a trigger it stores a pretrigger interval, captures additional samples, and then suppresses new triggers for a fixed holdoff period. A technician takes the intervals between file creation times, estimates an arrival rate and testifies that the environment contained few emissions. Yet the file count is influenced by holdoff, missed writes, file grouping and the distinction between arrival and completion time. How should the investigator characterise the resulting observed point process without pretending that the unobserved events have been recovered? What deliberate laboratory trials would reveal whether the holdoff behaves as documented, including events that straddle rearm boundaries? Finally, how would you report two performance measures: detector activity when available, and total operational coverage

Copyright 2026, James M. Atkinson

across the entire authorised survey interval? I ask you to keep the clocks of acquisition, trigger decision and file writing separate throughout your reply, since they need not coincide.

Abraham Wald, Cross-Peer Answer to Sir David Cox: Sir David, the first step is to preserve the definition of the recorded event. A file creation timestamp ordinarily describes an action by the storage system, not necessarily the time at which an RF burst reached the antenna. We should therefore use acquisition-side event counters and a documented clock map where available, and keep file-writing times as separate provenance data. We must also distinguish a new trigger from an extension of an existing capture. If the software merges adjacent alarms, the number of files is a coarsened representation of decisions. A statistical model of file arrivals may describe the writer's output process, but without further information it cannot be equated to a model of physical emission arrivals.

The known holdoff period should be represented as a state interval during which new decisions were disabled or constrained. A laboratory can inject reference bursts at measured delays before, during and after the nominal rearm boundary, including clustered bursts and events whose duration overlaps the boundary. Independent monitoring establishes the physical event times; the device ledger records decisions, suppressions and storage actions. By comparing these records one can test whether the implementation follows the documented policy and whether unexpected buffer or clock behaviour creates additional unavailability. Fault injection should include quota exhaustion and transport congestion so that an alarm with a failed write remains distinguishable from a deliberately suppressed alarm.

Copyright 2026, James M. Atkinson

Two performance measures answer the two questions you pose. Conditional detector performance concerns the probability of an alarm for a predefined class of reference events occurring while the instrument is declared available to detect them. Overall operational coverage concerns the fraction of the authorised survey interval during which the receiver was observing the relevant band with valid acquisition and permitted decision state. A machine can perform well conditionally while covering only a small fraction of the survey, especially if the scanner dwells briefly or the holdoff consumes substantial time. Combining the measures may be useful under an explicit event-time model, but the combination is not justified by file counts alone.

The report should give the valid exposure, holdoff exposure, untuned exposure, invalid or unknown intervals, number of reference events, number of alarms, and number of successfully retained files, with uncertainties and definitions beside each. Events arriving while the detector was unavailable are not retrospectively made absent because no file exists. Nor should they be counted as detector failures under a conditional performance measure whose eligibility rule expressly excludes those intervals. They remain relevant to the broader coverage assessment. If the experimental record cannot identify how many such events occurred, it must say unknown. A cautious chain of custody documents these distinctions and preserves the original decisions. It does not permit a reconstructed timeline to masquerade as an original RF observation.

Dr. James M. Atkinson, Moderator: I thank the panel for its precise and respectful examination. The common finding is that an alarm-only archive can establish what was retained under a documented policy, but cannot by

Copyright 2026, James M. Atkinson

itself establish the unconditional event population, the missed-event count, or source identity. We shall preserve the questions about independent reference observations, valid exposure, selection probabilities, storage failures and lawful minimisation for the formal verification register. The discussion is a fictional reconstruction for educational analysis, not recorded testimony from its historical contributors.

QUESTION 097. TEN HYPOTHETICAL WORKED EXAMPLES. Each example specifies its units, definitions and assumptions. These examples are not real RF survey measurements or source identification evidence.

EXAMPLE 1. Define N = 1000 valid one-second laboratory opportunities, E = 40 independently identified reference-event cells, D = 30 alarmed event cells and F = 20 alarmed background-only cells. Sensitivity is D/E = 30/40 = 0.75 = 75%. This is conditional upon a fixed matching rule, valid exposure and a correctly classified independent reference.

EXAMPLE 2. From Example 1, the number of true negative cells is TN = N − E − F = 1000 − 40 − 20 = 940. The background-only denominator is N − E = 960. Specificity is TN/(N−E) = 940/960 = 0.9791667 = 97.9167%, and the per-cell false-positive fraction is F/(N−E) = 20/960 = 0.0208333 = 2.08333%. The opportunities are defined cells, not necessarily independent trials.

EXAMPLE 3. In the same hypothetical reference population, the number of saved alarms is D+F = 50 if every alarm generates one successful file and no merging occurs. Positive predictive fraction is D/(D+F) = 30/50 = 0.60 = 60%. This quantity depends on reference-event prevalence and cannot be inferred from 50 unlabelled saved clips alone.

Copyright 2026, James M. Atkinson

EXAMPLE 4. For a planned survey with T_wall = 60 minutes of wall-clock time but T_valid = 10 minutes of verified in-band observing time, observing coverage C = T_valid/T_wall = 10/60 = 1/6 ≈ 16.6667%. The other 50 minutes are unavailable observation opportunities for that band, not demonstrated RF silence.

EXAMPLE 5. If A = 18 alarm decisions arise during T_valid = 6 hours of documented valid exposure, alarm-decision frequency is lambda_A = A/T_valid = 18/6 = 3 per valid observing hour. It is not an external-event occurrence rate until an independent physical reference has classified the alarms.

EXAMPLE 6. A hypothetical reference experiment produces R = 30 known bursts over T_valid = 5 hours. The reference-event frequency is lambda_R = R/T_valid = 30/5 = 6 bursts per valid hour. If 18 bursts yield matched surviving clips, the retention fraction for this specified event population is 18/30 = 0.60; this differs from detector sensitivity if alarms occurred but files were lost.

EXAMPLE 7. If independent reference scheduling identifies E = 20 eligible known bursts and the detector alarms on A_E = 12, its conditional alarm sensitivity is A_E/E = 12/20 = 0.60. If W = 10 of those alarm decisions yield intact files, writer success conditional on alarm is W/A_E = 10/12 ≈ 83.3333%. The event-to-retained-file fraction is W/E = 10/20 = 0.50; each fraction has a separate denominator.

EXAMPLE 8. At sampling rate F_s = 2,000,000 complex samples per second, pretrigger buffer length N_pre = 4096 valid consecutive complex samples corresponds to T_pre = N_pre/F_s = 4096/2,000,000 s = 0.002048 s = 2.048

Copyright 2026, James M. Atkinson

ms. This is nominal buffering duration, not an assurance that a burst beginning earlier was captured.

EXAMPLE 9. For intended capture window duration T_window = 0.10 second and mandated holdoff duration T_hold = 0.40 second after capture, one complete cycle can occupy T_cycle = T_window + T_hold = 0.50 second if configured as non-overlapping periods. Under that explicitly simplified assumption, a busy recorder cannot begin more than 1/T_cycle = 2 such new cycles per second. The bound is not a physical RF event-rate bound.

EXAMPLE 10. If background-only random sampling selects k = 50 of N = 500 predefined valid negative intervals, with equal independent inclusion probability pi = k/N = 0.10, a measured total of y = 7 alarms within the selected intervals yields design-weighted estimate y/pi = 7/0.1 = 70 alarms in the 500-interval frame under the stated sampling design. It remains an estimate with sampling uncertainty, not a recovered record of 70 observed alarm files.

QUESTION 097. SCHOLARLY AND TECHNICAL REFERENCE TRAIL. Jerzy Neyman, “On the Two Different Aspects of the Representative Method: The Method of Stratified Sampling and the Method of Purposive Selection,” Journal of the Royal Statistical Society 97, no. 4 (1934), 558–606, DOI 10.1111/j.2397-2335.1934.tb04184.x; NIST/SEMATECH Engineering Statistics Handbook, https://www.itl.nist.gov/div898/handbook/; NIST SP 800-86, Guide to Integrating Forensic Techniques into Incident Response (August 2006), DOI 10.6028/NIST.SP.800-86. These references give historical and technical background; they do not document the fictional dialogue. Source-to-claim checking of each technical assertion and review of any jurisdiction-specific retention rule remain Stage-B tasks.

Copyright 2026, James M. Atkinson

EDITORIAL QUALIFICATION. This is an explicitly fictional, contemporary scholarly reconstruction. No historical participant is represented as having engaged in an actual RF surveillance conference or speaking the generated words. The worked cases are hypothetical and are not measurements. The roundtable makes no attribution of an unknown emitter and no claim to authority to retain protected communication content.

Copyright 2026, James M. Atkinson

QUESTION 098

Copyright 2026, James M. Atkinson

How should calibration uncertainty and alternative explanations be communicated in technical testimony?

Dr. James M. Atkinson, Moderator: Sir Karl, I invite you to distinguish a receiver's numerical indication from the proposition a technical witness ultimately asks a tribunal to accept. Suppose an authorised engineer reports an unusual narrowband component in a spectrum display, with a calibrated reference source available but uncertain antenna factor, cable loss, clock integrity and front-end linearity. A neat screenshot may be accurate as an image yet insufficient to identify a real external transmitter, still less a particular unlawful apparatus. How should the scientist frame a claim so that calibration uncertainty, plausible rival explanations and the possibility of disconfirmation remain visible to the judge, jury or technical reviewer? Please also make clear where scientific reasoning ends and jurisdiction-specific legal evaluation begins. Our discussion is explicitly fictional and contemporary, not an historical quotation.

Copyright 2026, James M. Atkinson

Sir Karl Raimund Popper, Principal Contributor: Dr. Atkinson, I would begin with the grammar of the claim. A spectrum analyser may display a spectral feature at a coordinate labelled with a frequency and an amplitude. The instrument has not thereby pronounced the existence of a particular transmitter. The displayed feature is an observation mediated by apparatus, processing conventions and a model of what the apparatus measures. A responsible witness must state the proposition at the level actually tested. The narrow statement may be that a repeatable indication arose within a specified spectral interval while the receiver, antenna, cable assembly and software occupied documented states. A stronger statement, that the indication represents an external electromagnetic field, requires tests capable of excluding instrumental generation. A still stronger proposition about a named source requires yet more evidence. Each enlargement of the claim increases the burden of proposed disconfirmation.

It may be tempting to speak of falsifiability as a theatrical challenge to any expert. That would be mistaken. The practical question is what observation, if obtained under controlled conditions, would force the investigator to withdraw or materially revise the proposed interpretation. If the engineer suspects an external emission, an input termination, a change of preselector, a change of attenuation or an independent receiving chain may offer informative discriminating tests. If the feature persists under a proper termination in the same measurement path, the external-emission explanation becomes less credible; if it follows the external antenna but disappears under independent reference conditions, the inference remains incomplete. A single result should not be elevated into a universal theorem, because the behaviour of an instrument depends on its design and state.

Copyright 2026, James M. Atkinson

The tests should be selected according to plausible causal alternatives, not performed as ritual gestures in the hope of producing an impressive report.

The term uncertainty demands particular care. A numerical interval derived from a calibration budget quantifies aspects of a measurement model under specified assumptions. It does not automatically encompass every possible failure of the model, including an overlooked mixer spur, ADC overload, poor impedance match, software indexing fault or an unrecognised propagation path. The witness should name the measurand before offering its uncertainty. Is the relevant quantity power at a receiver input, incident field strength at an antenna position, an estimated carrier frequency, an event onset time or a derived classifier score? Each differs in units, reference plane and contributing physical effects. A standard uncertainty of a receiver-input power reading cannot be pasted without qualification onto a conclusion about field strength at an unknown emitter, because antennas, propagation and source conditions introduce additional and possibly unmeasured dependencies.

There is a difference between an uncertainty estimate and a guarantee. Under the widely used metrological framework, contributors may be evaluated from repeated observations or from calibration certificates, specifications and other defensible information. A combined standard uncertainty reflects those evaluated components and their relationships within the chosen model. An expanded uncertainty uses a stated coverage factor and needs careful interpretation of the intended coverage. If components are correlated, they should not be treated as independent merely to simplify an equation. If the apparatus changed configuration during the collection, measurements from the different states cannot be

Copyright 2026, James M. Atkinson

combined casually. An instrument can give numerous consistent digits while remaining systematically wrong. Reproducibility of the numerical calculation is necessary for an audit, but it is not proof that every relevant physical cause has been identified.

Consider a hypothetical frequency determination. An engineer reports a centre-frequency estimate for a controlled laboratory signal, accompanied by a reference-clock specification, sampling configuration, record duration, frequency-estimation method and uncertainty terms. That is a useful measurement account. But the same reported frequency could be influenced by an uncorrected receiver oscillator offset, a misinterpreted sample rate or an aliasing image. The witness should identify which controls distinguish these explanations. A comparison against a separate calibrated frequency reference may test one component; a change of sample rate and preselection may test another. If the suspected emission can be generated inside the front end by mixing of two lawful strong signals, a controlled variation of attenuation should reveal behaviour inconsistent with a simple linear external source. No single control guarantees the absence of every artefact, but a set of discriminating experiments can justify a graded conclusion.

The form of the technical report matters because language can hide a change in logical status. 'An energy component was observed' is not equivalent to 'a transmitter was located'. 'A waveform is consistent with a class of signals' is not equivalent to 'a particular device emitted it'. 'A clock comparison placed two events within a bounded time interval' is not equivalent to 'the events were generated simultaneously'. Precise evidence may support some statements strongly and leave the others unresolved.

Copyright 2026, James M. Atkinson

The witness should resist verbs that smuggle an assumption into the conclusion. It may be useful to provide a matrix whose rows contain the measured fact, the test method, the uncertainty and the alternative hypotheses, while a separate column identifies the source-attribution claims that have not been established.

I would ask an adversarial reviewer to prepare alternative reports from the same underlying test record. The first would use one point estimate and a striking display, omitting receiver state and competing mechanisms. The second would disclose the acquisition record, calibrated reference planes, uncertainty budget, independent controls, failure conditions and the precise boundary of the conclusion. The reviewer would then ask which statements could have been contradicted by available evidence, which assumptions remain untested, and whether the report invites readers to infer an individual source without the necessary physical chain of reasoning. The objective is not to make the report timid. It is to make its strongest assertions genuinely testable.

Chain of custody contributes to this enterprise, but it occupies its own logical place. A secure digest may establish, under properly protected reference conditions, that the submitted I/Q file matches a file preserved earlier. A manifest may document sample format, device state and the analyst's software transformations. Those are important propositions about records and their interpretation. They do not prove that the original antenna measured what the author thought it measured, that the acquisition was lawful, or that a particular external device was responsible. In the same way, a well-founded calibration interval does not determine whether a court should admit an expert opinion under the rules of its own jurisdiction. The

Copyright 2026, James M. Atkinson

scientific witness should describe his method and its limits; legal counsel and the tribunal perform the applicable legal examination.

An uncertainty statement should neither be hidden as a footnote nor converted into an incantation. If a measurement is represented as a value with an expanded uncertainty, the coverage factor and assumptions should be stated. If the issue is not a numerical uncertainty but a categorical alternative, such as an internal receiver spur versus an external emission, that alternative should be handled through discriminating evidence and explicit residual uncertainty, not forced into an unsupported percentage. It is better to say that two physically different explanations remain compatible with the available observations than to assign ninety-nine per cent certainty to one on intuition alone. Where a meaningful model comparison has been performed, its assumptions and conditional character should be reported plainly.

I would conclude by separating the quality of evidence from the social authority of its presentation. A polished graph, a familiar engineering degree or a confident voice can make an observation appear final. Yet the evidential question remains whether the investigator identified the measurand, tested relevant alternative explanations, accounted for sources of uncertainty and made the underlying records available for authorised scrutiny. The strongest expert can state a limitation without surrendering the value of the work. Indeed, careful limits protect the institution from treating an instrument's artefact as an accusation against a person. I pass the token to colleagues who can examine probability, confidence procedures, calibration mathematics and the logic of inference in greater technical detail.

Copyright 2026, James M. Atkinson

Solomon Kullback, Peer Question: Sir Karl, I accept the distinction between an instrument indication and a cause, yet a laboratory may face an apparently persuasive collection of observations: the feature recurs at the same displayed frequency, two operators recover the same trace, and the instrument's most recent certificate records a small frequency error. The prosecution or a commissioning client may ask whether that recurrence makes the suspected external transmitter virtually certain. I should like you to explain why reproducibility of a digital display is not equivalent to an independent physical replication, and how an uncertainty budget should be related to the hypotheses which remain open. Would a second receiver sharing the same antenna, reference oscillator, and power supply add independent evidence? If it would not, what should the report say about the common dependencies? Finally, suppose one of the proposed alternative explanations is vague and cannot presently be tested. Does the mere possibility of an unidentified mechanism require complete silence, or may the witness deliver a carefully limited finding without disguising what remains unresolved?

Sir Karl Raimund Popper, Response: Dr. Kullback, repeated agreement is evidentially valuable only when we know which parts of the apparatus and reasoning are being repeated. Two recordings processed by the same software and calibration table may reproduce the same mistake; two operators reading the same stored spectrum do not supply two independent physical observations. A genuinely independent experiment would vary the mechanisms plausibly responsible for error. For example, an appropriately configured reference source, another receiver architecture, a distinct preselection path and a terminated-input control can discriminate

Copyright 2026, James M. Atkinson

among external radiation, local-oscillator products, overload artefacts and computational mislabelling. The experiment should be designed with the alternative explanations in mind, and the expected results under each should be described before the new observation is examined. A repeated line at the same screen coordinate may establish excellent display consistency, while saying almost nothing about external causation.

A small calibration uncertainty for the frequency scale addresses a particular measurement quantity, often under conditions specified in the certificate. It does not become a small probability that every possible causal explanation is wrong. The laboratory ought to map the chain of claims. First, the instrument indicated a feature. Secondly, the feature was observed under certain independently checked input conditions. Thirdly, the indication is compatible with an external RF signal at a bounded frequency and level. Fourthly, perhaps after additional spatial and temporal controls, a particular class of source may be supported. A statement identifying an individual emitter stands at a further remove. Each proposition requires a stated basis and is vulnerable to a different disconfirming experiment. An uncertainty budget quantifies uncertainty in a defined measurand, not the truth of each proposition in the chain.

Your example of two receivers sharing the same antenna and clock reveals the danger of a common failure. An antenna-mounted active device could produce a spurious product seen by both receivers; a defective splitter or common reference might create correlated frequency errors; a shared acquisition computer could associate both channels with the same incorrect time origin. The report should identify those shared dependencies and describe the two records as partially corroborating, not fully independent. A

Copyright 2026, James M. Atkinson

more decisive control might separate antennas and gain paths, or introduce a reference whose physical origin is known. This is not a demand that every investigation own two perfect laboratories. It is a demand to refrain from calling evidence independent where dependence is obvious.

We must also distinguish an imaginable explanation from a physically articulated rival. The mere abstract possibility that an unknown mechanism could exist does not defeat all empirical judgement. A witness may say, with good reason, that a spectral feature was consistently registered and survived specified controls, while expressly declining to identify its source. A technically plausible rival which survives a discriminating test should remain in the report. An unsupported suggestion can be described as unsubstantiated without pretending it has been disproved by the instrument's calibration certificate. Appropriate confidence concerns the scope of a conclusion, not a theatrical assertion of universal certainty. The important discipline is to design experiments which might change the conclusion and then state candidly what happened when they were performed.

Dr. James M. Atkinson, Moderator: I thank Sir Karl and Dr. Kullback. With that division between measurement and causal explanation established, I respectfully pass the token to Sir Harold Jeffreys to examine how competing statistical models should be reported to a tribunal.

Copyright 2026, James M. Atkinson

Sir Harold Jeffreys, Second Principal Contributor: Dr. Atkinson, an evidential problem becomes especially treacherous when numerical precision is mistaken for explanatory probability. Suppose an authorised engineer estimates the power present at a receiver input as minus eighty decibels relative to one milliwatt and obtains a combined standard uncertainty of one decibel for the calibrated measurement chain. Those quantities may be perfectly meaningful, provided the measurand, reference plane, instrument state and uncertainty model are defined. The listener must not infer that there is a ninety-nine per cent probability that a named transmitter produced the signal. The first conclusion concerns the value of a measured quantity conditional on the appropriateness of the model; the second concerns alternative causes and requires evidence about those alternatives and their relative plausibility. The two inferential questions may inform one another, but one does not answer the other.

A probabilistic comparison begins by making hypotheses explicit. One might distinguish an external emission, an internal mixing product and a signal produced through conductive coupling into the instrument. Under each hypothesis, a discriminating experiment can produce different data. It matters whether the instrument input is terminated, whether an independently calibrated front end is substituted, whether the feature follows changes in antenna orientation and whether the observed level responds to input attenuation as an external signal ordinarily would. We may express probabilities of those observations conditional on each hypothesis, if defensible statistical models can be supplied. It would be folly to announce posterior probabilities merely because we have invented the

Copyright 2026, James M. Atkinson

names of the hypotheses. We must determine what model calibration, prior information and independent test data justify the figures.

The analyst must resist the inversion of conditional probability. A low false-positive probability under a specified background model does not mean that a detected feature has the same low probability of being false. Its evidential import depends on the prevalence and types of competing events, the chosen detection rule, missing observations and the degree to which the actual environment follows the model. A quiet controlled laboratory with a stable noise distribution may produce attractive performance figures which prove misleading in an industrial building dominated by switching supplies, impulsive noise and intermodulation. One may not transport the laboratory denominator into a different environment without describing the shift. Nor should multiple comparisons disappear from view merely because the final display shows only one surviving peak.

There are also dependencies within what appears to be a collection of observations. The same antenna, preamplifier, receiver reference and filtering code can make two records highly correlated. Four screenshots generated from one original IQ file are one acquisition with four derivatives; they are not four independent surveys. An expert who multiplies likelihoods on an unjustified assumption of conditional independence exaggerates evidence. A responsible comparison would document which data were independent and would test the joint model when possible. If the dependencies cannot be estimated, the witness should describe them qualitatively rather than supply spurious decimal places.

When presenting a Bayes factor or a likelihood ratio, the denominator matters at least as much as the numerator. A result may strongly favour a

Copyright 2026, James M. Atkinson

model of external radiation over a model of thermal noise and yet fail to distinguish an authorised industrial emitter from an unauthorised transmitter. The models are not synonymous with social accusations. If a report says that the data favour one specified physical process over another by some factor, it must identify the processes, the conditioned observations, the treatment of unknown parameters, the reliability of the models and the sensitivity of the result to their assumptions. Alternative explanations that were never modelled are not silently eliminated. The finding should be phrased as evidence relative to the stated hypotheses, not a universal measure of guilt.

A metrological uncertainty statement occupies a different place in this account. Type A evaluation uses statistical information from observations, while Type B evaluation draws upon other relevant information, including calibration certificates or suitable specifications. Neither label is a synonym for random versus systematic physical effects. The combined uncertainty of a derived result requires the measurement function and, when relevant, covariance among uncertain inputs. A probability assigned to an event's source cannot be manufactured by multiplying the combined standard uncertainty by a coverage factor. The factor describes an interval about a defined measurand under assumptions about its distribution; it is not an all-purpose credibility index.

The testimony should permit ordinary readers to understand the hierarchy. A table might state the frequency and receiver-input power estimates with their units, uncertainty conventions and reference conditions; a separate section might list tested causal explanations, observed outcomes and the alternatives remaining. The expert should declare when data were selected

Copyright 2026, James M. Atkinson

after seeing a plot, when a proposed discriminating experiment was not performed, and when instrument error might be common across purportedly separate observations. Mathematical formality does not require opaque language. Indeed, a well-conceived measurement report may be less rhetorically confident and more scientifically useful than an elaborate claim of near certainty. I return the token for testing against the most difficult statistical objections.

John Wilder Tukey, Peer Question: Sir Harold, your distinction between a calibrated measurement and a probability of source identity is vital, but I should like to press the practical consequences of exploratory data analysis. Suppose an expert surveys a vast collection of waterfall cells, notices one unusually narrow feature, and then chooses its frequency, time interval, smoothing method and background sample precisely because those choices make the feature prominent. The expert subsequently presents a small probability under a background model which was fitted on that same selected region. What part of the resulting number is evidential, and what part has been bought by selecting the most striking data? Please describe a defensible reporting method that makes the exploration visible, specifies which aspects of the analysis were fixed in advance, and conducts an independent test when the source observations permit. Would an honest account of unsuccessful searches and alternate processing settings matter, even if those records are less visually pleasing than the final chart?

Sir Harold Jeffreys, Response: Dr. Tukey, the scientist must not erase the route by which the conspicuous pattern was found. A feature selected because it is extreme under one of many candidate displays cannot ordinarily be evaluated with an error probability for a single prespecified

Copyright 2026, James M. Atkinson

comparison. The parameter search changes the reference distribution, and adaptive tuning may change it further. If the instrument scanned a million correlated cells, the analyst must define the effective search procedure, its dependence structure and the probability model for the maximum or other selected statistic. A decorative annotation which gives a single-cell tail area as though the selected feature had been nominated before acquisition is incomplete. We should first disclose the search, then distinguish exploratory description from independent confirmation.

A useful plan would preserve the original IQ data where lawful and necessary, or at least retain sufficient lawful numerical evidence and metadata for independent analysis. The investigator should record the range of frequencies, observation periods, FFT windows, thresholds, smoothing rules and candidate filters examined, together with failed and inconclusive tests when they bear upon selection. This log is not intended to inundate the tribunal with every mouse movement. It protects against treating the last successful configuration as the only configuration attempted. A follow-up capture under conditions stated before the new observation can test a specific proposition. That new observation must genuinely be independent in the relevant dimensions; saving a second image from the first file does not satisfy the requirement.

If independent acquisition is impossible, the witness should restrict the claim. For example, the report may state that an exploratory search found an indication warranting further investigation, that its frequency and duration are measured under named settings, and that a claimed nominal false-alarm rate does not account for the post-selection procedure. Nothing compels the witness to assign a likelihood ratio when the sampling and

Copyright 2026, James M. Atkinson

selection model is unknown. A properly qualified uncertainty interval for frequency may remain valid even though the inferential interpretation of the detector score is exploratory. The two results should not be merged. It is possible to be very certain about the location of a feature in stored data and uncertain about why the feature exists.

You ask about failed searches, and I agree that their evidential meaning depends on coverage. A negative result in a region which was actually observed with adequate sensitivity may constrain an intermittency model. A negative result in a band the receiver never watched does nothing of the sort. Rejected processing candidates may reveal how dependent the pattern is on an arbitrary window or threshold. The expert should communicate those findings concisely and retain the detailed audit trail. The purpose of transparency is not to reward caution with an absolute prohibition upon conclusions. It is to permit a critic to reproduce the reasoning, identify selection effects and assess what an independent test would have to show. Clear limits make the useful observation stronger, not weaker.

David Harold Blackwell, Peer Question: Sir Harold, consider two laboratories evaluating the same evidence after being informed that a suspect device is expected to transmit near a particular frequency. One laboratory receives the target frequency before analysis; the other is given coded recordings with both true and false reference sources, and the analyst remains unaware of the suspected attribution. Both report a peak, but only the second laboratory declares its identification rule and challenge set in advance. How would you compare their conclusions without treating blinding as an automatic proof of correctness? I am especially concerned that experts may select a plausible hypothesis after viewing the measured

Copyright 2026, James M. Atkinson

outcome and then report a ratio of likelihoods as though those two hypotheses were the only ones originally considered. What documentation would allow a later court or scientific reviewer to understand the distinction between model fit, source attribution and the underlying validity of the blinded reference data?

Sir Harold Jeffreys, Response: Dr. Blackwell, a blind analysis limits a particular path by which expectation can influence selection and interpretation, but it cannot cure a defective instrument, an unsuitable test population or an incorrect likelihood model. The two laboratories should therefore be compared along several dimensions. We should ask whether their measurement chains were calibrated for the task, whether their feature extraction methods were documented, whether the alternative hypotheses were defined before the decisive observations, and whether their conclusions were tested on data not used to construct the model. An analyst told the expected frequency may conduct a legitimate targeted examination if that fact and its effects are disclosed. The trouble begins when the resulting decision is presented as if the frequency had emerged independently from the evidence.

The blinded laboratory has a useful design advantage if it includes negative controls and physically plausible alternative sources. Yet its validation set might omit the very industrial interference encountered in the case at hand. A high identification score on that set would then have conditional relevance only. The report should describe the labelled challenge corpus, acquisition conditions, class prevalence, operating threshold and performance uncertainty. It should distinguish a waveform class assignment from a unique transmitter identification, and should not treat the absence of a

Copyright 2026, James M. Atkinson

known interfering source in the test collection as evidence that no such source could exist. Blinding protects a scientific procedure against one risk; it does not expand the hypothesis universe by magic.

A likelihood comparison requires even more disciplined language. If the numerator represents a specified external-emission model and the denominator represents a specified receiver-spur model, a strong ratio says that the selected observations are more compatible with one of those models than the other under their stated parameters. It does not say that the hypothesis in the numerator is probably true without additional prior or decision assumptions. It also does not distinguish among multiple external sources unless models of those alternatives have been included. A tribunal should not be offered an impressive number whose denominator silently excludes plausible causes. When several hypotheses were explored, the selection process and any subsequent model modification must be evident.

I would recommend a two-level report. The first level gives the measurement result, settings, calibration information, protected data identifiers and uncertainties in language that another engineer can check. The second gives the inferential pathway: the original questions, alternative models, blind or informed conditions, discriminating tests, limitations and explicitly unresolved possibilities. If the physical evidence supports only the statement that an external-like RF feature survived a control, that is the finding. A named device or human actor is a more specific inference requiring additional properly acquired evidence. The difference is not weakness; it is the essence of a scientific conclusion whose boundaries are visible.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Sir Harold has distinguished conditional probabilities from categorical accusations. I pass the token to Sir David Cox, whose contribution will examine measurement models, covariance and the difficulty of explaining them without transforming a technical report into a mathematical spectacle.

Copyright 2026, James M. Atkinson

Sir David Cox, Third Principal Contributor: Dr. Atkinson, uncertainty should be approached as a property of a specified measurement procedure and its evidential context, not as a number appended to an otherwise undefined conclusion. The first question is the measurand. For a measurement at a coaxial receiver input, the quantity may be the average received power in a defined bandwidth, during a defined interval, under an identified impedance reference and operating state. A field-strength estimate at an antenna position is a different output, since the antenna factor, polarisation, coupling, mismatch and environmental propagation enter the measurement function. A source-emission estimate at an unknown transmitter is different again. If a witness supplies an uncertainty interval without defining what the interval is intended to describe, an apparently precise claim may be physically empty.

A conventional model writes an output quantity y as a function of input quantities x1 through xn. The combined standard uncertainty depends on how the result changes when those inputs change and on the variability and covariance of the inputs. When the relationship is sufficiently smooth and a first-order approximation is appropriate, the variance of the output can be represented by a sum of sensitivity-weighted variances together with covariance terms. If two corrections derive from the same calibration reference, they may be positively correlated. Adding their standard uncertainties in quadrature as if independent can understate or overstate the uncertainty. A legitimate analyst must either evaluate the dependence, provide a justified bound or explain why the simplification is defensible for the intended decision.

Copyright 2026, James M. Atkinson

Consider an illustrative power-chain expression in logarithmic units: estimated receiver-input power equals an instrument indication plus an applicable attenuation correction minus an applicable gain correction. If the respective standard uncertainties are 0.6 dB, 0.8 dB and 0.5 dB, and they are independent on the adopted scale, the combined standard uncertainty is the square root of 0.36 plus 0.64 plus 0.25, approximately 1.118 dB. That arithmetic describes the uncertainty of the specified additive dB model. It is not lawful to sum a power expressed in milliwatts with an antenna factor expressed in inverse metres as though the numbers had interchangeable dimensions, nor to assume without examination that every physical transformation is additive in the same scale. For nonlinear transformations the measurement function and its derivative, or a suitable numerical propagation, must be used.

Distinctions between Type A and Type B evaluations are equally liable to be misunderstood. Type A concerns evaluation by statistical analysis of observations, while Type B concerns evaluation from other information, which may include calibration certificates, experience and technical data with appropriate justification. A Type B contribution can model a physical random variation; a Type A estimate may include effects of systematic conditions reflected in the measurements. The classification describes the method by which uncertainty was evaluated, not the metaphysical identity of the underlying error. An interval drawn from a modest repeated-sample set must also acknowledge the uncertainty of the estimated spread and, where appropriate, the effective degrees of freedom. A coverage factor has no universal authority outside the assumptions used to select it.

Copyright 2026, James M. Atkinson

The appearance of receiver-generated artefacts complicates the statistical model beyond a simple budget. If a narrowband feature may be created by front-end intermodulation or by inadequate reference rejection, a tight power uncertainty calculated under the assumption of a legitimate external signal does not incorporate the uncertainty that the model's premise is false. One may need a diagnostic decision tree in addition to a numerical uncertainty table. The witness should identify experiments that discriminate the hypotheses: controlled attenuation, alternative preselection, independent antenna and receiver chains, and checks at the relevant calibration reference plane. A model capable of quantifying one sort of error cannot automatically explain another sort which it has not represented.

In a courtroom or formal technical hearing, clarity about the estimand and about evidence selection is as important as the numerical work. If the analyst chose the measurement interval after observing an anomalous display, the resulting conditional inference may differ from one based on a prespecified interval. The expert must say when the selection occurred. It may still be legitimate to report the measured frequency of the selected feature with a well-founded conditional uncertainty statement. It is a separate question whether its occurrence rate or evidential significance can be inferred from that selected sample. Collapsing these questions into a single percentage of confidence invites confusion.

Suppose two receivers appear to agree within their stated uncertainties. An agreement test should recognise common calibration references and shared channel errors, and should not infer that the signals originate from the same external transmitter merely because their values overlap. Equally, a disagreement beyond nominal individual error bars may be evidence of an

Copyright 2026, James M. Atkinson

unmodelled systematic effect, a changing physical environment or different definitions of the measurand. The investigator ought to examine the instruments, rather than declare one witness incredible because two plotted intervals do not overlap. Measurements are not personal reputations; they are outputs of specified procedures which may be challenged scientifically.

The final report should present the numerical and categorical parts side by side without confusing them. It can give a measurement equation, a table of input corrections and uncertainties, covariance assumptions, expanded uncertainty if justified, and a concise plain-language statement of what the interval means. It should separately enumerate alternative explanations, tests performed, tests not performed and the conclusions actually warranted. Legal admissibility is then assessed according to the court's own rules, not determined by the engineer's choice of a metrological coverage factor. The result may be modest, but it will be technically testable and educationally durable. I pass the token to colleagues prepared to interrogate the mathematics and its practical communication.

Peter Elias, Peer Question: Sir David, when an engineer says that several uncertainty contributors have been combined, I worry that the audience hears a claim of complete accounting rather than a statement about a particular model. Suppose the receiver display has a calibration certificate, the preamplifier has a noise and gain specification, and the antenna factor is measured under one environment. A software implementation then changes the spectral window and the equivalent noise bandwidth without updating the reported amplitude correction. Which part of the numerical budget would alert a reviewer to that model failure? Please explain the difference between a parameter having an estimated uncertainty and an

Copyright 2026, James M. Atkinson

entirely missing term in the model. I should also like you to distinguish a reproducible numerical implementation from a valid physical measurement and to explain how the report can carry an explicit validity qualification without creating the impression that every omitted effect is encompassed by a generous coverage factor.

Sir David Cox, Response: Mr. Elias, the phrase combined uncertainty must always be read with the qualification under the stated measurement model. If the model omits an essential correction for the digital window and its effective noise bandwidth, the uncertainty calculation may be arithmetically immaculate and physically incomplete. The first step is to check that the value being estimated has a clear definition: power spectral density, integrated channel power, peak-bin amplitude and waveform amplitude are not interchangeable merely because the interface renders them in similar colours. The processing window, sample rate, FFT normalisation, detector type and averaging convention can change the mapping from raw samples to the displayed number. A measurement model that lacks these features should be repaired before its uncertainty is advertised.

An estimated input uncertainty addresses variability or incomplete knowledge of a parameter which has been recognised. An omitted effect is a different defect. One cannot recover it by multiplying an incomplete combined uncertainty by a larger arbitrary factor. The appropriate treatment may be a new correction term, a validation experiment, a numerical sensitivity study or a finding that the procedure is not valid for the desired measurand. The laboratory should compare the current analysis code against a certified reference waveform in several representative conditions. If a window correction changes under software revision, the

Copyright 2026, James M. Atkinson

procedure must either update its validated coefficients or be held outside the scope of qualified findings until retested. A reproducible mistake remains a mistake.

The report ought therefore to contain both an uncertainty budget and a validity ledger. The budget identifies the inputs, units, assumed dependencies, sensitivity coefficients and methods of evaluating each recognised component. The ledger records the measurement configuration, software revision, calibration boundary, operating ranges, reference measurements and any environmental or instrumental condition outside the validated domain. If the instrument was overloaded, or a sampling discontinuity makes the relevant frequency estimate untestable, an interval generated by the normal model must not be reported as if the excluded condition had been accommodated. The validity ledger can be short in the main testimony, with detailed records available to authorised review.

You ask how to communicate this without persuading the reader that the entire universe has been budgeted. I would use a formulation such as: within the verified receiver configuration and stated measurement function, the estimated input power is a specified value with a specified combined standard uncertainty; the interval does not address unresolved emitter attribution or the possibility of an unidentified spurious receiver product. That statement is not a blanket disclaimer inserted to protect an expert from criticism. It identifies concrete scientific boundaries, and it gives the reviewer a way to demand the test that would resolve them. The model's scope is as important as the decimal place shown in its result.

Grace Brewster Murray Hopper, Peer Question: Sir David, a report may be elegant yet impossible to reproduce when the numerical recipe is absent.

Copyright 2026, James M. Atkinson

Assume the original IQ file is preserved with a matching digest, but the software has silently changed the scaling convention, the order of I and Q samples, the FFT length or the treatment of invalid sample markers. A later examiner obtains a different power estimate while using a receiver calibration certificate which appears identical to the first examiner's. How should the witness state the technical basis of the discrepancy without treating the hash as proof that the earlier computed measurement was correct? I would also ask whether a separately protected manifest should contain explicit test vectors and expected numerical outputs, as well as an account of configuration changes over the acquisition interval. Finally, what relationship should exist between the engineering record and the simplified table shown to a tribunal?

Sir David Cox, Response: Admiral Hopper, the preserved file hash supports continuity of the byte sequence from a protected reference state. It does not specify how those bytes are to be interpreted and cannot certify the mathematical correctness of processing software. The second examiner may be reading the same samples under a different packing convention, gain calibration or algorithm. An effective record therefore needs a protected interpretation manifest and a reproducible processing recipe. The manifest should specify the numerical sample type, byte order, I/Q arrangement, scaling and clipping conventions, sample rate, clock source and frequency reference, as well as the validity indicators and any gaps. The processing recipe should specify the exact software and relevant dependencies, the window and FFT conventions, the channel bandwidth and the mapping from spectral estimates into final reported quantities.

Copyright 2026, James M. Atkinson

Test vectors are extremely useful when their provenance is independent and their expected outputs are correctly defined. The laboratory can prepare known synthetic inputs, controlled physical reference signals and deliberately corrupted files. The algorithm should produce outputs within prespecified tolerances. Those tests must be repeated after substantive software changes, and the results stored independently of the analyst's narrative. A test that merely reproduces the number in the current report may be circular; it should challenge the computation under cases chosen to expose common mistakes. A digest of the output file may establish that the same result was stored later, yet it cannot prove that the result was physically meaningful when first calculated.

The acquisition interval may contain configuration transitions. A gain change, clock relock or preselector movement can render the interpretation of one continuous file nonuniform. The manifest should include state epochs with their boundaries, the source of each state report and the uncertainty of the boundaries when relevant. A report which presents one calibration factor for the entire file must establish why that factor applies throughout. The custody ledger records transformations and transfers; the instrument-state log records the physical and software conditions of collection. They are related but distinct records, and neither substitutes for the other.

For a tribunal, I would present an intelligible table showing the measurand, estimated value, uncertainty convention, validated operating conditions and any material qualification. The full reproducibility record should remain available under appropriate lawful safeguards, including the precise processing manifest, relevant source-code or build identifiers where

Copyright 2026, James M. Atkinson

permitted, test vectors, calibration material and logs. It is not necessary to expose unrelated protected communications to demonstrate that the amplitude conversion was correct. The simplification is legitimate only when it faithfully reflects the fuller record. A technically impressive table which conceals a change in sample interpretation is not clarity; it is an omission which may alter the ultimate finding.

Dr. James M. Atkinson, Moderator: We have considered measurement models and competing explanations. I now pass the token respectfully to Dr. Jerzy Neyman to address coverage, planned decision rules and the limits of frequencies observed under repeated laboratory conditions.

Copyright 2026, James M. Atkinson

Jerzy Neyman, Fourth Principal Contributor: Dr. Atkinson, when an interval is called a confidence interval, the investigator must not obscure the procedure which produces it. A frequentist confidence procedure is constructed so that, under specified conditions and repeated applications of the procedure, intervals contain the fixed target parameter with a prescribed long-run frequency. The probability statement belongs to the random procedure and its assumptions. After one interval has been calculated, one should not, without a different inferential framework, describe the particular fixed parameter as randomly wandering into or out of a fixed interval. A witness may communicate this principle in ordinary language while keeping the engineering assumptions explicit. It is particularly important when the test conditions vary across receiver gain states or when the collected observations are selected because they triggered an alarm.

The first task in designing a defensible experiment is to specify the parameter and operating regime. For a frequency calibration, one might define the offset of an RF analyser relative to an independent frequency reference under stated temperature, warm-up, input power and signal-to-noise conditions. The experiment should include suitable independent reference observations, appropriate repeated measurements and a procedure for identifying drift or instability. If the resulting interval assumes constant bias over a period during which the clock loses discipline, the coverage assertion may fail. The resulting uncertainty should then be conditioned on the verified stable epochs, not extended by rhetoric across unobserved state changes.

Copyright 2026, James M. Atkinson

A second task is to distinguish coverage for one preselected measurand from simultaneous coverage across numerous reported quantities. If a witness extracts ten frequency peaks and constructs ten nominal ninety-five per cent confidence intervals independently, the probability that all ten intervals capture their targets is not automatically ninety-five per cent. Under an artificial independence assumption, it would be 0.95 raised to the tenth power, approximately 0.5987. In actual spectral data the estimates may be correlated, which changes the calculation but does not remove the conceptual problem. A tribunal should not be shown an attractive collection of nominal individual intervals and be invited to infer that the entire resulting narrative has the same advertised global coverage. The set of comparisons, their selection and dependence must be considered.

If the question is whether a detected signal exceeds a prespecified threshold, there must be a distinction between the procedure's false-alarm probability under a defined reference condition and the evidential weight of an observed alarm. The former can be measured in controlled trials or calculated under verified assumptions; the latter depends upon actual environmental conditions, the prevalence of alternative processes and subsequent investigation. If a threshold was adjusted after seeing an anomalous waterfall, the original reference operating characteristics do not apply unchanged to that new adaptive procedure. One may design a confirmatory trial with a fixed threshold, an independent period or a reserved dataset. Such control is essential when the finding is likely to influence an intrusive or consequential decision.

Coverage can fail for reasons outside the analyst's algebra. A stated sampling distribution may not describe impulsive industrial interference,

Copyright 2026, James M. Atkinson

heavy-tailed disturbances or correlated FFT cells. An electronic test source may have an unmodelled modulation or warm-up transient. A reference cable may be changed between trials, altering both loss and phase. Several measurements may share a drift component, violating independence. When the laboratory detects such departures it should change the model or qualify the conclusion. A nominal procedure cannot immunise evidence against an environment which lies outside its scope. To preserve credibility, the report should identify validation observations and state which configurations were not tested.

Uncertainty propagation also involves experimental design rather than merely final arithmetic. If two corrections have covariance, a combined budget cannot disregard that relationship; if an offset is estimated by regression, fitted coefficients may be correlated and a confidence band at a new frequency may differ from the uncertainty at the calibration points. A useful experiment samples the intended range of frequency, level, temperature and receiver state, rather than measuring only the condition most favourable to a precise certificate. Independent reference measurements can provide information that repeated readings from one unchanging display cannot. A well-designed measurement method records what was fixed before acquisition and what was changed after inspecting results.

I would propose a reporting hierarchy. The expert first identifies the calibrated quantity and experiment; next, the method of estimating corrections and uncertainty; next, the coverage interpretation, including assumptions and applicable range; next, tests of alternative physical explanations; and finally, the qualified finding. The tribunal need not be

Copyright 2026, James M. Atkinson

forced to follow every covariance calculation aloud, but must be given enough to understand what the interval guarantees and what it does not. If the expert cannot support a probability claim about a particular emission source, that inability should be stated plainly. Numerical humility is preferable to a confident percentage whose meaning is obscure.

A final point concerns apparent conflict between statistical and legal standards. A nominal confidence level of ninety-five per cent is not a legal threshold for admissibility, nor does it mean a court ought to find any particular person liable. Scientific reporting describes a procedure and its limits. Judicial rules may ask whether the method is reliable, relevant and appropriately applied, together with many other matters. In the federal United States system the present text of Rule 702 expressly imposes a more-likely-than-not burden on the proponent for specified admissibility elements; that burden should not be confused with a metrological coverage probability or a posterior probability of emitter identity. Other jurisdictions require their own analysis. I invite the peers to challenge the assumptions in a real measurement plan, rather than only the elegance of the mathematics.

Edsger Wybe Dijkstra, Peer Question: Dr. Neyman, a test procedure is often described as though its sampling mechanism were an immutable feature of nature, whereas in an SDR system it is partly a software configuration. Imagine that one application loses every twentieth buffer when a storage service becomes busy. A second version silently fills those gaps with zeros, and a third records the loss explicitly. The investigators then compute confidence intervals for spectral occupancy and for burst event times, using the number of stored windows as their sample size. How should the validity of their coverage claims be examined when the selection and missing-data

Copyright 2026, James M. Atkinson

mechanisms depend on the receiver's own state? Please separate the error in a formal statistical procedure from an error in its implementation, explain whether a deterministic replay of the file can certify the intended sampling distribution, and specify what tests would be required before the reported interval could accompany sworn technical evidence.

Jerzy Neyman, Response: Professor Dijkstra, a confidence procedure is a mapping from observations, taken under an assumed experimental design and probability model, to an interval. If the observation mechanism has changed, the same formula may no longer have its advertised coverage. When a busy storage system loses buffers nonrandomly, the resulting data may omit precisely the intervals containing high activity or long bursts. Treating the stored windows as an unbiased random sample of elapsed time is unjustified. Filling gaps with zeros is worse if those inserted values are subsequently analysed as genuine negative observations. Such a file can produce a perfectly deterministic and repeatable false occupancy estimate. Replay tests the computation; it does not validate the population represented by the data.

The first engineering test concerns the native acquisition record. Hardware sample counters, valid-sample markers, buffer-overflow indicators and timing references should be preserved with understood semantics. The laboratory should create known test signals and introduce controlled losses at each stage: acquisition, transfer, host queue and file writer. It should verify whether the instrument detects and correctly labels each interruption. If the recorder inserts zeros, the zeros must be tagged as invalid placeholders, not counted as radio silence. An interval estimation procedure should use the actual observation mask and describe any assumptions

Copyright 2026, James M. Atkinson

about the unobserved periods. If the gap mechanism is related to signal strength or processing load, standard missing-at-random arguments may fail, and sensitivity analysis or explicit bounds may be more defensible than a single narrow interval.

The second test concerns software implementation. The analyst should compare the code's output with independently computed reference examples, including constant signals, known pulses, phase discontinuities, deliberate saturation and missing windows. A change in FFT convention or sample-rate interpretation may alter the estimated statistic. Those results must be checked against documented acceptance tolerances before the inferential calculation is trusted. Yet even perfect numerical agreement is only an implementation check. It does not establish the statistical assumptions concerning event independence, background distribution or selection of the data. One must test those assumptions separately through physical controls and, where possible, independently acquired reference observations.

For testimony I would distinguish three conclusions. First, the algorithm returned a stated interval from a defined set of stored samples. Secondly, the implemented algorithm reproduces known reference calculations under its declared software version and numerical tolerances. Thirdly, the sampling design and physical model justify the interval's advertised interpretation for a particular class of RF observations. The first two may be established even when the third remains unsupported. A witness should say when that happens. An evidence record which separates them permits a judge to evaluate the true scope of the opinion and allows subsequent

Copyright 2026, James M. Atkinson

independent testing without pretending that lost observations were recovered.

Donald Watts Davies, Peer Question: Dr. Neyman, I should like to examine a different form of dependence. Two receivers monitor the same authorised reference source. Their displays appear to agree, but both are disciplined by one reference oscillator and receive their timestamps from a shared network time service. The experimenter treats the two observations as independent, combines uncertainties by a simple square root, and then describes the agreement as strong corroboration of the source's identity. How should the uncertainty and independence assertions be repaired? Please distinguish common-mode error, sample-time uncertainty, propagation delay and the categorical question whether the two receivers were actually measuring one external event. I also ask how a report should deal with a clock reference which changes state during acquisition, especially where the change appears only in a later log and the witness cannot identify exactly which captured samples were affected. How should the report record the differing uncertainty of the stable and unstable epochs, and what observations, if any, could permit a later independent examiner to reconstruct that boundary without inventing missing evidence?

Jerzy Neyman, Response: Mr. Davies, a shared oscillator introduces common structure into the error of two frequency measurements. A simple calculation that assumes independent errors may underestimate uncertainty in a difference or in a combined estimate, depending upon the quantity and covariance. The appropriate measurement equation should identify common and instrument-specific contributions. For example, if both receivers share one reference-frequency error, repeating the reading on the

Copyright 2026, James M. Atkinson

second receiver does not average that component away. The two receivers may still provide useful comparison of independent analogue paths, but the common reference limits their evidential independence for frequency accuracy. Shared network timestamps introduce further uncertainty about the relation between host events and actual ADC aperture times.

The timing measurement must specify which interval or event is being timed. A hardware sample counter gives ordering and nominal intervals within its own clock domain. A host timestamp may report when data were written rather than when RF energy arrived at the antenna. Propagation delay, antenna and cable group delay, digital filtering and buffer latency may all enter a cross-receiver comparison. If their values are unknown, one cannot replace them with a small network synchronisation figure merely because the computer clocks agree. Reference pulses at known positions and independently monitored times may reveal some of these delays, subject to their own uncertainty. The fact that two displays show energy near the same wall-clock label is weaker than a calibrated arrival-time finding.

The categorical assertion that both receivers measured one external source requires further physical evidence. Distinct emitters can transmit in the same frequency interval; an external interferer can affect several receivers; a shared accessory can generate an artefact visible in both. Independent antennas, path substitutions, spatial tests and controlled-source observations can help discriminate the possibilities. Agreement within numerical uncertainty is relevant to consistency of measurements, but it is not a source identifier. If the same signal-processing software creates the

Copyright 2026, James M. Atkinson

same spectral spur in both chains, apparent agreement may have almost no value for external attribution.

When clock discipline changes, I would segment the record into evidenced state epochs. If the change boundary is uncertain, the affected interval should carry an uncertain status rather than an invented precise timestamp. The uncertainty budget may then need to be enlarged or the analysis restricted to verified stable epochs. If neither is scientifically defensible, the witness can state that the data do not support a precise cross-receiver alignment in that interval. Such a limitation does not invalidate every other measured property. A frequency or occupancy result from an independently established stable period may remain useful. The purpose of a careful report is to assign each conclusion to the observations and conditions that actually support it.

Dr. James M. Atkinson, Moderator: Dr. Neyman has distinguished statistical coverage from the validity of the acquisition design. I respectfully pass the token to Charles Sanders Peirce to examine the logic of explanatory inference and the boundary between plausible hypotheses and proven causes.

Copyright 2026, James M. Atkinson

Charles Sanders Peirce, Fifth Principal Contributor: Dr. Atkinson, technical testimony often begins where an investigator notices an unexpected phenomenon and asks what could have produced it. That is a proper starting point for inquiry, but it is not the end of inquiry. A spectral line may suggest a local emitter, a harmonic of an external device, a product of mixer nonlinearity, a clock-related internal spur or a software artefact. The imagination supplies candidate explanations; disciplined observation and experimentation discriminate among them. The danger lies in confusing the first plausible explanation with a conclusion which has survived deliberate testing. A fine instrument can make an initial suggestion more vivid without making it more certain.

I would distinguish three activities. In the first, the investigator forms a hypothesis capable of explaining the observation. In the second, consequences of that hypothesis are derived: how should the feature behave when input attenuation is varied, when the antenna is substituted or terminated, when the receiver's preselector changes or when another physical location is examined? In the third, those consequences are tested under recorded conditions. The strongest testimony explains this movement from conjecture through expectation to observation. A mere catalogue of plausible causes is not enough. Yet neither is a single confirming display. The engineer must ask what rival hypothesis would have produced the same result and whether a practical test can distinguish it.

When the measured quantity itself is uncertain, the inference must not conceal that problem. Suppose a reported receiver-input power is calculated from a displayed level corrected for cable attenuation and amplifier gain. The witness should name the reference plane and operating conditions,

Copyright 2026, James M. Atkinson

because an uncertainty interval refers to that defined quantity. If a preamplifier operated in compression, the linear correction model may be invalid. A large coverage factor cannot convert the invalid model into an honest estimate. The correct finding may be that a prominent feature was detected but its true power was not established under the recorded conditions. That limited conclusion can still guide a subsequent controlled investigation.

Alternatives differ in evidential weight. An external transmitter and an internal mixing product may each have testable consequences. A highly specific allegation about a named individual may require evidence far beyond RF amplitude and frequency. A speculative explanation which supplies no physical mechanism and no possible test should not automatically erase the significance of controlled observations, but the engineer should avoid claiming exhaustive exclusion of all alternatives. What was actually tested matters more than what could theoretically be imagined. The report should give the reader a map of those tests and what each could and could not rule out.

A vivid example is the interpretation of motion. If a narrowband peak changes level as an antenna is rotated, the operator may infer that the source lies in a particular direction. But the same pattern could arise from reflections, near-field coupling, antenna-pattern nulls or motion of the receiver itself. The measured level, its uncertainty and the antenna's calibration are necessary inputs, but the spatial attribution requires a model of the environment and corroborating observations. The investigator may report a direction of greatest response under specified conditions without claiming that the apparent bearing directly identifies the emitter. The

Copyright 2026, James M. Atkinson

distinction is one of the logical reach of evidence, not merely numerical precision.

The law introduces an additional discipline. The witness offers scientific explanation under the court's rules, while the court determines admissibility and ultimately resolves disputed facts through the relevant legal processes. A metrological interval cannot determine whether a defendant acted unlawfully; a careful logical argument cannot substitute for authentication of a file or lawful acquisition of evidence. The expert should not assume that a criterion borrowed from one jurisdiction applies to every hearing. Where the proceeding is in the United States federal courts, the current Rule 702 language and applicable case law must be checked by qualified counsel. Where it is elsewhere, the applicable evidentiary framework may differ in important ways.

I would encourage an expert to use an inference table which distinguishes observed fact, processing operation, measurement model, alternative cause, attempted discrimination and residual limitation. Such a table reduces the temptation to make the conclusion more memorable than the evidence. It also allows a hostile yet competent reviewer to identify the point at which one may reasonably disagree. Perhaps both experts accept the sample file, its digest, the calibrated frequency and the level correction, but disagree about whether a control test excludes receiver intermodulation. That is a precise disagreement which can be investigated. It should not be disguised as a quarrel over character or authority.

The final statement should resemble a scientific finding, not a proclamation. One might say that a defined RF indication persisted under specified controls, its frequency and receiver-input level were measured with stated

Copyright 2026, James M. Atkinson

uncertainty under verified configurations, and the available tests support but do not uniquely identify an external emitter. If later authorised investigation supplies discriminating evidence, the conclusion may justly grow stronger. Until then, the narrower proposition is the proper product of inquiry. It conveys something worthwhile, preserves the independence of the tribunal and leaves clear what experiment would change the judgement. I pass the token to colleagues who will test whether this account remains defensible under direct challenge.

Sir Harold Jeffreys, Cross-Peer Question to Sir Karl Raimund Popper: Sir Karl, your emphasis on disconfirming tests is attractive, yet I fear that it can be misunderstood as a demand for a single decisive experiment when the measurement process is itself probabilistic. Consider an external low-duty-cycle source whose emissions are rare, an overloaded receiver which sometimes produces spurious peaks, and a short authorised observation interval. The feature disappears when the antenna is disconnected, but so does a conductive disturbance coupled through the antenna cable; the result therefore does not distinguish all the alternatives. How would you propose a sequence of tests without asserting that a failure to detect the feature has disproved an intermittent source? Please also explain what should be said when two hypotheses remain compatible with the evidence after several controls, and whether a technical report may legitimately prefer one explanation while admitting that the preference is conditional on assumptions which have not yet been directly verified.

Sir Karl Raimund Popper, Cross-Peer Answer to Sir Harold Jeffreys: Sir Harold, an effective critical test need not be logically infallible in order to be scientifically useful. Its purpose is to make explicit the observations which

Copyright 2026, James M. Atkinson

different hypotheses lead us to expect and to examine those expectations under adequately controlled conditions. Where an emission is intermittent, a negative observation has meaning only in relation to actual coverage, receiver sensitivity and an appropriate model of event occurrence. Disconnecting an antenna can eliminate an external radiated signal, a conductively coupled disturbance and certain receiver-generated mixing products simultaneously. The disappearance of the feature therefore narrows the possibilities only to the degree warranted by the circuit and experimental design. The report must not describe such an outcome as unique proof of a radiating transmitter.

A discriminating sequence can begin with the least intrusive controls: record the instrument state, verify a known reference signal, examine overload indications, apply attenuation and preselection changes, and compare a suitably isolated reference input. Where lawful and technically justified, employ a distinct antenna path and independent receiver technology. Each result should be interpreted against hypotheses articulated before the test. If input attenuation changes an intermodulation product by a different law than an actual input tone, that response may supply evidence, but even then the law depends on the operating regime and measurement uncertainty. If a second site records a related feature, one must still consider common infrastructure and environmental signals.

When two physical explanations survive, the scientist may report that the findings are consistent with both, and may describe which is favoured by a properly specified statistical or physical model. The word favoured must not be promoted to identified merely because one explanation is familiar. If the preference depends on an assumed event distribution or on a

Copyright 2026, James M. Atkinson

manufacturer's claim about the receiver's suppression of spurs, the assumption belongs in the conclusion. A technical opinion can be useful without eliminating every plausible possibility. The logical virtue lies in its vulnerability to future correction.

The strongest protection against overstatement is to connect every conclusion to the experiment which would require revision. One can report that a narrowband indication recurred under verified conditions and that no internal product was produced in specified reference tests, while acknowledging that untested external coupling remains possible. The expert may then propose a later experiment to discriminate that possibility. A tribunal receives not merely a numerical answer, but a transparent account of how far the evidence reaches. Critical scrutiny of hypotheses is a continuing method, not a theatrical demand that nature supply a perfectly clean yes-or-no answer.

Jerzy Neyman, Cross-Peer Question to Sir Harold Jeffreys: Sir Harold, your likelihood comparisons may be informative, but a witness might present a probability of source identity after selecting both the candidate source and the data used to compare it. Suppose the instrument initially surveys one hundred candidate signal forms, retains only the strongest, and then assigns that result a high probability under a model whose parameters were estimated from the same retained recording. How would you disclose the effect of this two-stage selection and the role of prior assumptions? I should also like an explanation of how the witness would distinguish a posterior probability, a likelihood ratio and a frequentist operating characteristic in ordinary testimony, particularly when the judge or jury may hear the same word confidence used for all three. Finally, how would your conclusion

Copyright 2026, James M. Atkinson

change if the only alternative hypothesis modelled was background thermal noise, while physically credible receiver intermodulation and industrial emissions were omitted?

Sir Harold Jeffreys, Cross-Peer Answer to Jerzy Neyman: Dr. Neyman, any model comparison whose candidate and data were chosen because they showed a conspicuous result should disclose that selection. The nominal distribution of a statistic chosen in advance need not match the distribution of the maximum among many explored statistics. If parameter estimates were also tuned to the retained observation, the data have performed more than one analytical role. One might construct a joint model for the full search and selection procedure, or reserve independent observations for an honest validation. If neither can be done, the witness should report a conditional exploratory comparison rather than decorate the result with an unjustified probability of truth.

A likelihood ratio compares how compatible particular data are with two specified hypotheses, given their parameter choices or treatment of nuisance quantities. It is not by itself the probability that either hypothesis is true. A posterior probability incorporates prior assumptions and a model for the observed data. A frequentist operating characteristic concerns the frequency of outcomes under repeated application of a specified procedure. Each can be meaningful, but the labels cannot be exchanged. A report might explain that the observations are, under two stated physical models, more likely under one model than the other, while avoiding the unsupported sentence that there is a matching percentage probability that the suspected device caused the emission.

Copyright 2026, James M. Atkinson

If the denominator contains only thermal noise, a large likelihood ratio establishes at most a contrast against that restricted alternative. Industrial emissions and receiver nonlinearities may produce observations much more similar to the chosen feature than thermal noise does. Excluding them from the model does not eliminate them from the world. A responsible witness should identify which plausible classes were modelled, which were physically challenged and which remain outside the calculation. Even a sophisticated Bayesian analysis should not conceal model misspecification under a forest of equations.

The practical solution is transparent sensitivity analysis. The expert should show how the inference changes under reasonable alternative priors, interference models, instrument states and inclusion rules. If the result changes markedly, its fragility belongs in the final opinion. If it remains robust, that is useful evidence, but only in the tested range. The tribunal need not accept any particular mathematical philosophy to understand this boundary: a reported probability or ratio answers a defined question using identified assumptions, and it cannot answer a larger accusation by mere force of numerical precision.

Sir Karl Raimund Popper, Cross-Peer Question to Sir David Cox: Sir David, suppose two laboratories produce nearly identical receiver-input power estimates, each with a stated expanded uncertainty, but one has retained only the final screenshot while the other has preserved the IQ samples, source manifest, calibration record and controlled reference tests. An advocate may say that the numerical agreement settles scientific validity, and that any missing records merely concern the formality of custody. I invite you to explain why the same numerical output can have very different

Copyright 2026, James M. Atkinson

evidential foundations. In particular, when does missing documentation make the uncertainty budget unverifiable rather than simply wider, and how should the witness avoid a claim that recalculating the displayed number on another computer proves the underlying physical event? Would you also explain whether agreement of two intervals supports a common source where the receiving chains may share the same reference and environmental disturbance?

Sir David Cox, Cross-Peer Answer to Sir Karl Raimund Popper: Sir Karl, agreement of two reported numbers is a property of those numbers, and sometimes of the processes which generated them. It does not by itself verify the validity of either measurement. The laboratory retaining IQ samples and a protected manifest can permit a second examiner to challenge sample interpretation, windowing, gain corrections, clock state and artefacts. The laboratory retaining only a screenshot may have lost the information required to test alternative processing choices or reconstruct the reference plane. The two laboratories may therefore arrive at similar displayed values with radically different opportunities for independent scrutiny. An evidential assessment cannot ignore that asymmetry.

Missing documentation does not always justify an arbitrary increase in a numerical uncertainty. If the calibration factor is unknown but bounded by a defensible test, a wider interval may be appropriate. If the measurement's units, bandwidth or source data cannot be established, there may be no valid model to which an expanded uncertainty can meaningfully attach. One must distinguish a quantified input uncertainty from failure to verify that the underlying measurand was measured at all. The careful expert should

Copyright 2026, James M. Atkinson

describe the missing basis and, if necessary, decline to provide a numerical estimate that would imply unjustified physical knowledge.

Recalculation on another computer is a software reproducibility check. It can detect implementation differences, demonstrate byte continuity or verify arithmetic. It cannot prove that an RF field existed at the claimed antenna location, that the original receiver was not overloaded, or that a particular transmitter was the source. Those questions require independent physical observations and controls. A preserved file may be authentic as a computer record yet a poor representation of an electromagnetic event; conversely, a real event may have been captured in circumstances that do not support a quantitative power conclusion. The report should distinguish those two conditions.

Finally, numerical interval overlap is not a test for source identity. Shared references and environmental inputs may induce correlated error, and multiple emitters may generate consistent numerical features. One may report compatibility of two measurement results under a stated model. Any inference of common external cause needs its own chain of evidence, including timing, location, physical propagation and control of common-mode artefacts. The apparent agreement should motivate those tests, not substitute for them. Scientific communication succeeds when the boundary between numerical comparison and causal explanation can be seen without guesswork.

Sir David Cox, Cross-Peer Question to Charles Sanders Peirce: Mr. Peirce, an abductive explanation is often chosen because it makes scattered observations intelligible. Yet in a forensic report such intelligibility can exert a persuasive force out of proportion to the data. Imagine a witness offering

Copyright 2026, James M. Atkinson

a coherent story that a concealed emitter generated a repeating narrowband signal, while an alternative account involving industrial switching noise is less dramatic but compatible with the waveform and measured uncertainty. How can the investigator use causal explanation without turning coherence into proof? I should like you to specify how a falsifiable test plan, a metrological uncertainty statement and a legally cautious conclusion fit into one narrative. Finally, if the most decisive test cannot be carried out because lawful authority or available records do not permit it, should the witness still provide a preference among hypotheses, or must the report stop at an unresolved observation?

Charles Sanders Peirce, Cross-Peer Answer to Sir David Cox: Sir David, a coherent explanation is an invitation to inquiry, not a licence to declare an accusation true. The investigator should first state the observation and its chain of acquisition; next, the suggested causes; then, the predicted consequences which differentiate those causes; and finally, the tests actually undertaken. The industrial-noise hypothesis may be less narratively attractive than a deliberately concealed transmitter, but that has no bearing upon its physical adequacy. If both hypotheses predict the observed feature, the observation alone cannot distinguish them. A report that places causal alternatives next to the evidence prevents eloquence from masquerading as an additional measurement.

Metrological uncertainty describes a defined quantity under the assumptions of a measurement model. It may be appropriate to state the observed feature's frequency and receiver-input power with corresponding uncertainties, while remaining undecided about the emitter. The causal test plan is separate: vary the input attenuation, inspect harmonics, substitute

Copyright 2026, James M. Atkinson

independent receiving hardware, examine the effect of an antenna termination and compare environmental operating cycles. Each test should be linked to the prediction it challenges and should acknowledge conditions in which it is not decisive. The witness should never claim that a tight frequency interval narrows causal identity to one named apparatus unless distinct attribution evidence supports that proposition.

Where an essential test cannot lawfully or practically be performed, the constraint must be disclosed. A witness may explain that the present observations are more consistent with one hypothesis under specified assumptions, if there is a reasoned basis for that comparative statement. The report must not describe the hypothesis as identified or exclude a plausible rival which was never examined. Sometimes the honest result will be a narrow observation and an explicit unresolved alternative. That is not a collapse of scientific inquiry. It is the correct description of its present state, leaving the next permissible experiment identifiable.

A disciplined final narrative can therefore be both useful and restrained. It gives the measurable facts, data-provenance record, calibration limitations, tested physical alternatives and residual uncertainty. It separates expert interpretation from any finding about an individual's intent, identity or liability. If later authorised experiments differentiate the hypotheses, the inference may change and the report should be capable of revision. A strong scientific explanation is one that specifies what could prove it wrong and records whether those observations were actually available. It does not gain authority merely because it has the pleasing form of a story.

QUESTION 098. TECHNICAL EXAMPLES AND REPORTING CONVENTIONS. All numbers below describe invented authorised laboratory observations. They

Copyright 2026, James M. Atkinson

are not historical statements, real surveillance findings or measurements of an unknown person's equipment.

EXAMPLE 1. Let I denote an instrument indication in dBm, A an attenuation correction in dB, and G a gain correction in dB. For I = −80 dBm, A = 3 dB and G = 10 dB, the estimated receiver-input power is P = I + A − G = −87 dBm. This assumes the gains and losses refer to the same signal path and the instrument is operating in its validated linear range.

EXAMPLE 2. If independent standard uncertainties in the same additive logarithmic model are uI = 0.6 dB, uA = 0.8 dB and uG = 0.5 dB, the combined standard uncertainty is uc = sqrt(uI^2 + uA^2 + uG^2) = sqrt(0.36 + 0.64 + 0.25) = sqrt(1.25) ≈ 1.1180 dB. Independence is an assumption, not an observed fact.

EXAMPLE 3. Under a specified conventional coverage factor k = 2, the expanded uncertainty from Example 2 is U = k uc = 2 × 1.1180 ≈ 2.2361 dB. The interval P ± U would be −87 ± 2.24 dBm after appropriate rounding. It is not by itself a claim of exactly ninety-five per cent coverage or a probability of source identity.

EXAMPLE 4. Suppose two standard corrections have standard uncertainties u1 = 0.6 dB and u2 = 0.8 dB and correlation coefficient rho = 0.5, and both enter the measurement equation with positive sensitivity coefficient one. Their combined variance is $u1^2$ + $u2^2$ + 2 rho u1 u2 = 0.36 + 0.64 + 0.48 = 1.48 dB^2, yielding standard uncertainty sqrt(1.48) ≈ 1.2166 dB, rather than 1.0 dB under a false independence assumption.

EXAMPLE 5. For a hypothetical frequency estimate f = 150,000,000 Hz with justified standard uncertainty uf = 15 Hz and conventional coverage factor k

Copyright 2026, James M. Atkinson

= 2, the expanded uncertainty is U = 30 Hz and the reported frequency interval is 149,999,970 Hz to 150,000,030 Hz under the adopted model. This interval describes frequency, not the source's location or identity.

EXAMPLE 6. For N = 10 independently selected hypothetical one-parameter confidence intervals, each with 0.95 coverage, the simultaneous all-cover probability would be 0.95^10 ≈ 0.5987 under independence. This simplified calculation cannot be transferred to overlapping spectral cells with substantial dependence.

EXAMPLE 7. For a sample of n = 25 independent, identically distributed reference readings whose sample standard deviation is s = 0.50 dB, the estimated standard uncertainty of the sample mean is s/sqrt(n) = 0.50/5 = 0.10 dB, conditional upon the appropriateness of the statistical assumptions. This excludes external calibration effects and systematic model failures.

EXAMPLE 8. Let x = −87 dBm denote a receiver-input logarithmic power estimate. Its corresponding linear power in milliwatts is p = 10^(x/10) mW = 10^(−8.7) mW ≈ 1.9953 × 10^−9 mW. A numerical standard uncertainty expressed in dB must be propagated through this nonlinear transformation before it is described as an absolute uncertainty in milliwatts.

EXAMPLE 9. In a simplified distance-based free-space delay comparison with path difference d = 300 metres and propagation speed c = 299,792,458 metres per second, the nominal time difference is t = d/c ≈ 1.00069 microseconds. Actual cable, antenna and multipath delays are additional terms and must not be silently assigned zero.

EXAMPLE 10. If a hypothetical receiver produces 1,000 candidate alarms during a survey but 100 matched independent reference checks are selected

Copyright 2026, James M. Atkinson

under a defined random design, an observed 12 false alarms among those checks represents 12/100 = 0.12 of that sampled reference set. It does not by itself establish a 12 per cent false-positive fraction for all 1,000 alarms if the sampling design or reference labels are unrepresentative.

QUESTION 098. REFERENCE AND EDITORIAL QUALIFICATION. Relevant background includes the BIPM JCGM 100:2008 Guide to the Expression of Uncertainty in Measurement and its subsequently published amendment, NIST Technical Note 1297, and the text and 2023 Advisory Committee Notes to United States Federal Rule of Evidence 702. The named historical scholars never held this joint discussion; every contribution is a present-day fictional educational reconstruction. Source-to-claim verification, historical suitability, jurisdiction-specific legal proof and whole-manuscript pagination remain necessary before publication. This manuscript does not claim that an instrument's uncertainty establishes an individual's identity, wrongdoing or legal liability.

Copyright 2026, James M. Atkinson

QUESTION 099

Copyright 2026, James M. Atkinson

What evidence separates waveform detection, device class and individual-emitter attribution?

Dr. James M. Atkinson, Moderator: Dr. Bracewell, an RF practitioner may detect a brief component, decide that it resembles a familiar modulation, label it as the work of a particular class of apparatus, and then be tempted to name an individual transmitter or owner. Please distinguish the evidential requirements at each transition. In your contribution, address receiver-generated products, spatial ambiguity, environmental changes, representative reference populations, calibration uncertainty and the danger that a classifier must choose one of its known classes even when the true source is outside them. We must draw the scientific inference as narrowly as the evidence permits and avoid implying either unauthorised interception or personal culpability.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell, Principal Contributor: Dr. Atkinson, the initial observation is usually a quantity measured through a system, not an object identified in the world. A spectrum receiver delivers estimates shaped by its antenna, gain distribution, filtering, sampling clock, digital processing and display conventions. If a feature appears at a frequency coordinate, that observation can be checked against the instrument's reference standards and acquisition records. But a peak on a screen may arise from an external field, an internal spur, nonlinear intermodulation, a numerical representation error or interference coupled through the measurement chain. Before the analyst assigns a waveform family, the physical origin and the fidelity of the sampled data must be examined. An identical line appearing in two exported plots offers little corroboration if both plots derive from the same stored samples or share the same defective front end.

The next stage is detection of a pattern under a specified model. A matched-filter response, cyclic correlation or repeatable burst shape may increase the plausibility of a waveform class, but only against the comparison alternatives that were actually tested. A strong match to one reference waveform does not establish that the source is a particular transmitter. The reference might be common to numerous devices, a generic clock artefact or a signal reproduced through different propagation paths. Receiver bandwidth, window selection, time alignment and thresholding influence the discriminating statistic. Those choices should be documented and, when the evidence is consequential, validated on independent records. A detector tuned to one laboratory waveform may perform poorly in an industrial environment with strong impulsive interference.

Copyright 2026, James M. Atkinson

The movement from waveform detection to device class requires information about what separates that class from plausible rivals. We might compare spectral masks, oscillator settling, burst timing, modulation behaviour and controlled responses to changes in the authorised reference transmitter. But such features can depend on temperature, supply voltage, firmware, output power, antenna loading or the channel between transmitter and receiver. A particular transient shape may be stable in one laboratory and vary considerably after the same apparatus is moved. Conversely, two distinct transmitters of one design may present very similar traces through one receiver. The analyst should not confuse repeatable measurement of a feature with proof that the feature uniquely identifies the device class.

Individual-unit attribution is more demanding. An inference that one specific apparatus produced a recorded signal requires tested between-device discrimination, within-device variability, independent conditions, an adequate reference population and an accounting of unknown alternatives. A classifier whose output must always be one of five reference units will name one even when the true source is a sixth instrument never included in its development. Such a system needs a defensible unknown-source or rejection state and an empirically characterised rate of mistaken attribution under representative tests. Distance, multipath, receiver nonlinearity and normal ageing can make apparent fingerprints shift across circumstances. Any claim of uniqueness must be challenged with physically similar devices, not merely compared against an easy collection of unrelated signals.

A rigorous validation trial would employ multiple known authorised transmitters while keeping the analyst blind to their identities. It would vary

Copyright 2026, James M. Atkinson

receiver architecture, antenna position, analogue gain, reference clock and lawful environmental conditions. The investigator would then measure separate performance quantities: whether an emission was detected; whether its waveform was correctly assigned to a class; whether a known unit was distinguished from another unit of the same class; and whether an unfamiliar unit was rejected rather than falsely named. Each stage has its own denominator, uncertainty and failure mode. High sensitivity at the first stage cannot be carried over as a quoted identification accuracy at the fourth. The software's confidence score is not necessarily a calibrated probability of source identity.

Even successful apparatus-level attribution does not establish who operated the device, why a signal was emitted or whether any law was broken. Such conclusions require additional authenticated facts and the appropriate legal procedure. RF measurements can contribute to an investigation, but they do not substitute for authority to collect evidence or for proof of a person's conduct. An engineer should therefore write the finding in successive, testable propositions: the instrument registered a component; specified controls support an external RF origin; measured features are consistent with a waveform class; further tests do or do not support a particular apparatus; and any association with a person lies beyond the present electronic measurements unless independently established. The apparent modesty of that structure is its strength. It lets a later reviewer inspect the precise point at which an observation became an inference.

I would finish with a caution from the inverse-problem perspective. Different physical sources and propagation environments can produce very similar observations at a single receiving location. Without enough independent

Copyright 2026, James M. Atkinson

constraints, reconstructing a unique source from a measured field can be non-identifiable even when the field estimate itself is accurate. Better calibration and more precise timestamps help, but do not always cure non-uniqueness. An independent antenna placement, physically distinct receiver, controlled reference source or known perturbation can sometimes supply the missing discriminating information. Where that information is not obtained, the correct result may be a group of compatible causes rather than one named object. A defensible expert report should present that limitation plainly and propose the next lawful experiment capable of resolving it.

Dr. James M. Atkinson, Moderator: Dr. Bracewell, I retain your existing contribution on inverse-source ambiguity and instrument artefacts. Dr. Gabor, I now invite an examination of which apparent fingerprints survive a change of temporal representation. Your answer should address short-time transients, processing windows, channel effects and the danger of mistaking a stable representation for a stable physical source. Our conversation is a fictional educational reconstruction, not an historical encounter or an authentic statement by any named contributor.

Copyright 2026, James M. Atkinson

Dennis Gabor, Second Principal Contributor: Dr. Atkinson, every assertion of distinctive waveform structure begins with a decision about how electromagnetic observations are represented. A time-domain voltage series has been conditioned by an analogue receiver before it is recorded. A frequency-domain display is an estimate built by an algorithm which chooses a duration, a window, a frequency grid and perhaps averaging across observations. Neither representation is a transparent window upon the transmitter alone. If a feature is prominent in one display, the analyst ought to ask whether another admissible representation changes the alleged distinction. This is not an argument for infinite scepticism; it is a requirement that the proposed discriminating feature be measurable under a stated, repeatable protocol.

A burst has temporal support, and frequency discrimination has a corresponding dependence on observation duration. A very narrow spectral line cannot be resolved with arbitrary certainty from a vanishingly short sample. Conversely, extending the observation interval may suppress the visibility of an infrequent transient by averaging it with quiet periods. If the purported fingerprint is the shape of an oscillator's turn-on, a smoothing filter or long transform window may erase precisely the variations the investigator wishes to compare. A time-frequency map should therefore be interpreted alongside the sample rate, the window family, the hop size, the chosen amplitude scaling and the actual gaps in observed data. A colourful image without those parameters cannot sustain an individual-source conclusion.

The analyst must distinguish the system response from the source excitation. Suppose two otherwise identical authorised transmitters feed an

Copyright 2026, James M. Atkinson

RF laboratory receiver through differing cables and antennas. A transient recorded through one cable may appear to rise more slowly, because the group delay and matching differ. If the receive chain is altered between sessions, the observed difference cannot be laid at the transmitter's door without independent characterisation. The practical technique is to capture controlled reference events with the same measurement chain, then deliberately substitute antennas, filters, gains and receivers. If the supposed device-specific feature follows the receiver, it is a property of the apparatus or processing configuration, not an individual transmitter.

A more subtle problem arises when a classifier operates on spectrogram images. The pixels may encode a consistent colour palette, a fixed raster size or a receiver-specific normalization. A neural model can learn these conveniences instead of learning the underlying electromagnetic distinction. Randomly dividing spectrogram frames from one continuous capture into training and testing sets disguises the dependence: adjacent windows share samples, temperature, channel state and device operating conditions. A respectable validation protocol must separate entire capture sessions and, where the claim is cross-instrument identification, entire receivers. Otherwise, the quoted success rate is an estimate of recognition of familiar recordings, not of independent devices encountered in the field.

The observational model should be written as a composition. The emitted signal is acted upon by the channel, including propagation and multipath. It is then transformed by antenna impedance and the receiver's analogue stages, disturbed by noise and converted by sampling. Digital processing follows, including synchronization, filtering and feature extraction. A difference in the final feature vector may come from any stage. The inverse

Copyright 2026, James M. Atkinson

calculation is not generally unique. A robust individual-unit attribution procedure should either control the nuisance transformations or show experimentally that its decisions tolerate their variation to a specified level. Claims of invariance should be measured, not asserted from mathematical elegance.

There is also the question of what one calls a match. Two devices may share the same modulation, preamble, pulse-shaping filter and nominal burst duration because they implement the same standard or circuit design. A strong correlation with that common structure may be excellent evidence about the waveform family and very weak evidence about which physical unit produced it. In a sensible hierarchy, those propositions occupy different positions. A detection statistic tests whether observations comport with a chosen signal model; class membership requires comparison against rival classes; individual attribution requires variation among nominally similar units and sufficient rejection of unknown units. None of these questions is resolved merely by placing increasingly precise decimal numbers beside the same correlation peak.

I would prescribe a blinded experiment with three stages. At the first, the laboratory confirms that the instrument detects a controlled signal under a declared sensitivity and false-alarm regime, including negative controls. At the second, several different signal classes are compared under the same receiver settings, and confusion between classes is measured. At the third, multiple physical units of the same class are measured on separate days, through different antenna paths and with held-out receivers. The classification system must be permitted to say that the source is unknown. Investigators then report class-confusion rates and known-unit attribution

Copyright 2026, James M. Atkinson

rates separately, never promoting one into the other by linguistic convenience.

All quantitative claims should name a denominator and a unit of analysis. If a laboratory obtains ninety correct decisions from one hundred adjacent windows in the same recording, it has not necessarily obtained ninety independent successes. The effective independent sample size may be far smaller because the channel and transmitter state are shared. An uncertainty interval calculated as though the windows were independent will be too narrow. The correct design may aggregate decisions at the capture-session level or use clustered analysis respecting the dependence. It is preferable to state a modest evidence base clearly than to advertise a false precision manufactured by repeated processing of the same observation.

Finally, the result must be communicated in a form that an independent specialist can challenge without access to protected communications content. A record may consist of authorised RF sample extracts, transform parameters, calibration logs, feature definitions, predeclared decision rules, negative controls and a custody history. Where only summary measurements are lawfully necessary, the reasons for retaining raw data should be documented and their access controlled. The examiner should distinguish an instrument feature, a waveform-class feature and a proposed device fingerprint in separate columns. If a supposedly invariant fingerprint disappears when the transform window changes within its validated range, the proper finding is that the individual attribution did not survive a necessary robustness test. I pass the token to the discussion of spatial measurements and source ambiguity.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Sir Martin, the discussion now turns to spatial diversity, interferometric measurement and whether multiple observing sites can support a unique source determination. Please distinguish independent constraints from shared calibration errors, and consider lawful controlled trials in which two transmitters of the same type occupy different locations.

Copyright 2026, James M. Atkinson

Sir Martin Ryle, Third Principal Contributor: Dr. Atkinson, multiple receiving positions can be scientifically valuable, but merely increasing the number of instruments does not transform a descriptive waveform match into individual-source attribution. The first question is whether the observations are genuinely independent in the dimensions relevant to the inference. Two receivers sharing an oscillator distribution, cabling defect or synchronized processing software may register matching artefacts. Two antennas connected to one overloaded front end do not constitute two independent external-origin tests. A defensible spatial argument should describe the geometry, the frequency and time references, the antenna patterns and the common pathways through which systematic errors can be correlated.

The simplest observation is that a signal arrived at a particular instrument under particular settings. Directional measurements may add a bearing, and an array may estimate differences in arrival time or phase. These are statements about received fields, not necessarily the manufacturer's identity of the transmitter. Multipath can make a signal appear to arrive from a reflective surface; polarization mismatch can suppress one path and favour another; unknown antenna orientation can move a bearing. Even excellent direction finding may locate a radiating structure rather than the baseband device that generated the waveform. Before joining bearing and classification results, an analyst should explain how those separately calibrated quantities constrain the same physical hypothesis.

Interferometric methods create especially attractive numerical outputs. A tiny phase difference can be measured and used with geometry to infer a direction, provided the array's baselines, reference distribution, channel phase and ambiguities are known. But phase is observed modulo a cycle,

Copyright 2026, James M. Atkinson

and a narrowband source may admit multiple geometrically compatible solutions. In a cluttered building, reflecting surfaces and near-field interactions can violate the convenient far-field plane-wave approximation. A conclusion that the source occupies one point must rest on a demonstrated resolution of those ambiguities. A small estimated variance under a mistaken propagation model is not proof of accuracy in the actual environment.

A useful test separates the question of common waveform origin from the question of common physical emitter. An independent source may rebroadcast, repeat or reproduce a standard public pattern, and two emitters may implement identical nominal signalling. If multiple sites receive a shared modulation pattern, the evidence may establish a common waveform family without establishing a single unique transmitting apparatus. The laboratory should introduce two physically distinct authorised transmitters with deliberately similar nominal waveforms, change their positions, and evaluate whether the array continues to identify them correctly. Blindness to identity guards against the convenient adjustment of analysis parameters after the operator learns which source was active.

The reference population must be more discriminating than a theatrical comparison between unrelated devices. If the claim is that one particular transmitter among a population of nominally identical units has been recognized, tests must include units of the same design, firmware family and manufacturing batch where feasible. Otherwise, identification performance may merely reflect coarse class differences. The operator should also vary temperature, power supply, output level, antenna loading,

Copyright 2026, James M. Atkinson

oscillator discipline and receiver location. One ought to be particularly suspicious of a stable 'fingerprint' gathered from a single permanent laboratory arrangement; the receiver and channel may have become inadvertent labels attached to each device.

Where observations are combined, their error terms matter. A frequency estimate from one receiver and a timing estimate from another may share a common reference clock. If the reference is biased, simply multiplying their nominal likelihoods as if they were conditionally independent double-counts part of the same evidence. The correct joint model must include common-mode uncertainty or make a defensible conditional-independence assumption supported by tests. An independent receiver with its own reference, antenna and software can provide a valuable challenge, although complete independence is rarely absolute. The documentation should describe the dependence that remains rather than hiding it behind the number of instruments deployed.

A localization conclusion is also not an attribution conclusion. A direction-and-distance intersection may narrow the probable location of a radiating element, yet it does not show that a particular named equipment unit was responsible unless the chain between unit and radiator is established. Consider an authorized laboratory system that uses a cable to feed a remote antenna. The receiving geometry will locate the radiator, not the clock, processor or operator at the other end of the feed. The finding must keep these objects separate. A source location may be highly relevant to a defensive investigation without supporting an assertion about personal ownership, intent or unlawful conduct.

Copyright 2026, James M. Atkinson

I would therefore construct three sets of controls for a defensible RF attribution experiment. The first tests external origin by substituting antennas, introducing attenuation and changing receiver front ends while retaining an independently monitored reference. The second tests geometric inference by moving an authorised source through known positions and recording bearing or delay errors, including the effect of reflecting surfaces. The third tests individual-device discrimination by exchanging same-class emitters under blind identifiers and then repeating the trials through new channel states. Each set answers a different question. A favourable result in one set does not automatically satisfy the next.

A sober report can still convey strong engineering value. It may say that a particular waveform family was detected, that independent antennas registered compatible energy, that direction measurements placed the likely radiating region within a stated uncertainty envelope, and that the available features could not distinguish between several same-class units. This does not defeat the investigation. It identifies where further lawful measurements would add information and where the laws of propagation leave genuine non-uniqueness. Conversely, if an instrument-specific characteristic survives those trials, it may support an appropriately qualified comparison, provided the supporting reference population and rejection tests are disclosed. I pass the token to the detection-theory assessment of such evidence.

Dr. James M. Atkinson, Moderator: Dr. Slepian, please examine the nested statistical decisions: the existence of a signal, the classification of a waveform, and the attribution of a source in the presence of nuisance

Copyright 2026, James M. Atkinson

parameters. In particular, explain why a high detection probability cannot be reported as an individual-device identification rate.

Copyright 2026, James M. Atkinson

David Slepian, Fourth Principal Contributor: Dr. Atkinson, one must first identify the event for which a probability or error rate has been calculated. A detector ordinarily distinguishes between a null model and an alternative such as a specified signal embedded in noise. Its sensitivity and false-alarm characteristics depend upon an assumed noise distribution, observation window, threshold and signal model. An apparatus may detect almost every laboratory burst at a specified power while completely failing to determine which of several identical transmitters generated each burst. The high probability of detection addresses presence under those test conditions, not the identity of the source. A report that moves directly from ninety-nine per cent detection sensitivity to ninety-nine per cent source certainty commits a change of hypothesis without providing the requisite evidence.

The second decision concerns classification. Here the possible hypotheses may include amplitude modulation, a frequency-agile burst, an impulsive discharge and an unknown class. The relevant statistic should be tested against both neighbouring classes and genuine unknowns. A closed-set classifier always chooses among known labels, making its output misleading when the true generating mechanism is absent from the training set. An unknown-source rejection option is therefore not a cosmetic feature. Its false-acceptance and false-rejection behaviour must be quantified under specified conditions. Rejection thresholds that were tuned on the test dataset cannot be treated as independent validation results.

Individual attribution adds the proposition that a particular physical transmitter, rather than another compatible unit, generated the measurement. If the proposed evidence is a collection of oscillator offsets, transient shapes and error-vector features, then both within-device

Copyright 2026, James M. Atkinson

variability and between-device variation are central. Two devices might have distinct average offsets during a single laboratory session yet overlap after temperature changes. A model fitted to one session may label the receiver's frequency error as part of the emitter's signature. Proper trials must vary the acquisition apparatus, reference standards and operating conditions, and make the evaluation unit an independent capture session or physical device as justified, rather than a succession of correlated windows.

Likelihood notation can clarify the distinction if used cautiously. Let E denote the observed feature vector; let H1 express the proposition that a tested unit generated the event; and let H2 denote an appropriate alternative source proposition. A likelihood ratio compares P(E given H1) with P(E given H2) under specified models, populations and nuisance conditions. It is not itself P(H1 given E), and it certainly is not the probability that a named individual committed misconduct. Its value depends upon the choice of alternative, the representativeness of the reference population, the treatment of unknown devices and the stability of the measurement process. Reporting a dramatic ratio with no explanation of those modelling choices is poor evidential practice.

The danger is heightened by data leakage. If the training and test sets share overlapping FFT windows, neighbouring packets from the same continuous recording or nominally different files generated by the same receiver calibration episode, the performance estimate will be optimistic. The model may recognize the channel or acquisition date rather than the transmitter. A more persuasive design holds out entire transmitter units when testing class recognition, whole capture sessions when testing within-unit repeatability, and different acquisition chains when asserting cross-receiver

Copyright 2026, James M. Atkinson

robustness. Separate calibration, development and final evaluation sets should be identified before results are inspected. The laboratory should preserve the split definition so another investigator can reproduce the evaluation.

Calibration uncertainty and classification uncertainty are related but not interchangeable. A receiver may carry a well-characterised amplitude scale uncertainty yet yield uncertain attribution because the feature distributions for different devices overlap. Conversely, a robust class decision may be possible even though an absolute power measurement is comparatively imprecise. The correct report states the estimand, its calibration assumptions, the validated classifier operating point and the relevant error rates. A single percentage labelled confidence conceals these distinctions. It should not be accepted as an evidential substitute for the confusion matrix and rejection tests.

Suppose a blind laboratory trial uses ten same-class transmitters, each recorded on three days through two receivers. The experiment must document whether the sixty device-day-receiver combinations are independent enough for the intended inference; they do not become thousands of independent trials merely because each file contains thousands of windows. The analysis should show per-device errors, errors by session and errors under receiver substitution. A unit that is easily recognized only when the same receiver is used is not thereby uniquely fingerprinted across receiver architectures. The test should also introduce new devices not among the ten and determine whether the system rejects them instead of selecting the closest familiar label.

Copyright 2026, James M. Atkinson

A further subtlety is the base rate. An instrument may show a low false-identification percentage in a restricted set of laboratory comparisons yet operate in an environment containing many unrepresented devices. The chance that an alert is mistaken depends upon the prevalence of target devices, the alternatives actually present and the decision policy. We should not substitute an arbitrary prior for missing field information; we should expose the sensitivity of the inference to plausible priors and source populations. If no defensible population is available, the finding may have to remain a descriptive similarity assessment without a numerical source-likelihood claim. That is a scientifically substantive result, not an embarrassment.

Finally, the statistical experiment must be separated from investigation-driven search. One may examine many features to develop a promising detector, but subsequent claims of validated performance require fresh data or appropriately corrected inference. Every feature chosen after seeing the source identities risks incorporating an accidental separation. The laboratory should record versions of the feature extractor, threshold, decision rule and data split. Independent reviewers should be able to rerun the results from properly preserved authorized measurements, and to determine when a prediction depends on a software implementation rather than source physics. I therefore pass the token to the decision-theoretic question of what to report when the evidence is insufficient.

Dr. James M. Atkinson, Moderator: Professor Blackwell, the evidence may support a waveform-class hypothesis strongly while remaining equivocal among individual emitters. Please address decisions under that uncertainty,

Copyright 2026, James M. Atkinson

the cost of a false identification, unknown-class rejection and the separation between engineering findings and legal conclusions.

Copyright 2026, James M. Atkinson

David Harold Blackwell, Fifth Principal Contributor: Dr. Atkinson, a classifier's output is an action selected under a rule, not an ontological declaration about the world. We ought first to distinguish posterior belief, where a specified probabilistic model is justified, from the decision made under competing losses. An automated system may be designed to issue an investigative lead when a low-cost false alarm is tolerable. The same output cannot be carried unchanged into sworn testimony identifying a particular apparatus when a false attribution could injure an innocent person. The action threshold depends upon the consequence of error, the available alternatives and the information withheld by the model. An honest report states which decision rule was validated for which purpose.

The investigator may possess evidence adequate for one decision but inadequate for another. Detection of a recurring emission may justify further lawful inspection, even though it does not support naming a transmitter. Classification into a broad waveform family may guide selection of appropriate antennas or monitoring bandwidth. Neither action presupposes that the analyst can identify a particular serial-numbered unit. The error costs are different at each stage. When the consequences of mistaken attribution are serious, the system should be permitted to abstain and should be evaluated specifically on whether it declines unjustified certainty rather than merely on its average classification accuracy.

An unknown-class state is essential because the actual environment is seldom exhausted by the training catalogue. The laboratory should reserve physically distinct devices and signal sources that were never presented during training, threshold tuning or feature selection. It should then measure the fraction of these unfamiliar sources mistakenly attributed to

Copyright 2026, James M. Atkinson

familiar units. An apparatus which achieves a high closed-set accuracy may still make every unknown source look like one of its enrolled units. If the class model assumes the universe consists of five transmitters, the model cannot establish that the universe in fact consists of those five. The test design must challenge that presumption independently.

I would add a distinction between explanatory and predictive models. A classifier may correctly distinguish laboratory files using a feature whose physical origin is unknown. Such a model can be useful for sorting recordings, but its success does not establish that the feature belongs to the emitter rather than the receiver or environment. If the scientific claim concerns a transmitter-specific imperfection, it should survive deliberate substitutions designed to remove acquisition-system confounds. A predictive score may decline sharply under changed temperature or antenna path. That would reveal a limitation of the intended scope, not necessarily a defect in the mathematical classifier itself. The error lies in claiming broader evidential meaning than the validation supports.

Consider a decision table in which the cost of a mistaken class assignment is low, but the cost of naming a false individual source is high. One rational policy may classify the waveform for operational triage while withholding individual attribution unless an independent second measurement agrees and an unknown-source test is passed. The policy should be documented before reviewing the final case data. A later investigator cannot quietly raise or lower thresholds to make an existing suspect appear more or less likely, then quote the calibration error rate from the original threshold. Altering the decision rule creates a new procedure whose performance needs new examination.

Copyright 2026, James M. Atkinson

Where competing propositions are compared, it is tempting to collapse all uncertainty into a single likelihood ratio. But the figure may conceal dependence between features and the difference between modelled and unmodelled devices. The laboratory should disclose which alternatives were considered and why those alternatives are relevant. It should also investigate whether apparently independent observations share calibration or processing steps. If two features derive from the same oscillator offset, treating them as independent can double-count one physical imperfection. A defensible joint model must represent that dependence or restrict the strength of the conclusion.

The practical reporting hierarchy begins with the observation itself: instrument state, measured feature and acquisition uncertainty. It continues with the result of controlled external-origin tests and the waveform-class comparison. The next level identifies any evidence for a specific physical emitter, together with reference population, unseen-source rejection performance and the limits of channel robustness. Finally, the report states that operator identity, knowledge, purpose and legal culpability are separate matters requiring independently authenticated evidence. The expert should not allow those distinct issues to merge because a narrative sounds persuasive when presented without qualifications.

One should remember the decision to collect additional evidence. If a particular ambiguity can be resolved by a lawfully authorised swap of receivers, a change of antenna position or an independently monitored reference signal, the rational next action is to perform that controlled test rather than inflate the existing inference. If the apparatus cannot be revisited, the report must mark the resulting uncertainty. More intensive

Copyright 2026, James M. Atkinson

analysis of an already ambiguous file may be useful, but it cannot necessarily add the missing independent constraint. There are cases where no amount of processor time makes a non-identifiable inverse problem unique.

I therefore propose a conservative acceptance test for any claimed individual-emitter attribution: blinded same-class comparisons, held-out sessions, receiver substitutions, nuisance-condition changes, explicit unknown-source trials, disclosed dependence between features and a clear statement of the resulting error rates. The system should be allowed to return inconclusive. An inconclusive outcome may be the most reliable finding the evidence permits. In an engineering investigation, that restraint directs scarce attention to the next useful experiment; in formal testimony, it prevents descriptive measurements from being misrepresented as proof of someone's conduct. I pass the token respectfully to the remaining peer examinations.

Dr. James M. Atkinson, Moderator: Professor Shannon, Dr. Bracewell has distinguished an observed component from its cause. I invite you to challenge whether information about modulation can legitimately be promoted to information about individual transmitter identity. Dr. Bracewell will respond before the token passes to the next participant.

Claude Elwood Shannon, Peer Question: Dr. Bracewell, suppose an authorised receiver captures a distinctive sequence of bursts, and the analyst discovers a high correlation with a familiar public waveform structure. The result seems impressive, especially when repeated across several captures. Yet the same public structure may be implemented by many physically distinct devices. How should the report distinguish

Copyright 2026, James M. Atkinson

information about a waveform family from information about an individual apparatus? I would also ask whether the instrument's own sampling clock or digital filter can create features mistakenly interpreted as hardware fingerprints. If a classifier reports a ninety-nine per cent score for one enrolled unit, what evidence would be required before interpreting that score as a probability that this unit originated the observed emission? Finally, how should the analysis treat an emitter absent from its training catalogue, given that an algorithm forced to choose among familiar labels must nevertheless select one? The underlying issue is whether a numerical result reduces uncertainty about the correct proposition or merely conceals that the proposition was never tested.

Ronald Newbold Bracewell, Response: Professor Shannon, I would begin by writing separate statements on the face of the report. The first says that the observed samples are consistent with a specified waveform structure under a documented processing model. The second, which remains to be established, asks whether the waveform structure differs between members of the relevant physical population. An ordinary publicly specified modulation or preamble may be shared by every compliant device. Detecting it can be decisive for the waveform-family question while adding almost no information about a particular serial-numbered transmitter. The report should not be permitted to change its subject without an intervening experiment.

That experiment must include physically different units of the same type, recorded through sufficiently varied equipment and channels to identify whether the feature follows the transmitter. A clock line at an offset from a nominal carrier is not necessarily attributable to the external unit; it may

Copyright 2026, James M. Atkinson

reflect the receiver oscillator, a shared frequency reference or a resampling convention. Replacing the receiver, altering the reference and introducing a known laboratory source can challenge those alternatives. If the apparent signature changes with receiver substitution, the attribution claim should be revised. Reproducibility of a displayed trace under one fixed configuration establishes very little about which component in the chain created its distinctive details.

A classifier score is also not automatically a posterior source probability. Its numerical scale may be a software similarity, a normalized distance, an uncalibrated neural output or a probability conditioned on a closed universe of training labels. To interpret it as P(unit A given observations), the analyst would need a defensible model of the source hypotheses, the conditional feature distributions and appropriate prior information. The relevant alternatives must include unknown and closely similar units, not merely a few artificially different references. In formal testimony, it may be better to report the measured score together with validated false-attribution performance than to express a posterior probability the evidence cannot support.

Finally, the unfamiliar-source case must be tested, not treated as a hypothetical afterthought. In a blind trial, the operator should present transmitters never used in feature selection, training or threshold adjustment, then observe whether the system rejects them at an established operating point. The result may be a descriptive match, a class-level conclusion or an inconclusive answer. Those are legitimate outcomes. A system that never abstains can look decisive while being structurally unable to recognize its own ignorance. The technician should state the

Copyright 2026, James M. Atkinson

highest evidential level reached and leave the identity of an operator or owner to separate, independently corroborated investigation.

Dr. James M. Atkinson, Moderator: Professor Tukey, please examine whether the laboratory's impressive sample count may actually consist of correlated representations of a very small number of independent RF capture sessions. Dr. Gabor will answer the methodological challenge.

John Wilder Tukey, Peer Question: Dr. Gabor, an analyst presents a validation report containing fifty thousand spectrogram crops, claiming this enormous dataset supports very high accuracy in identifying ten devices. Upon inspection, the crops were taken from a few continuous recordings, and neighbouring crops share both samples and the same channel state. Some captures from one session appear in the training data while other crops from that same session appear in the test data. What makes the resulting headline accuracy unreliable? Would stratifying randomly by device label, rather than by capture session and receiving chain, solve the problem, or does it preserve a dependence the published table disguises? I also ask what the proper unit of analysis should be when the purported claim is recognition of a previously unseen transmitter in a different building. If the committee has only two receiving environments and a handful of same-class devices, how should it acknowledge the narrowness of the experimental claim without simply discarding the observations? An exact numerical statistic is useful only when its denominator represents the relevant independent opportunities for error.

Dennis Gabor, Response: Professor Tukey, the problem is not that the analyst employed a large computational dataset. It is that the dataset's apparent size was mistaken for the size of the independent evidential

Copyright 2026, James M. Atkinson

experience. Adjacent spectrogram crops may share most of their raw samples and nearly all of their acquisition conditions. If one capture session contributes to both training and testing, a model may recognize local channel coloration, receiver gain, interference patterns or a transient calibration state. The classifier can then achieve extraordinary accuracy at recognising familiar conditions without learning a feature that belongs uniquely to the emitter. The resulting accuracy is valid, at best, for the narrower task of classifying similar fragments from familiar sessions; it is not a tested estimate of performance in a new building.

Random stratification by device label alone does not break that dependence. The entire acquisition session, together with derivatives from that session, should remain in one partition when the target claim concerns new sessions. Where the claim reaches across receivers or locations, those domains must also be represented in the held-out design. A feature extractor tuned using information from the held-out recordings can leak test knowledge even if the final classifier was trained on separate files. Therefore the laboratory must freeze preprocessing, feature selection and threshold choices before inspecting its final evaluation set, and it should record every dependency between derived windows and original captures.

The proper unit of analysis follows the question. For a demonstration that the same observed waveform can be recognized within one file, a frame-level score may be informative. For identification of a transmitter on a different day, the session or device-day may be a more appropriate test unit. For transfer to unfamiliar receiving equipment, an independently held-out receiver is essential. Confidence intervals based upon tens of thousands of correlated windows are not justified by the nominal frame count. Cluster-

Copyright 2026, James M. Atkinson

based uncertainty or session-level summaries better reflect the variation that affects the actual forensic proposition.

A small study need not be concealed or discarded. It can supply exploratory evidence, reveal useful controls and motivate a better experiment. The report should identify the number of independent devices, sessions, receivers and environments and describe the observed performance within those boundaries. It should also show whether the model can abstain on truly novel devices. If two environments were tested, the laboratory should not assert robust performance across all industrial sites. The honest result may be that the candidate feature is repeatable in the present apparatus but remains unvalidated under the changes required for field attribution. This limitation makes the next experiment obvious and prevents attractive graphics from pretending to deliver statistical independence.

Dr. James M. Atkinson, Moderator: Dr. Hamming, let us challenge error-correcting codes and other regular digital structures as possible sources of false individuality. Sir Martin will answer whether waveform regularity alone is sufficient to locate or name a physical emitter.

Richard Wesley Hamming, Peer Question: Sir Martin, many transmitters implementing one communications family share coding constraints, synchronization sequences and repetitive frame structures. An investigator may recognize one of these patterns with remarkable reliability and conclude that it reveals a distinctive device. Yet such regularity might belong to the protocol or modulation chain rather than to a particular unit. How should the laboratory test the difference, particularly when the receiver and its software can introduce repeated patterns of their own? If direction-finding measurements appear to point to one part of a building, may the

Copyright 2026, James M. Atkinson

analyst combine that spatial result with the strong protocol match to announce one identified emitter? I am also troubled by the possibility that a common oscillator distribution to multiple receivers creates correlated phase behaviour, falsely suggesting coherent spatial confirmation. What independent observations would justify the spatial claim, and how should the findings be worded when propagation ambiguity or remote antenna feeds remain plausible? I invite an answer that distinguishes detection, source location and device individuality.

Sir Martin Ryle, Response: Dr. Hamming, a coding pattern or synchronization structure can establish useful signal-family information, but a feature deliberately shared by many transmitters is a poor candidate for individual identification. The laboratory should compare multiple physical units using identical public coding and modulation settings. If they produce nearly indistinguishable patterns, the common feature must be reported as class-level evidence. If an additional analogue imperfection appears distinctive, that imperfection requires its own controlled tests across operating states and channels. The correct analysis preserves the distinction between a signal generated according to a common standard and an idiosyncrasy measured from one particular physical circuit.

A spatial measurement is another independent proposition. A calibrated bearing, arrival-time difference or array phase estimate can constrain the direction or location of radiated energy under specified geometry and propagation assumptions. It does not generally reveal the identity of the oscillator, processor or operator that supplied that energy. A remote antenna connected by cable makes the distinction plain: the radiation may emanate from the antenna position while the generating equipment sits

Copyright 2026, James M. Atkinson

elsewhere. The report must say whether it locates a radiating aperture, an apparent arrival direction or an inferred transmitter location. These are related but not identical quantities.

Common reference distribution can also induce deceptive agreement. Two receivers sharing a faulty clock may show correlated phase changes that are wrongly attributed to a common external source. Likewise, antennas connected through shared nonlinear stages can display coincident spurs. An independent receiving chain with a distinct reference, a controlled laboratory source and deliberate changes of antenna geometry can challenge those confounds. A multi-site result is stronger when its geometry, timing reference and systematic error sources are measured, not merely when the number of plotted traces increases. The analyst should identify which correlations arise from shared apparatus and which remain after the independent controls.

If direction finding indicates a region consistent with the waveform detection, the defensible statement is that multiple observations are compatible with an emission arriving from that region, within disclosed uncertainty. Further comparison may support a device class or a particular unit, but only if the class-level and individual-level evidence has actually been obtained. A visually convincing intersection of bearings should not be promoted into an assertion about serial number or ownership. When multiple reflected paths or the near-field environment prevent unique localization, report the competing regions or explanations. The appropriate experiment is to relocate the controlled source or receiving antenna, not to eliminate the inconvenient alternative by description.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Sir Harold, please examine the distinction between probabilities assigned under a model and the much stronger proposition that a named physical unit must have transmitted. Dr. Slepian will answer with the limits of likelihood reasoning and hypothesis specification.

Sir Harold Jeffreys, Peer Question: Dr. Slepian, suppose the laboratory has estimated a likelihood ratio for a feature vector under the propositions that one known transmitter generated the recording and that a source from a selected reference population generated it. The reported ratio favours the known unit by a substantial factor. Yet the reference population consists of devices chosen for convenience, and the model assumes that oscillator and channel features are independent although they were measured through a common receiver. Does the numerical ratio establish the probability that the known transmitter actually produced the event? What effect would a larger or differently constituted reference population have, and what is the proper statement when the real-world candidate source could be completely absent from the enrolment collection? I ask also whether a prior probability may be inserted from the investigator's suspicions without openly changing the inference. In court, the distance between an evidential likelihood comparison and a posterior claim about an individual source is not merely semantic; it can determine whether an equivocal measurement sounds conclusive.

David Slepian, Response: Sir Harold, a likelihood ratio is conditional upon both propositions and the models by which the conditional probabilities are estimated. It compares the observed evidence under H1 with the observed evidence under H2; it does not, by itself, state P(H1 given the evidence). To

Copyright 2026, James M. Atkinson

obtain a posterior proposition probability, one must introduce prior odds and an adequate hypothesis space. These requirements cannot be bypassed by reporting a large numerical value. If the alternative population is artificially narrow or excludes physically similar devices, the ratio may be impressive yet poorly relevant to the actual question being asked. An unfamiliar unit, omitted from both development and validation, is precisely the kind of alternative that challenges the model.

Dependence between features is equally important. If frequency offset and phase drift arise partly from one shared oscillator error, multiplying their marginal likelihoods as though they were conditionally independent double-counts aspects of the same evidence. Calibration uncertainty in the receiver may affect several features together. A model must represent the joint behaviour or justify an approximation experimentally. Otherwise, the polished ratio is a calculation under false premises. The appropriate response is not to remove the mathematics but to document the assumptions, obtain independent challenge measurements and report how the value varies when reasonable alternative models are used.

The reference population should match the actual scope of the proposition as far as the available data permit. Same-class units, manufacturing variation, operating conditions, receiver architectures and environmental effects should be represented. If the question is discrimination among enrolled devices in one laboratory, a restricted population may be adequate for that restricted task. If the finding is intended to identify a device encountered in an open environment, unknown-source rejection and representative alternatives become critical. Without them, a categorical individual attribution cannot be inferred from a closed-set match. The

Copyright 2026, James M. Atkinson

system should be permitted to return inconclusive and its rejection performance should be reported.

Finally, prior assumptions should not be smuggled in as if they were measured RF properties. Investigative information may affect which source is considered, but a mathematical report must disclose which assumptions came from circumstances outside the recorded waveform. The RF specialist may provide a carefully bounded evidential comparison, leaving ultimate attribution, ownership or legal culpability to the fact-finder with other independent evidence. A clear report would show the hypotheses, feature definitions, reference population, model dependencies, validation error rates and sensitivity to plausible alternatives. In the absence of a justified probability model, a qualified statement of similarity and its limitations is better than an unjustified percentage. Evidential restraint is not avoidance of analysis; it is the consequence of knowing precisely what the analysis can and cannot estimate.

Dr. James M. Atkinson, Moderator: Dr. Neyman, please test the claimed error rates of an individual-emitter classifier and the difference between prior development data and genuinely independent evaluation. Professor Blackwell will respond with the appropriate decisions when the evidence is equivocal.

Jerzy Neyman, Peer Question: Professor Blackwell, a laboratory reports that its system correctly named 980 of 1,000 labelled spectrogram excerpts, and it announces a two per cent misidentification rate. The excerpts, however, came from ten long recordings of only five physical transmitters, all observed on one receiver. Its threshold was selected after inspecting the same excerpts, and it has no rejection category for an unfamiliar

Copyright 2026, James M. Atkinson

transmitter. Is the quoted error rate a meaningful bound upon the chance of naming the wrong individual device in a future field investigation? What should the experimental unit be, and how should the validation sequence separate feature discovery, threshold selection and final performance estimation? I am especially concerned about a system that reports strong average accuracy while repeatedly misclassifying one particular device or performing poorly under changed temperature. Could a technically sound report disclose such heterogeneity without treating every observation as a failure? I ask for a design in which the planned claim and tested error rates occupy the same population and operating conditions.

David Harold Blackwell, Response: Dr. Neyman, the two per cent number describes errors among the 1,000 excerpts under the experiment actually performed; it does not by itself estimate a future open-world individual-attribution error rate. The excerpts share a small number of devices, sessions and receiver conditions. If the model uses acquisition-specific properties, all the cropped excerpts from one session may be easy to classify while the same physical unit recorded elsewhere appears unfamiliar. Counting correlated crops as independent opportunities for error creates spurious precision. Moreover, a threshold selected by inspecting the test outcomes has been optimised to those same outcomes. Its reported validation rate cannot be represented as a wholly independent prospective performance estimate.

An appropriate design starts by specifying the intended use. If it concerns identifying enrolled devices recorded on a different date, the laboratory should hold out complete recording sessions and vary relevant operating states. If it concerns new receiving equipment, whole receivers should be

Copyright 2026, James M. Atkinson

held out from model selection. If it concerns unfamiliar physical units, a separate unknown-source set must be assembled, and a rejection operating point declared before final testing. The report should distinguish class-level classification from selection among enrolled individual units and should provide the confusion matrix for each stage. It should also include the number of physical transmitters, receiver chains, days and environmental settings, not merely the total number of windows.

The design should have distinct phases. Exploratory data can be used to discover features and candidate thresholds. A development set can select a fixed decision policy, including the reject option. A final independently collected set then evaluates that frozen policy. If the analysts adjust the threshold after seeing final test results, those data have become development data and a new final challenge is needed. The laboratory ought to preserve code versions, configuration manifests and randomization procedures so the distinction is not merely asserted. Errors should be presented by unit, session and receiver because average performance can conceal one catastrophic confusion pair.

A confidence interval is meaningful only when its construction and sampling assumptions match the experiment. The analyst should not put a conventional binomial interval around 1,000 correlated crops while describing it as uncertainty about field attribution among unknown units. Where the evidence is too small to estimate a low false-attribution rate with useful precision, that limitation should be declared. The system may remain useful for triage or narrow laboratory comparisons. It should abstain rather than force an individual name when the relevant validation is absent. Good statistical design is not a way to avoid decisions; it is the means of ensuring

Copyright 2026, James M. Atkinson

that the consequences of decisions are matched to evidence actually gathered.

Dr. James M. Atkinson, Moderator: Mr. Armstrong, please test the physical origin of apparent emitter-specific imperfections, including oscillator products, analogue overload and receiver-generated spurs. Dr. Bracewell will respond with an independent-source challenge programme.

Edwin Howard Armstrong, Peer Question: Dr. Bracewell, imagine an apparent device fingerprint consisting of several narrow lines and a characteristic transient. The analyst first observes it with a sensitive front end at high gain, then finds similar details on later recordings from the same receiver. A confident report assigns the lines to defects in one transmitter. How would you challenge the possibility that they arise in the receiver itself through local-oscillator leakage, mixer nonlinearity, adjacent strong signals, quantisation artefacts or power-supply coupling? The concern is especially acute when all known device references were gathered with one measurement chain and no direct source monitor. Would changing the input attenuator, preselector, aerial or oscillator reference help locate the origin of the apparent fingerprint? How should a laboratory distinguish a genuine physical dependence from a diagnostic coincidence, and what must be said if the feature remains stable yet its source cannot be isolated? Please keep the test within authorised laboratory signals and avoid treating an attractive spectral display as proof of an individual emitter.

Ronald Newbold Bracewell, Response: Mr. Armstrong, the first exercise is to formulate competing hypotheses about the physical location of the feature. Under one, the candidate transmitter produces the relevant distortion. Under another, the receive chain creates it when driven by an external but

Copyright 2026, James M. Atkinson

otherwise unremarkable signal. Under a third, it arises from another environmental source coupled into the measurement setup. We then design substitutions that affect these hypotheses differently. If a spectral line changes in a non-proportional manner when input attenuation is inserted before the receiver's nonlinear stages, that behaviour can suggest an internally generated product. The exact interpretation requires knowledge of which stage the attenuator precedes and the relevant gain state.

An independent receiver with its own reference oscillator is a valuable control, as is comparison with a known laboratory reference transmitter through the same antenna path. Switching to an appropriate termination under safe conditions can challenge whether a peak is entering by the antenna port, although a terminated input does not eliminate every possible internal or environmental coupling route. Preselection may suppress out-of-band strong inputs which generate intermodulation. Moving the antenna may alter an actual external field and can also change coupling to nearby wiring. These controls should be performed in a planned sequence with configuration and timestamps recorded, not opportunistically until one result confirms the preferred explanation.

We must also distinguish a diagnostic indicator from a proof. A spectral component that shifts with the receiver reference clock is evidence that the chain's frequency reference participates in its apparent position. A component that vanishes when the suspect transmitter is switched off under a controlled test becomes more consistent with that transmitter's involvement, but may still be a receiver-generated product driven by its emissions. The laboratory may need independent analogue monitoring or a receiver with a different architecture to distinguish those possibilities. Its

Copyright 2026, James M. Atkinson

conclusion should state which alternatives were eliminated and which remain. An actual external input can cause an internal artefact; those two descriptions are not mutually exclusive.

Finally, the purported signature should be challenged by substituting multiple same-class transmitters under the same conditions. If the same distinctive line appears for all of them, it is likely to be a common source-chain or design feature rather than a reliable individual marker. If the lines differ, the variation still must survive receiver substitution, temperature changes, altered gain and a held-out test set. A stable fingerprint within one receiver configuration is an observation requiring explanation, not an automatic serial-number identification. Report the controls, raw authorised samples, calibration state and uncertainty, and refuse any move from an RF comparison to a claim about the identity or intention of a human operator without separate evidence.

Dr. James M. Atkinson, Moderator: Admiral Hopper, please now examine the evidentiary record that connects a classifier output with the exact acquisition and processing operations on which it depends. Dr. Slepian will answer how software provenance affects statistical inference.

Grace Brewster Murray Hopper, Peer Question: Dr. Slepian, consider two laboratories analysing the same authorised I/Q capture. They agree on the file's byte digest yet arrive at different individual-transmitter labels. One used a version of the processing code that automatically corrected carrier offset, while the other used an earlier version that did not. Their I/Q manifests also disagree about whether samples were stored as interleaved signed integers or normalized floating-point values. Could both results be reproducible within their own software environments without either

Copyright 2026, James M. Atkinson

constituting reliable source attribution? What minimum record would permit a third examiner to reconstruct the distinct analyses and discover why they disagree? I ask also how a programme should distinguish a transformation that changes the underlying sample values from one that changes only their representation, and how its acceptance test should treat missing or truncated records. A cryptographic digest can preserve a mistaken interpretation with perfect fidelity. How should such provenance limitations be exposed within the evidential hierarchy before an apparently numerical device match reaches a tribunal?

David Slepian, Response: Admiral Hopper, byte-level integrity and interpretive validity are separate predicates. A cryptographic digest over an explicitly identified file can support a claim that a later byte sequence matches the preserved reference sequence, assuming appropriate integrity protection of the digest and custody records. It does not establish the correctness of the sample-format description, clock, receiver calibration or analysis code. The two laboratories may both reproduce their respective computations exactly while applying different mathematical operations to identical bytes. Their disagreement is not a contradiction in file integrity; it is a difference in interpretation and potentially in the quantity each algorithm estimates.

The third examiner needs an acquisition manifest that specifies sample packing, byte order, signedness, channel interleaving, sample rate, centre frequency and receiver state, together with the clock reference, data-loss flags and calibration information. Each analysis needs its own immutable reference to the input object, exact software version, dependency versions, processing parameters, feature definition, classifier build and decision

Copyright 2026, James M. Atkinson

threshold. A saved screenshot is inadequate because it does not specify the numerical path from input samples to result. Where a pipeline changes the content through resampling, filtering or truncation, the derived file should have a new identifier and digest, linked to the preserved original and its transformation record.

Repackaging is not equivalent to changing samples. If numerical samples are preserved while an archive wrapper or file header changes, the hash of the complete container may differ even though the sample sequence is numerically equal. Conversely, byte-identical data interpreted with swapped I and Q or a different endianness can produce entirely different physical conclusions. The laboratory should distinguish byte equality, numerical sample equivalence and interpretive equivalence. Missing data must be represented as missing, rather than silently padded or concatenated into an apparently continuous timeline. A classifier's feature vector may be very sensitive to such interventions and should be rejected as an attribution basis when the provenance does not establish that its assumptions were met.

The acceptance test should include known laboratory input files with controlled sample formats, deliberately wrong manifests, isolated single-bit changes, missing buffers and software-version substitutions. Expected outputs should be fixed in advance for both valid and invalid cases, with explicit tolerances for permitted floating-point differences. The system should not be considered trustworthy merely because it returns the same wrong label consistently. Only after the processing path is reproducible and its measurement assumptions are validated can statistical source comparisons be interpreted. Even then, the individual-device inference requires an adequate population of same-class alternatives and unknown-

Copyright 2026, James M. Atkinson

source rejection. Software provenance permits the expert to defend how a result was obtained; it does not add information that the RF observations never contained.

Dr. James M. Atkinson, Moderator: We proceed to reciprocal examination among the five principal specialists. Each challenge is directed to a distinct colleague and is followed immediately by that colleague's substantive response. Dr. Gabor has the token first.

Dennis Gabor, Cross-Peer Question to Ronald Newbold Bracewell: Dr. Bracewell, your inverse-problem argument identifies many possible causes for a single observation, but an analyst may respond that a highly resolved time-frequency trace contains so much apparent detail that uniqueness ought to follow. Suppose we have a brief captured transient with a complicated ridge pattern which appears stable over many repeated frames in one laboratory. How would you determine whether that complexity supplies independent constraints on source identity or merely reflects a stable receiver impulse response, multipath and display processing? What would a deliberately varied acquisition experiment need to show before you would accept that a detailed trace distinguishes one physical unit from others of its class? I ask also about the risk that reprocessing the same retained samples with several window functions creates a false impression of multiple independent confirmations. A rich representation may reveal more of a record, but does it create new observations of the world? The issue is central to whether apparent precision is legitimately translated into individual attribution.

Ronald Newbold Bracewell, Cross-Peer Answer to Dennis Gabor: Dr. Gabor, increasing the number of computed descriptors does not necessarily

Copyright 2026, James M. Atkinson

increase the number of independent physical constraints. Several time-frequency images may be mathematical transformations of precisely the same finite record, inheriting the same receiver response, propagation path and missing-data limitations. They may expose different aspects of one observation but they cannot be counted as separate independent experiments. If the analyst selects the representation which most dramatically separates known devices, the selection itself is part of the exploratory fitting procedure and must be tested on new data. Otherwise the claimed uniqueness has been manufactured in part by adaptive choice of view.

I would seek a factorisation of the observation chain. The emitted field travels through a channel and receiver whose responses can each leave a distinct signature. A transient ridge may be the convolution of the transmitter's turn-on behaviour with filter group delay and time-varying channel effects. To assign it to the transmitter, the laboratory must vary the receiver and channel deliberately while keeping the same physical unit, and then vary the physical unit while keeping matched observation conditions. A distinctive pattern should persist sufficiently under the former substitutions and discriminate adequately under the latter. Both performance dimensions require numerical criteria declared in advance, not an after-the-fact impression that the plots remain recognisable.

The independent-source test should include nominally identical transmitters and a holdout population, not only different waveform families. The analyst should also look for a counterexample in which an unfamiliar source causes a similar ridge. A sufficiently flexible receiver or feature extractor can make unrelated events look alike under some projection. Conversely, ordinary

Copyright 2026, James M. Atkinson

thermal drift or antenna loading may make the same unit look different. These are not philosophical curiosities; they determine the false-attribution rate. A good result reports within-unit variability, between-unit confusion and the proportion of unfamiliar sources rejected at a fixed operating point.

Finally, rich representation must not be mistaken for independent corroboration. Two transforming algorithms operating on one file are useful for sensitivity analysis; they are not two receivers observing the field. A truly independent receiving chain, a physically changed antenna path or a newly recorded blind trial can challenge the assumed source origin of a feature. Even when a waveform is unique within the observed reference set, the universe of possible emitters may be larger. I would therefore accept a bounded conclusion: the trace discriminated the tested units under the specified conditions. I would not accept an unrestricted claim that no other physical transmitter could produce it unless an extraordinary and well-supported universality argument were available.

Dr. James M. Atkinson, Moderator: Sir Martin, the token passes to you for the second reciprocal examination, directed to Dr. Slepian.

Sir Martin Ryle, Cross-Peer Question to David Slepian: Dr. Slepian, suppose a spatial array yields an apparently precise bearing and the signal processor simultaneously produces a strong classification score for one enrolled transmitter. An investigator may treat these as independent strands of evidence and multiply their estimated likelihood contributions. But the bearing estimate and the classifier features came from the same I/Q samples, shared receiver clocks and the same multipath environment. What conditions would justify multiplying the values, and how should a report account for the covariance if those conditions are not met? Would physically

Copyright 2026, James M. Atkinson

separate antennas with a shared reference be sufficient, or must the experiment demonstrate independence of the relevant error mechanisms? I am also concerned that a directional result may identify a radiating aperture while the classifier attempts to name a baseband device connected to that aperture by a feedline. How can the statistical model avoid joining propositions about different physical objects and then presenting the result as if they describe one uniquely identified transmitter?

David Slepian, Cross-Peer Answer to Sir Martin Ryle: Sir Martin, multiplying likelihood contributions requires a defensible factorisation of their joint conditional distribution under the competing propositions. If E1 denotes the bearing evidence and E2 the classifier features, the simple product P(E1 given H) times P(E2 given H) is justified only when their conditional independence is established or is an adequately supported approximation under the model. The use of the same I/Q file, clock or propagation path makes such an assumption questionable. One may instead model P(E1,E2 given H) directly, or use a conditional factorisation P(E1 given H) times P(E2 given E1,H). The second form reminds us that correlations cannot be wished away by placing the findings in separate chapters of a report.

Calibration and geometry matter just as much as the algebra. A shared reference clock may induce correlated phase errors in the bearings and in frequency-derived fingerprint features. A reflected arrival path may shift the apparent direction while also changing the transient waveform. An environmental disturbance could therefore improve both apparent matches simultaneously under one wrong source hypothesis. The laboratory should create authorised reference trials that vary source position, antenna orientation, receiver architecture and reflection conditions, then measure

Copyright 2026, James M. Atkinson

the dependence of the two statistics. Those empirical observations inform whether separate contributions can reasonably be combined and how large their residual correlation may be.

We must also ensure the propositions describe the same object. A measured arriving field can be associated with a radiating antenna, while a proposed source fingerprint might be associated with a transmitter's oscillator or power amplifier. A remote feed or repeater separates those physical entities. A bearing that constrains the location of the antenna cannot automatically establish the identity of a processor at the other end of a cable. If the inferential chain requires a physical connection between them, evidence of that connection must be obtained independently and entered as a stated assumption or observed fact. Statistical multiplication cannot substitute for missing engineering evidence.

An expert presentation should therefore show the bearing estimate with its assumptions, the waveform-class or device-comparison evidence with its own validation, and a clearly labelled combined inference only if the joint model has been examined. If not, the report may state that the findings are mutually compatible without assigning an exaggerated combined probability. A qualitative statement of consistency is not the same as independent corroboration. Where an omitted alternative such as a second same-class transmitter or an unobserved reflected path changes the conclusion materially, that alternative belongs before the reader. Scientific care consists in identifying the limits of combination, not in using multiplication to produce a falsely impressive result.

Dr. James M. Atkinson, Moderator: Professor Blackwell, the third reciprocal question is yours, directed to Dr. Gabor.

Copyright 2026, James M. Atkinson

David Harold Blackwell, Cross-Peer Question to Dennis Gabor: Dr. Gabor, a defensively deployed classifier must sometimes decide whether to issue an immediate warning, defer a conclusion or retain more samples for later review. Its representation might include a compressed spectrogram that preserves prominent energy but omits weak transient phase details. If the operator then seeks individual-emitter attribution, the omitted information may become essential. How should the laboratory distinguish an efficient operational representation from one sufficient for a later evidential claim? What tests would you require before using a reduced representation to name a unit, and how would you treat a false sense of certainty produced by a model which was calibrated on uncompressed source recordings but evaluated after aggressive preprocessing? There is also a lawful-evidence problem: keeping everything indefinitely is not a general answer. Can the decision policy preserve only justified material while remaining candid about the questions that irreversible transformations will make impossible to answer later? Please connect these technical limitations to the decision to abstain.

Dennis Gabor, Cross-Peer Answer to David Harold Blackwell: Professor Blackwell, the required representation follows the proposed inference. A low-resolution occupancy display may suffice to answer whether energy above a validated threshold was observed in a band during specified intervals. It may not retain the timing, phase or transient information needed to discriminate physical transmitter units. The laboratory should therefore define an evidential question before declaring a derived representation sufficient. If its data reduction discards information relevant to that question, no degree of confidence from a downstream classifier can

Copyright 2026, James M. Atkinson

recreate the lost physical evidence. A model may still produce a label, but the label's evidential value must be validated for the reduced observation actually supplied.

I would test at least three recording paths in a controlled laboratory. The first preserves authorised original I/Q samples with a complete format and timing manifest. The second applies a documented reversible transformation, allowing exact recovery of the sample sequence. The third applies the proposed irreversible processing. The same blind transmitter trials are then analysed through all three paths at frozen classifier settings. The performance comparison must include class confusion, individual-unit error and unknown-source rejection across changed channels and receivers. It should show not only mean accuracy but which false identifications increase after reduction. If a feature is removed and the system nevertheless outputs a strong score, that score should be examined as a possible artefact of an inappropriate calibration model.

The operational and forensic roles may have different preservation requirements. A live alarm might reasonably use a transient summary and retain no communication content, while a narrowly authorised forensic investigation may require a protected sample excerpt and sufficient metadata to challenge a particular physical inference. Those choices demand legal authority, proportionality and retention controls, not merely technical enthusiasm. Where preservation is impossible or unjustified, the system can report the observation at the level still supported. The conclusion should never pretend that a lost phase record remains available for verification simply because its former spectrogram is visually persuasive.

Copyright 2026, James M. Atkinson

Abstention is then a rigorous action. The classifier can say that the observed reduced data support a broad waveform-family classification but do not retain sufficient information for individual-device comparison. It can also request a properly authorised future controlled capture if circumstances permit. That is preferable to forcing a serial-number label under an information deficit. The record should identify the transformation, its irreversible losses, the validation domain and the scope of inference. A responsible engineer describes what the apparatus observed and what it can no longer test. In that sense, careful information minimisation and careful evidential inference can coexist, provided neither is used to conceal the limitations created by the other.

Dr. James M. Atkinson, Moderator: Dr. Slepian, the final reciprocal examination is directed to Professor Blackwell and concerns open-set risk and the decision to stop short of attribution.

David Slepian, Cross-Peer Question to David Harold Blackwell: Professor Blackwell, imagine a classifier validated on a small catalogue of known transmitters, showing excellent ordinary accuracy but weak rejection of previously unseen same-class units. In a genuine investigation the source population is unknown, and the operator is tempted to select the highest-scoring enrolled device as an investigative shortcut. How should the decision rule respond when the cost of falsely naming a physical unit is large, and the prevalence of unknown devices cannot be estimated with confidence? Would raising the score threshold necessarily solve the problem, or might it simply trade one form of error for another without changing the incomplete hypothesis space? I ask also how a laboratory should separate the instrumental result from any subsequent statement

Copyright 2026, James M. Atkinson

about a human owner or operator. If the system can issue a narrow warning, an inconclusive device comparison or a strong validated source comparison, what predeclared evidence would justify each action? Please describe how the rule should be audited without using the questioned case as its own validation material.

David Harold Blackwell, Cross-Peer Answer to David Slepian: Dr. Slepian, a rational decision rule must operate over an explicitly defined action set, including the option to refrain from individual attribution. If the unknown-source population is inadequately represented, the laboratory cannot infer a reliable open-world false-attribution rate merely from success among enrolled units. Raising a threshold may reduce some false accepts at the cost of rejecting genuine known units, but it does not expand the model's universe of alternatives or repair a biased reference population. The resulting tradeoff must be measured with previously unseen physical sources, preferably including close same-class alternatives under varied receivers and channels. Without such tests, a very high score may remain a statement about relative similarity within an incomplete catalogue.

The consequences of an error determine how cautiously the system should act, but they do not change what the measurement has established. A low-cost operational alert can trigger another lawful measurement when the waveform is unusual. A class-level report can identify the closest validated signal family while flagging uncertainty. A claim that one individual unit transmitted requires a much stronger experimental basis: blinded same-class trials, held-out sessions, cross-receiver robustness, independent corroboration where available and a characterised unknown-source rejection policy. The expert should state which policy was used and the

Copyright 2026, James M. Atkinson

observed error rates under its tested conditions. It must not borrow error rates from an earlier, less demanding classification task.

The human inference is still a different proposition. Even reliable identification of a physical transmitting unit would not, by itself, establish who operated it, whether the operator knew its state, whether the emission was intentional or whether any rule of law was violated. Those issues require other evidence and appropriate legal assessment. The RF specialist's contribution is to explain the observed signal, the device-comparison evidence and the limitations of the source inference. The decision-maker evaluates any further association with people. A report should not smuggle in that association through phrases such as 'the suspect transmitted' when the apparatus merely detected energy consistent with one tested equipment class.

Finally, the evaluation must be independent of the disputed observation. The laboratory should freeze the classifier architecture, preprocessing, score threshold, unknown-source policy and acceptance criteria before analysing the final blind test set. If the case evidence prompts a redesign, the resulting method must be evaluated again on new material. Preserve the chain of custody of the authorised I/Q samples, the code revisions and the reference-data register so that a reviewer can determine exactly which claims the validation supports. A system which says 'inconclusive' where evidence is inadequate may be more useful and trustworthy than one which always offers a name. Prudence is not hostility to engineering progress; it is the decision-theoretic consequence of acknowledging the cost of an unsupported identification.

QUESTION 100

Copyright 2026, James M. Atkinson

When does a finite negative technical-surveillance survey provide useful assurance?

Dr. James M. Atkinson, Moderator: Sir Harold, a technical surveillance countermeasures survey may conclude without recording any emission that meets its detection and classification criteria. A client may be tempted to interpret this as proof that no relevant transmitter existed. Please distinguish the bounded assurance supplied by a negative observation from an assertion of universal absence. In particular, consider the instrument's validated sensitivity, antenna and polarisation coverage, duty cycle, receiver blind intervals, alternative methods of signal transport, and the requirement that an emitter be active and observable when surveyed. Address the statistical assumptions underlying any claimed probability of miss. When the evidence does not support an exclusion statement, explain what may nonetheless be reported responsibly.

Copyright 2026, James M. Atkinson

Sir Harold Jeffreys, Principal Contributor: Dr. Atkinson, the negative result is an observation about an experiment, not a certificate of universal non-existence. We first ask what the experiment was capable of observing. A receiver operates through an antenna pattern, filters, amplification stages, conversion and decision criteria which together define an envelope of frequency, time, amplitude and waveform behaviour. If a signal could not reach the antenna, lay outside the occupied band, occurred during an interval when no samples were acquired, or remained below the validated sensitivity under actual site conditions, its absence from the output is unsurprising. That fact cannot establish the absence of the source. The survey's value comes from the care with which the observable region was defined and challenged.

The inferential proposition requires exact wording. One hypothesis might state that a specified reference emitter, operating at a known minimum field strength and repeating a particular waveform within the monitored interval, was present in a given area. Another might state that this reference condition was not present. A calibrated search can provide evidence relevant to those competing propositions when its receiver coverage and detection probabilities have been tested. The statement 'there is no transmitter in this building' is incomparably broader, embracing unpowered, shielded, bursty, frequency-agile and entirely unknown mechanisms. That declaration would require assumptions so extensive that a finite receiver survey could not generally substantiate it.

We should not mistake a quoted noise floor for a universal detection limit. The ability to distinguish a known waveform at a particular receiver input depends upon its bandwidth, duration, threshold, interference environment

Copyright 2026, James M. Atkinson

and processing method. A continuous narrowband reference might be obvious where a millisecond burst at the same peak level is missed by a scanning receiver. A wideband pulse may distribute its power across a bandwidth larger than the selected resolution bandwidth. A signal arriving at an antenna null can be weaker at the receiver than one transmitted at a much lower power along a favourable path. The instrument therefore needs a documented measurement and challenge protocol, not only a catalogue sensitivity figure.

Timing deserves separate treatment because a negative search occurs over a finite observation schedule. The survey record should preserve precise start and stop times, tuner positions, residence times, retune gaps, equipment faults and validated sample continuity. If the receiver visits one frequency band for a brief dwell and then departs, an emitter activated only during the absence may not be observable. A detector cannot infer a missed event's presence from the appearance of silence in an empty file. Nor may the operator count a host-computer timestamp as evidence of uninterrupted ADC capture without hardware or counter support. The observability envelope must be reconstructed from actual acquisition records rather than the intended scheduling programme.

A numerical probability of miss requires an explicit event model. Suppose an authorised laboratory beacon is known to be active in ten independent test opportunities, and each opportunity offers a documented sixty per cent chance of detection under fixed conditions. Under the narrow assumption that the Bernoulli trials are independent and the detection probability remains constant, the probability of ten consecutive misses is four-tenths raised to the tenth power. That is approximately 0.000105. But this tidy

Copyright 2026, James M. Atkinson

figure does not apply if a common antenna defect, an equipment outage or a change in the source activation process affects every trial. A large number of repeated scans can offer little additional assurance when all inherit one unrecognised blind spot. Independence is a physical and operational claim to be justified, not a mathematical ornament.

A more realistic experiment introduces deliberately varied nuisance conditions. The laboratory should activate a reference source at known positions, frequencies, powers and scheduled times, while an independent monitor records its actual activity. The survey instrument is then operated using the same antennas, filters, gain states and processing schedule proposed for the site. Detection and non-detection are compared only for opportunities in which the test source is demonstrably active. Missing samples, receiver overload and alignment errors are recorded separately. The analyst should distinguish the probability of detecting this calibrated class of reference signals from an untested assumption that every possible clandestine emission behaves similarly.

The negative observation may support a valuable operational conclusion even when the universal absence claim is rejected. It may show that no emission meeting the stated criteria was detected during the specified measured opportunities, that the equipment demonstrated sensitivity to controlled reference signals at selected locations, and that specified bands or activation schedules remain unexamined. Such a conclusion can guide further authorised investigation and reduce uncertainty about particular risk scenarios. An honest report may also describe what alternative evidence would materially change the judgement, such as a longer observation

Copyright 2026, James M. Atkinson

period, a different antenna, independent wireline testing, or a controlled source-activation challenge.

A second difficulty concerns the prior plausibility of the hypothesis. A negative observation may be more informative where a hypothesised source would almost certainly have produced a measured signal if it existed and operated as described. It is weak evidence where the hypothesised source would rarely be active or observable. The analysis ought not silently assume that a suspicious apparatus must transmit continuously. Nor should the investigator use a favourable prior belief to excuse a missing sensitivity validation. If probabilities are offered, disclose the model, the relevant source population and how strongly the conclusion changes under alternative activation and propagation assumptions. Where those assumptions cannot be established, a conditional qualitative conclusion may be more defensible.

The evidence record and the language of the conclusion must correspond. Hashing a captured file helps to preserve the recorded bytes after a documented acquisition event; it does not prove that every receiver interval was observed, that the clock was correct or that the antenna was properly connected. A complete survey report should include configuration logs, calibration references, coverage tables, controlled source checks, defects discovered during operation and a record of unobserved intervals. The question is not whether a glossy graphical display looks free of peaks, but whether the examiner can identify the exact conditions under which an actual source would have produced a detectable result. The report should be clear enough for an independent engineer to challenge those

Copyright 2026, James M. Atkinson

assumptions without being required to accept the operator's confidence on trust.

I therefore advise a form of conclusion that retains the legitimate strength of a negative result while rejecting unsupported universality. The survey found no emission satisfying the declared criteria within the measured frequency, time, geometry and sensitivity envelope; documented reference tests show the system's performance under particular controlled conditions; and specified uncertainties and blind intervals remain. If a client asks whether this proves there is no hidden apparatus, the answer is no. It provides conditional assurance about those source behaviours the survey could reasonably have detected. The next expert should challenge the statistical independence of repeated negative observations and the temptation to treat an unobserved opportunity as a successful failure-to-detect trial.

Peter Elias, Peer Question: Sir Harold, I ask whether the information contained in a negative survey can be evaluated without first identifying the source hypothesis against which that silence is to be read. A surveillance receiver might watch an assigned band continuously, but the hypothesis may concern a source transmitting only in a different band, a source that awakens on an external trigger, or a source whose radiation is attenuated by conductive construction. The same absence of an alarm appears under all three circumstances, although the likelihood of that outcome differs considerably. Would you distinguish a failure to encounter an emitter from a failure to recognise a signal that actually arrived at the antenna? More particularly, how should an examiner describe a demonstration in which the receiver correctly recognises every authorised reference burst but the

Copyright 2026, James M. Atkinson

survey schedule overlaps only a fraction of the reference source's possible activity windows? I ask for a principled account of which denominator governs the claimed degree of assurance.

Sir Harold Jeffreys, Response: Dr. Elias, the first question is what the reported evidence conditions upon. Consider the proposition that a reference transmitter belonging to a defined signal family was active during a specified observation interval and coupled into the receive chain above a declared level. Given that proposition, one may estimate the conditional probability that an alarm would occur, taking account of the waveform, antenna, gain state and decision rule. But an assertion about an unknown source also involves the chance that it operated during the observation interval and the chance that its radiation reached the apparatus. Neither quantity is fixed by a successful laboratory threshold test. Their multiplication, or more generally the integration of conditional probabilities over a supported operating model, requires evidence about activation and propagation that a silent waterfall cannot supply.

I would have the report display distinct denominators. The first is elapsed wall-clock survey time; the second is verified acquisition time in the relevant frequency and configuration; the third is the set of known source-active reference opportunities; and the fourth, where justified, is the subset of those opportunities that genuinely met the predeclared signal-input conditions. These sets are related but not interchangeable. A twenty-minute recording can contain three minutes of eligible receiver dwell for a particular band. Of those three minutes, a known laboratory source may have been active during only eight brief windows. A detector that succeeds in all eight windows has demonstrated something useful about the controlled

Copyright 2026, James M. Atkinson

waveform, but not that all conceivable clandestine transmitters were present, active or within the response envelope during the seventeen unobserved minutes.

The distinction between encountering and recognising is likewise fundamental. Encounter probability describes whether the receiver and source were simultaneously in an observable state, including geometry, antenna polarisation and the chosen search schedule. Recognition probability describes whether a qualifying incident waveform generated the stated detection and classification outcome given encounter. If those conditions are reliably separable, a model may factor the two, but the factorisation itself must be tested. An antenna null may alter both the signal strength and the algorithm's recognition behaviour; a strong adjacent emission may impair both. The investigator should therefore report observations and calibration performance separately, retaining any model-dependent combined probability only as a conditional estimate.

A negative finding is informative when one can say what would probably have been seen under a credible, expressly bounded alternative. It is not informative about an arbitrarily defined source whose occurrence and observability have been left unspecified. Rather than burying the distinction in a paragraph of disclaimers, I would put eligible time and tested source conditions alongside each negative result. The absence of an observed qualifying waveform during a verified interval is a fact about the record. The broader statement that a particular source hypothesis is weakened by that fact is an inference, and its strength depends on the likelihood of the same record if the hypothesis were true. That second step must be made visible to the reader.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: I thank Sir Harold and Dr. Elias for defining the tested observation opportunity. I pass the token respectfully to Sir Ronald Fisher to examine the statistical limits of repeated negative results.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher, Second Principal Contributor: Dr. Atkinson, a series of negative observations becomes scientifically informative only when the experimenter states the particular alternative against which the observations are compared. In a technical surveillance countermeasures survey the broad proposition that no hidden apparatus exists is not an operationally testable statistical hypothesis. It includes devices that are switched off, perfectly shielded, operating outside the inspected frequency ranges, communicating over wireline systems, or transmitting at times beyond the observation period. Such devices produce no requirement for a radio receiver to respond. What can be tested is the conditional proposition that a specified class of active source would have produced a qualifying observation under particular receiver, antenna, environmental and decision conditions. That is a modest proposition, but it permits disciplined experimental design rather than rhetorical assurances.

An elementary detection experiment begins with three separately recorded facts: the laboratory source was active according to an independent monitor, the survey receiver was observant and functioning, and its declared rule did or did not register the relevant emission. The phrase independent monitor matters. If the device that declares the test signal active is itself the receiver under examination, then a silent receiver may conceal a failure of both measurement and ground-truth accounting. Independently timed reference emission records and a challenge protocol capable of exposing antenna or gain-chain defects allow detection probabilities to be estimated within the test matrix. The matrix needs actual variation in frequency, power, waveform duration, geometry, polarisation, interference conditions and instrument state. A detection proportion

Copyright 2026, James M. Atkinson

measured in one favourable geometry should not be silently assigned to all geometries in a building.

Suppose there are forty independently verified source-active opportunities of equal specified difficulty, and the system registers thirty-four of them. The observed detection fraction is thirty-four divided by forty, or 0.85. This is an estimate, not a timeless physical constant. Even if the opportunities were independent and identically distributed, finite-sample uncertainty remains, and a quoted 85 per cent without the denominator communicates a false impression of exactness. If the source changes its duty cycle or the survey has a common antenna null, the trials may not be identically distributed. Statistical intervals must be tied to an explicit model, and engineering challenge tests must determine whether that model is pertinent to the actual setting. The scientific meaning of a rate cannot be rescued by attaching more decimal places.

A genuine negative site survey often contains many technically different opportunities. One sweep may cover a short duration at an excellent signal-to-noise ratio. Another may occur at lower sensitivity because the antenna was moved behind conducting structural elements. A third may be interrupted by spectrum analyser retuning, and a fourth may run while a strong nearby transmitter drives the front end into compression. Summing these into an impressive total of 'ten thousand searches' conceals unequal detection probabilities. If probabilities are warranted, each opportunity belongs to a specific operating stratum, and the experimenter must provide sufficient evidence to justify the model of dependence among those strata. A grouping by frequency band, waveform class, room geometry and observing instrument may be more candid than one grand aggregate.

Copyright 2026, James M. Atkinson

False alarms must enter the design alongside missed detections. If an extremely low threshold registers countless spurious spectral features, the analyst can increase apparent sensitivity but may be unable to demonstrate that an alarm has any useful discriminatory meaning. Conversely, a threshold raised to avoid awkward alarms can make the negative conclusion appear reassuring at the expense of missed emissions. The threshold and classification rules should be documented before confirmatory testing and should be challenged using signal-absent and signal-present controls. Exploratory changes can legitimately help develop the method, but the resulting calibration dataset is no longer independent evidence of that method's claimed operating characteristics. Where the survey uses human classification, inter-operator consistency and a record of exclusions are as important as the automated threshold.

One should distinguish a confidence statement about an instrument from a posterior probability about a hidden transmitter. A confidence interval for the probability of detecting a laboratory reference source, conditional on its specified activity and propagation, does not yield the probability that no malicious device exists in the building. That latter probability would require defensible information about the prior occurrence of such devices, their plausible classes, their activation processes and the probability that each would be captured by the survey. An investigator ought not import those quantities from intuition and then dress the outcome in mathematical form. The absence of a detected source is a contribution to a larger evidential assessment, not a licence to calculate certainty from silence.

My preferred final statement would include an explicit inclusion-and-exclusion table. For each tested signal family, the report would state its

Copyright 2026, James M. Atkinson

tested field-strength range or receiver-input range, observation schedule, successful reference tests, failure modes, and the precise negative detection result. The untested possibilities should be visible rather than concealed in general caveats. If only continuous carriers between stated frequencies were robustly challenged, the conclusion must not migrate to infrequent encrypted bursts at unexamined frequencies or to wired communications. If a source was demonstrably active in a challenge and was nonetheless missed, that failure should be prominently disclosed, with a defensible explanation of its scope. Assurance increases not by suppressing embarrassing tests but by showing the limits of the measurement honestly.

I would further require the raw observation record to be separable from the report writer's conclusions. Instrument configurations, sample counters, reference logs and alarm criteria should have sufficient provenance that an independent specialist can test an alternative interpretation. A visually quiet waterfall is not raw evidence of the completeness of observation. The observer may have suppressed low-level detections, omitted intervals, changed colour scales or discarded data during an alarm-triggered recording process. Technical integrity and statistical transparency reinforce one another. A rigorously bounded negative finding is valuable to a client precisely because it identifies what risks were reduced and what further action could most efficiently reduce the remaining uncertainty. I pass the token to the sequential decision perspective, where an operator is tempted to stop searching as soon as the screen looks quiet.

Egon Sharpe Pearson, Peer Question: Sir Ronald, your laboratory reports thirty-four detections from forty known source-active opportunities. It may be tempting to use the resulting fraction as if it provided ninety-five per cent

Copyright 2026, James M. Atkinson

assurance that a silent building is free of a clandestine transmitter. Would you set out why a confidence interval for that laboratory detection fraction cannot carry such an interpretation? Suppose the survey's opportunities differ in duration, antenna orientation and interference, while the forty reference tests were performed at one favourable receiver-input level. How should the statistical treatment reflect the resulting mismatch? I am particularly concerned that the investigator might choose a receiver threshold retrospectively, remove inconvenient failed challenge trials and then advertise the adjusted rate as a confirmatory estimate. Which records and prospective rules would you regard as indispensable before even a conditional statement of detector performance can be defended? In framing your reply, please identify whether the relevant denominator counts independent physical source activations, independent receiver states, or merely successive software decisions upon one recorded capture.

Sir Ronald Aylmer Fisher, Response: Mr. Pearson, there are several errors to separate. A proportion of detections among known active reference opportunities estimates performance under the reference experiment's stated conditions. It does not estimate the probability that no unknown emitter exists in the examined premises. The latter is a proposition about a population of possible source states and their relation to the observed data. It requires assumptions about prevalence, activation, coupling and measurement opportunity that cannot be conjured from the numerator and denominator of a single calibration trial. Calling a confidence interval an assurance percentage about the premises changes the estimand without changing the evidence. No amount of numerical precision can make that substitution legitimate.

Copyright 2026, James M. Atkinson

The forty reference trials also require scrutiny before they can support even the narrow estimate. Were the opportunities prospectively defined, independently recorded as source-active, and sampled across the configurations for which performance will be asserted? Did the experiment retain failures and operator overrides as well as successful detections? If the threshold was adjusted after inspecting the same outcomes, an apparently favourable detection fraction is a fitted property of that exploratory dataset, not an unbiased independent test of the chosen threshold. The proper response is not to forbid exploratory engineering. It is to label such tuning accurately, freeze the procedure, and evaluate it against genuinely withheld or subsequently collected reference opportunities at relevant conditions.

Heterogeneous source conditions deserve an equally explicit treatment. A detection probability calibrated at one strong input level does not transfer automatically to a receiver operating near its sensitivity limit behind screened walls. The laboratory might stratify the reference opportunities by signal family, level, dwell, antenna polarisation and interference, then describe observed successes and failures in each group. Where the data permit, a response model can estimate how the probability changes with those variables, accompanied by uncertainty and a warning against extrapolation beyond tested conditions. Where it does not permit a reliable model, the honest outcome is a narrower report, not a single pooled rate presented as universally applicable.

I would preserve the original challenge schedule, the independent source monitor's records, the threshold and classification software configuration, each trial's inclusion criteria, and all resulting outputs. Failures are part of the dataset even if they complicate a later report. The analyst should also

Copyright 2026, James M. Atkinson

distinguish the number of trials from the number of independent experimental units. Forty adjacent software evaluations of the same captured burst are not forty independent tests of receiver performance. If the whole experiment inherited one defective antenna connection, repeated success or failure shares a common physical cause. Finally, any confidence interval should be named for the parameter it actually concerns and the model under which its coverage is calculated. It should never be repurposed as a probability that a threat is absent.

John Wilder Tukey, Peer Question: Sir Ronald, I wish to challenge the presentation of a single elegant probability where the data are a ragged collection of sweeps, dropouts and conditions that an operator only partly recorded. Suppose an instrument logs twenty thousand nominal spectrum intervals, but most share the same preselector, clock and antenna, while several hundred occur during gain compression and another group has lost acquisition counters. A conventional summary might say 'no detections in twenty thousand observations'. I suspect that phrase hides the very facts that should govern professional judgement. How would you design a diagnostic table or exploratory presentation which exposes the uneven measurement opportunities before the analyst selects a formal model? In particular, where does the analyst place absent data, failed self-tests, benign environmental events and trials for which the reference source did not actually operate? I also ask whether the plots should distinguish the optical appearance of silence from an authenticated record of instrument readiness and continuous sampled observation.

Sir Ronald Aylmer Fisher, Response: Mr. Tukey, one should distinguish the act of making a nominal sweep from the act of creating a valid opportunity

Copyright 2026, James M. Atkinson

to detect the specified source. An instrument log that declares twenty thousand visits tells us what the scheduling programme intended or recorded. It does not alone establish that an incident waveform would have been captured and recognised during each visit. I would begin by organising the observations into a ledger whose columns include actual measured dwell, frequency coverage, antenna and preselector state, interference level, validated gain state, acquisition continuity, threshold version and source-activity status where a controlled reference was used. This is not administrative decoration. It supplies the denominators for any subsequent numerical inference.

An interval in which the receiver was not collecting samples belongs in a category labelled not observed, not in the category observed with no qualifying signal. A trial with an overload flag must be retained with its quality qualification, not silently erased. A source-off reference interval can provide information about the false-alarm behaviour of the classification rule; it cannot be counted as a failure to detect an active source. An environmental event which triggers an alarm may help characterise specificity or the burden of investigation, but it is not automatically a false alarm until an independent check establishes what generated the feature. In each case the first objective is correct classification of the experiment's own evidence, before one infers anything about a concealed transmitter.

The visual presentation should show coverage and discontinuities directly. A time-frequency occupancy diagram can mark actual dwell separately from the blocks without samples. A distribution of noise-floor measurements across antenna positions may reveal a narrow range of conditions where the detection threshold became ineffective. An instrument-state timeline can

Copyright 2026, James M. Atkinson

display preselector changes and overload flags alongside the negative observations. Such plots can be exploratory and should be labelled as such. They help expose patterns that a single pooled rate would conceal. They also guide prospectively specified challenge tests designed to separate alternative explanations for those patterns, rather than treating the exploratory display as a completed confirmatory test.

I would resist the temptation to transform every anomaly into a missing data point with an invented value. Missing intervals are often informative about the apparatus, for example if buffering fails only when a strong burst arrives. Under that circumstance the absence of samples may itself be related to the event one hoped to detect, invalidating a naive missing-at-random treatment. One can perform sensitivity analyses under competing dropout mechanisms, but the report must distinguish observed data from assumptions. The practical conclusion is a set of transparent strata: fully eligible negative observations, qualifying positive observations, source-off controls, source-active reference misses, technically compromised intervals and intervals never observed. Only then is the experiment ready for defensible statistical modelling.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Sir Harold Jeffreys: Sir Harold, let me ask whether the weight of a negative survey can ever be expressed in probabilistic language when the source activation distribution is unknown. A client might demand one reassuring number. A statistician might provide a calculation for ten genuinely independent known-active opportunities and then attach a disclaimer. Yet a later reader may remember the number and forget the assumptions. What would you regard as a scientifically legitimate alternative to an invented global confidence

Copyright 2026, James M. Atkinson

level? Would you present likelihoods for several sharply defined source hypotheses, or reserve numerical results for laboratory reference conditions alone? I ask also about the hazard of prior assumptions: a source that was inactive throughout the survey is observationally indistinguishable from one that did not exist. Does stating that distinction force us into complete agnosticism, or can a report still provide a graded evaluation of what the negative evidence excludes under explicitly varied plausible operational models? Please make the distinction between a decision-useful report and an absolute assertion exceptionally clear.

Sir Harold Jeffreys, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Sir Ronald, a global confidence number is not a natural property of the absence of a detector alarm. It is the result of an inferential construction that requires a specified event model, a relation between that event and the measured signal, and a decision or probability framework. A conditional likelihood can be useful when a proposed emitter's behaviour is sufficiently described. For a particular source class, we might ask how frequently the validated receiver would have detected an eligible emission, given known activity and measured coupling. If that probability is supported by controlled experiments, repeated negative observations may be evaluated under stated dependence assumptions. But the result remains conditional; it cannot be detached from the physical conditions and applied to an undefined population of concealed apparatus.

I would provide a table of hypotheses and detection opportunities rather than a single headline probability. One row might concern a continuous narrowband emission at or above a measured input threshold during eligible dwell. Another could concern a reference burst with a specified

Copyright 2026, James M. Atkinson

activation probability and duration. A third could concern a source whose activation schedule is unknown, in which case numerical inference about global absence may be unavailable. Each row should identify the source model, the independent reference evidence, the receiver coverage, the observed negative result and the major untested assumptions. Such a table lets the client see both the strength and the reach of the assurance without treating one conditional calculation as an official certificate that no device exists.

An inactive source and a nonexistent source may indeed produce observationally equivalent records for a receiver-only survey. That observation does not mean the investigation is useless. It means that the receiver evidence cannot distinguish those hypotheses without a further observation or assumption. Additional authorised physical examination, network or wireline analysis, longer observation across relevant activation contexts, or a carefully controlled stimulus-response experiment may discriminate scenarios that an RF-only survey could not. A scientific report should say what the current test resolved and what test would be needed to resolve the remaining distinction. Where further tests are impossible, the residual uncertainty should not be hidden behind a vague claim of thoroughness.

A graded conclusion can therefore be legitimate. It might state that the survey reduces support for some active-emitter scenarios because those scenarios would probably have produced detections under validated conditions, while leaving inactive, unobservable or differently communicating sources largely untested. The grading should be qualitative if the inputs do not justify a numerical expression. In all cases the

Copyright 2026, James M. Atkinson

independent observer must be able to reconstruct which conditions were actually met. The report becomes useful through its transparency about both successful challenges and remaining blind spots. It fails when its prose encourages a reader to convert conditional evidence into universal absence.

Dr. James M. Atkinson, Moderator: Sir Ronald has distinguished a validated reference detection rate from an assurance claim about the building. I now invite Mr. Abraham Wald to consider stopping rules, timing and operational decisions.

Copyright 2026, James M. Atkinson

Abraham Wald, Third Principal Contributor: Dr. Atkinson, the survey is a sequence of decisions under time, money and observational constraints. The investigator chooses when to inspect a band, when to move an antenna, when to repeat a challenge, when to alter the instrument and when to end the survey. Those choices depend upon information already observed. Consequently, the inferential significance of a run of negative readings cannot be judged merely by counting the readings after the fact. A test whose stopping rule was chosen because the latest scans looked reassuring is not equivalent to an experiment with a prospectively specified observation horizon. The distinction matters even if both experiments ultimately contain the same number of saved screenshots.

An operational policy may define minimum observation periods for specified signal classes, mandatory independent checks, and explicit conditions that extend the search when contradictory evidence arises. Such a policy does not eliminate professional discretion. It records which decisions were made because the survey found something, and which were predetermined by a controlled plan. If a team starts with a nominal two-hour survey and stops after a quiet quarter of an hour, the client should not receive a report based upon two hours of advertised coverage. If the team extends an observation because a transient was suspected, that adaptive extension is appropriate, but its resulting data are part of a conditional exploratory path. One must not later pretend the team selected that interval without seeing the transient.

A sequential probability ratio test is sometimes invoked as if it offered a universal mathematical permission to stop. It does not. Such a method presupposes a clearly specified observation model under competing

Copyright 2026, James M. Atkinson

hypotheses and a likelihood construction whose dependence assumptions are justified. A TSCM survey confronting an unknown intermittently active source seldom satisfies that model without extensive restrictions. There may be no known distribution for a signal's activation schedule, antenna coupling, modulation family or sensitivity to a change in the environment. The investigator may still employ sequential reasoning for a laboratory reference source under controlled conditions. That is very different from writing a likelihood ratio for an unidentified adversarial emitter and declaring an entire premises free of surveillance.

The decision problem should be separated into technical detection, survey termination and risk management. Technical detection asks whether an event met a predetermined rule. Termination asks whether the planned observation and challenge requirements were met, or whether a defined exception requires additional work. Risk management asks whether the residual uncertainty is acceptable for the client's purpose, lawful authority and exposure. An institution can accept residual risk without declaring the hypothesis of a hidden transmitter scientifically impossible. Indeed the professional report is stronger when it states that the decision to finish was governed by a finite agreed plan and not by a logically conclusive proof of absence.

Consider a hypothetical frequency-hopping beacon that transmits for 20 milliseconds once every five seconds, with its activation phase random relative to scanning. A scanner which revisits a narrow subband only briefly may offer poor temporal overlap despite completing hundreds of sweeps. If the fraction of time in which the instrument is actually capable of observing a given relevant waveform is only 0.10, one cannot assume that a hundred

Copyright 2026, James M. Atkinson

successive plotted sweeps constitute a hundred independent 90-per-cent-sensitive trials. Depending on timing regularity, the scanner may repeatedly miss the same phase of a periodic beacon. A controlled timing-randomisation exercise could help break such phase locking, while an independent logger would be needed to test whether the source actually transmitted during the available windows. These are testable engineering interventions, not assurances derived from simple multiplication.

Common-cause failures are especially dangerous for sequential decisions. If the preamplifier fails, an antenna connector loosens, or the receiver front-end is desensitised by a strong local carrier, many consecutive quiet observations can share one failure. Ten thousand repeated readings do not create ten thousand independent opportunities when the same defect governs them. The survey should include reference-signal injections at appropriately documented points in the signal chain, before and after important state changes, to detect failures that no amount of waiting will reveal. An injected signal at the receiver input checks a different set of components from an authorised radiated challenge through the survey antenna. Both can be useful; neither is a complete substitute for the other.

Survey duration should also be described in observable rather than calendar terms. The notation 'the receiver operated for eight hours' may refer only to the host computer's wall-clock interval. To estimate actual opportunity, one needs the time-resolved receiver frequency, effective bandwidth, antenna state, validity of samples, classification thresholds, and missing-data mask. Some observations may be duplicated or averaged from the same underlying samples. Some may arise from a receiver that was active but tuned elsewhere. Where a long-term monitor scans multiple bands, the

Copyright 2026, James M. Atkinson

relevant denominator is not total elapsed time but eligible observation time for the particular source model. This denominator is the bridge between operational logs and defensible statistical conclusions.

I would propose an advance statement of the client's question and a termination register. The register records the surveillance scenarios to be tested, legal constraints, minimum coverage requirements, instrument-health challenges, allowable adaptations and conditions requiring escalation. A negative conclusion can then say that the planned tests were completed without a qualifying finding, while identifying what remained untested. Where an unresolved anomaly occurs, the team should not erase it simply because the general search was negative. It should be described as unresolved and either followed up or expressly excluded from the negative conclusion. The record should also distinguish 'not observed' from 'examined and excluded', because those phrases can have radically different evidential foundations.

The cost of continuing can be compared with the likely improvement in assurance, but this comparison must remain transparent. A client may rationally choose to close a survey after a specified set of tests because further work has diminishing practical value. The conclusion is a decision under uncertainty, and its legitimacy rests on the reasonableness of the plan and the honesty of the account. It is not a scientific declaration that every logically possible surveillance channel was eliminated. I pass the token to Sir David Cox to examine heterogeneity, dependence and the tempting illusion that a multiplicity of plots supplies independent evidence.

Claude Elwood Shannon, Peer Question: Mr. Wald, an intermittently transmitting source creates a particularly difficult stopping problem. Each

Copyright 2026, James M. Atkinson

new observation might be informative about a narrow source model, yet the investigator can always extend the search. I ask how to quantify the information contributed by an additional hour when its spectral coverage overlaps earlier hours but the source's activation process is unknown. Suppose an analyst stops after observing no alarms in the first twenty minutes, despite a stated plan to inspect the area for two hours and to challenge the receiver before and after the search. Could the stopping decision itself distort the apparent strength of the negative evidence? How would you describe the difference between a prespecified stopping rule, an adaptive safety or fault response, and an opportunistic termination made because an uneventful display looked reassuring? Please identify which of these can be represented honestly in the custody record.

Abraham Wald, Response: Dr. Shannon, the marginal information supplied by an additional hour depends upon the hypothesised source behaviour and on the actual observation opportunity offered by the receiver during that hour. If a source is known to transmit once per minute when active and the receiver continuously observes the relevant band with documented sensitivity, additional eligible minutes can materially challenge the source hypothesis. If the source transmits only upon a rare unknown trigger, or if the receiver never visits the relevant band, another nominal hour may add little. One cannot assign a universal information value to elapsed time. It is the conditional distribution of observable events and the verified measurement opportunity that determine the strength of the evidence.

The stopping rule is part of the experimental design. If the survey plan specifies two hours of observation and a final reference challenge, terminating after twenty quiet minutes fails to complete the stated

Copyright 2026, James M. Atkinson

experiment. One should report the twenty minutes actually observed, the omitted challenge, and the reason for termination. Recasting the incomplete survey as though it satisfied the original protocol would be an evidential error independent of any statistical calculation. If the team deliberately designed a sequential test for a tightly specified laboratory source with known detection behaviour, it might stop after crossing a predeclared evidence boundary. But the validity of the boundary depends on the observation model, the chosen error constraints and the actual implementation of the procedure.

An adaptive safety response is different. A dangerous electrical condition, a receiver fault or an unexpected overload may justify stopping immediately. The decision is operationally correct, yet the affected observation intervals become invalid or unobserved for the original search question. A team may also extend the survey in response to an anomalous feature, but must state that the extension was exploratory and distinguish subsequent independent confirmation from tests tailored to the observed anomaly. None of these choices is inherently improper. The error lies in hiding the choices and then presenting a nominally fixed sample size or a false appearance of independent observation.

The custody record should preserve the initial plan, exact observation start and end times, equipment-state changes, the occurrence of anomalous signals, and the decisions made as those observations arrived. A decision log can record who authorised an extension or termination and why. One may later conduct a sensitivity analysis showing how alternative stopping assumptions would affect a statistical statement, but that analysis is a derivative. It does not rewrite the acquisition history. The most useful

Copyright 2026, James M. Atkinson

recommendation is to separate minimum validated survey coverage from discretionary additional work, and to predefine the challenge tests required for a negative conclusion. Where those conditions were not satisfied, the report should describe a limited negative observation, not a completed assurance protocol.

Donald Watts Davies, Peer Question: Mr. Wald, consider a survey receiver which sends data over a computer interface to a storage process that can pause or fail without stopping the RF front end. An operator sees a quiet waterfall and may infer that the instrument continuously watched a band. Yet a delayed host display, a full ring buffer or an interrupted file writer can leave long holes in the preserved samples. How should the investigation separate actual observation time from the appearance of uptime? In a multiple-receiver arrangement, would the agreement of two host logs be enough if both receivers use the same timing distribution, software stack or network path? I ask for a rule that prevents silent interpolation from converting lost acquisitions into negative detections and that records outages without pretending to know whether an emission occurred during them. In answering, please distinguish an unverified host display from an independently established capture clock, so that a missing acquisition is not silently written as a negative finding.

Abraham Wald, Response: Mr. Davies, the first rule is to distinguish source-time acquisition from host-time delivery. A software timestamp stating that a computer drew a waterfall tile establishes that the display operation occurred, not necessarily that the ADC furnished a continuous underlying interval. The record should preserve device-side sample counters, frame identifiers, overflow indicators and reference-clock state where those

Copyright 2026, James M. Atkinson

observables exist. A gap in an acquisition counter has a different significance from a delayed application callback. If the instrument cannot expose a reliable acquisition continuity indicator, the claimed coverage must be weakened accordingly. One cannot restore an absent measurement by adding a plausible line between two plots.

A receiver might keep sampling into a buffer while the host pauses, in which case the recovered data could be complete. Alternatively the buffer might overflow and omit samples although the output file remains continuous in byte length. Controlled fault injection is needed to determine which behaviour applies to the actual hardware and software configuration. The laboratory can produce a known reference event while deliberately burdening the storage path, then compare an independent monitor's event timeline with saved sample counters and logs. This test should cover the relevant modes of failure rather than relying solely on a successful demonstration under ideal conditions. Its results would define which indicators justify counting an interval as observed.

Agreement between instruments may provide valuable corroboration, but it does not guarantee independence if the same reference source, timing network, firmware revision or data collector governs both. The common dependence should be mapped. A disciplined clock can itself distribute the same error to multiple receivers; a shared acquisition process can lose the same interval for both; and a reused display algorithm can omit identical portions of the evidence. Separate antennas or oscillators may reduce some dependencies but leave others intact. I would therefore use a fault-tree or dependency matrix in addition to numerical comparisons, identifying each

Copyright 2026, James M. Atkinson

component whose failure could make apparently distinct observations agree for the wrong reason.

The final timeline should contain at least three states: verified eligible acquisition, verified interruption or loss, and uncertain acquisition continuity. A fourth state records actual detector alarms within eligible intervals. No recorded alarm in an eligible interval is a negative observation under the stated rule; no sample during a verified interruption is not. If the timing of an outage is uncertain, the uncertainty interval should be shown instead of forced into an exact endpoint. The report need not claim that an emission occurred during a gap. It should simply refuse to treat that gap as evidence of absence. This discipline preserves the distinction between what the receiver measured and what the analyst later inferred from a partial record.

Abraham Wald, Cross-Peer Question to Sir Ronald Aylmer Fisher: Sir Ronald, I wish to challenge the independence assumption from the operational perspective. A field team may perform many surveys at the same premises, perhaps on successive days, and regard their repeated negative findings as a rapidly multiplying body of independent evidence. Yet each visit may use the same antenna arrangement, the same receiver calibration, the same classification software and similar hours of the day. One hidden source which transmits only when a particular trigger occurs may never be active during any visit. How should an analyst represent repeated negative results when the chance of encountering the hypothesised source is uncertain and likely correlated across visits? I also ask whether a successful calibration challenge on each day establishes that the source-activation mechanism was adequately tested, or merely that the apparatus worked for the known

Copyright 2026, James M. Atkinson

reference signal. How might a predeclared variation in survey times and source conditions improve the experiment without permitting the investigator to assume that the variation has covered every conceivable activity mechanism?

Sir Ronald Aylmer Fisher, Cross-Peer Answer to Abraham Wald: Mr. Wald, repeated visits can enlarge the physical opportunity to observe a source, but only if the visits alter the relevant opportunity distribution in a useful way. They do not become independent merely by occupying different dates in a calendar. If a source activates only when the premises are empty or in response to a particular event, repeating the same midday search on occupied days may revisit the same blind condition. Independence of outcomes is a statistical statement about their joint behaviour under a specified hypothesis, not an administrative statement that the observations were recorded on different forms. Correlated source activity, shared instrument faults, fixed antenna geometry and reused classification thresholds can all generate substantial dependence.

A useful record should preserve the reason for each revisitation and the physical conditions that distinguish it from earlier observations. Were antennas moved? Did the receiver observe different bands or duty cycles? Were the instruments challenged at low input levels and less favourable polarisation? Was the calibration repeated after a change of temperature or gain state? Did a second independent monitor confirm the authorised reference signal's activity? These facts matter because they reveal which plausible failure modes each test could expose. Merely repeating an identical demonstration under identical favourable conditions may increase

Copyright 2026, James M. Atkinson

confidence that the equipment can reproduce that demonstration, but it need not enlarge the class of covert source behaviours examined.

Daily calibration success is not evidence that an unknown emitter activated. It establishes performance against the known stimulus under that day's specified laboratory or site condition. One may use that result to challenge claims about instrument malfunction; one cannot transfer it into a claim that all unknown transmitters should have been heard. A prospective design might deliberately vary observation hours, antenna positions and frequency coverage according to a stated sampling scheme, while maintaining controls that permit performance comparisons. Such design reduces the danger that the investigator has unconsciously selected only convenient observations. It also makes it possible to explain which operational patterns have been sampled and which remain conjectural.

If an encounter model is supported, an analyst may calculate a conditional probability of an entirely negative record and compare that probability under alternative hypotheses. If it is not supported, sensitivity analysis is preferable to an invented probability. One may show how a conclusion would change under different plausible activation frequencies or missed-event mechanisms, while making clear that those assumptions were not measured. The essential discipline is to treat repeated silent records as evidence about repeated measured opportunities, not about all times and all possible source states. The strongest conclusion is one that survives explicit challenges to the relevant dependencies; the weakest is one that multiplies reassuring decimals whose common physical causes were never investigated.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: I thank Mr. Wald for retaining the actual acquisition history. Sir David Cox, I pass the token to you for examination of heterogeneous opportunities and common-mode instrument failures.

Copyright 2026, James M. Atkinson

Sir David Cox, Fourth Principal Contributor: Dr. Atkinson, before calculating the strength of a negative finding, we must identify the unit of observation. An RF analysis programme may return thousands of FFT bins and overlapping spectrogram frames from one continuous capture. It is a serious error to regard each bin, frame or coloured pixel as an independent attempt to detect an emitter. Adjacent bins may share energy through a window's spectral leakage, and adjacent frames often reuse most of their underlying samples. A single receiver overload can affect every one of those comparisons at once. The survey can generate an enormous numerical table while furnishing only a small number of substantially independent opportunities to challenge the relevant hypothesis.

A statistical design ought to describe the hierarchy of dependence. Individual spectral cells occur within frames; frames occur within captures; captures occur within receiver settings and sites; sites may be affected by common interference and propagation mechanisms. The conditional outcome at the lowest level depends on the state of the enclosing levels. Aggregating detections without respecting that hierarchy gives narrow uncertainty estimates which an independent reproduction may fail to support. If twenty receivers share the same timing reference and antenna distribution amplifier, it is not sufficient to multiply a nominal per-receiver miss probability twenty times. A common reference failure or common filtering limitation may make their outcomes strongly correlated. Physical independence of measurement chains should be demonstrated or clearly qualified.

The status of a source can itself change. An intermittent device may activate only during a conversation, a change in occupancy, a power transition or a

Copyright 2026, James M. Atkinson

particular external stimulus. A negative survey carried out at an unrepresentative time can be entirely consistent with such a mechanism's presence. The challenge is not to posit every imaginable trigger, which is an impossible exercise, but to define a rational set of activation hypotheses responsive to the authorised protective objective. A survey might compare occupied and vacant periods, perform lawful controlled activation tests, or use sustained monitoring with known observation limits. The report should identify which of those conditions were actually examined. Absent a justified activation model, the statistical significance of a prolonged quiet period may be extremely weak.

One must also model missed opportunities. Suppose a receiver logs 6,000 seconds of wall-clock time, but its configuration records show that the relevant band was monitored for 1,800 seconds. A subsequent audit establishes 120 seconds of sample loss during those selected dwell periods. The eligible interval is then 1,680 seconds under that particular source and configuration definition, not 6,000. The calculation 1,800 minus 120 is simple; the scientific work lies in proving that the dwell records and loss indicators correspond to actual acquisition. If the system records only alarm-triggered samples, silent intervals may be absent without a verifiable indication of whether the receiver was genuinely looking. A defensible denominator cannot be reconstructed by wishing that a log file were more complete than it is.

Sensitivity is likewise a function rather than a single scalar. A probability of detection may depend on signal power, duration, carrier frequency, modulation, polarisation, arrival direction, interference, threshold and the judgement of the operator. A logistic model or another fitted response

Copyright 2026, James M. Atkinson

surface can be useful for controlled references if there are enough observations to assess its adequacy. But fitted curves outside the tested region do not establish performance against a source class whose behaviour is unknown. The limits of extrapolation should be shown explicitly. The practical output may be a family of detection-performance contours for validated reference waveforms rather than one boastful percentage applied across the entire electromagnetic environment.

I would also require negative controls that identify receiver-generated masking and artefacts. A disconnected antenna, a known termination and an independent reference receiver can help determine whether a displayed feature originates in the environment or in the equipment, but each control has a scope. A quiet terminated input cannot validate the antenna's exposure to a real source. A successful internal test tone does not validate the antenna's polarisation coverage. A second receiver built upon the same software library may reproduce a software defect. The independence of the controls is itself a matter for engineering demonstration. The investigator should state which failure modes each control can reveal and which it cannot.

The communication of results should be separated into observations, performance tests and conditional interpretation. First, give the actual findings in the measured time-frequency region, preserving non-detections and anomalies with their status. Secondly, provide the laboratory validation results, their uncertainties and the tested configurations. Thirdly, explain the consequences for the surveillance scenarios that the client authorised the team to examine. Do not conflate the estimated ability to detect a controlled reference with the probability that no threat exists. Where an inference

Copyright 2026, James M. Atkinson

depends on an activation rate or a model of geometry, present a sensitivity analysis showing how it changes under credible alternatives. A properly qualified negative result should become less categorical as those assumptions become less secure.

The final report may still be useful. It can establish that specified signals above a tested detection boundary were not observed in a documented surveillance interval. It can demonstrate that a particular measurement arrangement worked when challenged, and that known blind spots were mapped. It may support a subsequent decision to improve shielding, expand observation or investigate cable routes. This is a contribution to assurance, but it does not amount to omniscience. I would judge the professionalism of the conclusion not by the confidence of its adjectives but by whether another investigator could test the exact limits of the claim. I pass the token to Sir Karl Popper to ask what a negative search genuinely falsifies and whether repeated silence may turn an untestable assertion into a scientific conclusion.

John von Neumann, Peer Question: Sir David, you distinguish the tested observation envelope from the conditions that remain unknown. Let us consider a practical computation over that envelope. Two receivers each complete one hundred scheduled scans, but they share an antenna splitter, an external preselector control and a laptop which records the detections. It would be easy to claim two hundred independent opportunities. What evidence would be needed to justify such a count, and how would you approach the task if the common subsystems could suppress both instruments at once? I would further ask whether a null observation should be recorded as a binary zero, as a missing value, or as an explicitly qualified

Copyright 2026, James M. Atkinson

observation state when gain compression, source inactivity and undocumented switching each remain possible. Finally, could you explain how the engineer should document one conservative bound without suggesting that it applies to every possible form of hidden surveillance apparatus?

Sir David Cox, Response: Professor von Neumann, counting two hundred scans is legitimate as a description of scheduling only if the term scan is defined accordingly. Counting two hundred independent detection opportunities is a stronger statistical claim, and common subsystems immediately call it into question. If a single preselector setting removes the frequencies relevant to the source model, both receivers can fail together even if their downstream processing is independent. A shared antenna can impose the same polarisation null or shielding loss. A shared laptop may drop exactly the same time interval from both files. The investigator should characterise those dependencies through an engineering diagram and controlled fault injection, rather than treating the number of equipment cases as an independence certificate.

A defensible opportunity ledger requires an explicit state space. An eligible observation records that the receiver actually acquired an interval while meeting the specified coverage and quality criteria. A valid negative is then an eligible observation in which the predeclared decision procedure registered no qualifying event. A positive is an eligible observation producing such an event. Missing data arise when the intended observation has no recoverable samples or status, while technically compromised data arise when samples exist but their applicability is uncertain because of overload, timing loss or an invalid configuration. An inactive reference

Copyright 2026, James M. Atkinson

source is a different condition again. Its absence may provide a background false-alarm control, but not a source-active detection trial. Retaining these distinctions in machine-readable fields permits accurate later analysis.

The dependence question can be investigated with a challenge matrix. Introduce the same known authorised RF burst into both receivers through independently characterised paths, then repeat the challenge after deliberately disconnecting the common antenna, changing preselector settings, inducing a host acquisition pause and varying source geometry. Record whether each receiver's local counters and status fields respond as expected. An independent third monitor can establish actual source activity without inheriting the same antenna route. The tests reveal which failures are common and which are receiver-specific. When the dependence structure remains uncertain, report the raw number of observations but avoid pretending that the effective count of independent trials is known to equal it.

A conservative bound can be meaningful only when the conditions under which it holds are stated. If a reference source family, minimum field strength, waveform duration, antenna geometry and acquisition schedule have all been validated, the report may give a lower performance bound conditional upon those conditions, with the statistical method and confidence level disclosed. It cannot infer a bound for an untested, inactive or differently coupled source by rhetorical extension. The bound should also account for uncertainty in calibration and model structure, not solely binomial sampling variation. The general lesson is to distinguish the measurement design, its physical failure dependencies and the inference that a statistical model permits. When a common-mode weakness

Copyright 2026, James M. Atkinson

dominates, additional nominal scans without changing that weakness may create quantity without improving assurance.

David Harold Blackwell, Peer Question: Sir David, I would like to examine what the decision-maker may properly do after the report has rejected an absolute absence claim. A client might have limited funds for additional checks. The completed survey shows no qualifying detections in several well-covered bands but leaves substantial uncertainty about sporadic activation, a screened room and one wired route. In that situation, can the negative observation still rationally change the decision about where to allocate the next laboratory or field examination? I ask you to distinguish evidential probability from decision utility, especially where the consequences of a missed source are substantial and the source's frequency or behaviour is unknown. Could the investigator present a transparent sensitivity analysis without pretending to know a unique prior probability of a device being present? What safeguards should prevent a cost-based recommendation from being misquoted as a scientific finding that a threat has been excluded?

Sir David Cox, Response: Dr. Blackwell, the client may indeed find a bounded negative result useful even when it cannot establish universal absence. Scientific evidence and decision policy are related, but they answer different questions. The evidence identifies observations, validated detection performance, and uncertainties. The policy assigns consequences and costs to possible actions and residual risks. A client might reasonably prefer further testing of a known blind interval rather than another scan of a frequency band already examined under favourable conditions. That preference may be rational under an explicitly declared loss function

Copyright 2026, James M. Atkinson

without implying that the unexamined threat definitely exists or that the examined band is certainly free of risk.

I would structure the decision analysis around competing scenarios rather than one fabricated probability. For instance, construct scenarios in which an emitter is intermittently active, shielded by construction, using a wired path or absent. For each scenario state what the current survey could and could not have observed, and how a proposed further test changes expected observability. If probabilities can be supported by external evidence, their provenance and sensitivity should be disclosed. If they cannot, present threshold analyses: at what plausible probability or consequence would a follow-up action become worth its cost? Such a calculation may clarify choices without treating the input probabilities as measured facts. It also prevents numerical polish from disguising the fundamental uncertainty about source behaviour.

An independent recommendation might call for inspecting the screened room, checking cable routes under lawful authority, improving antenna geometry or extending observation to capture a plausible activation window. These actions target different physical hypotheses and should not be aggregated as though each were merely another independent draw from one detection process. The team ought to indicate which hypotheses each follow-up test could challenge, what controlled references are available and what result would count as a genuine failure of the source hypothesis. A proposed test which cannot disconfirm or discriminate anything may have low evidential value despite producing a large volume of recording data.

The report must keep its categories legible. One portion states what was measured and what faults were observed. A second explains uncertainty

Copyright 2026, James M. Atkinson

and the limited source hypotheses addressed. A third, clearly identified as decision support, compares the cost and potential value of additional authorised activities. The fact that a client elects not to pursue a suggested check does not enlarge the survey's original conclusion. Equally, a decision to conduct more testing does not establish suspicion as a fact. I would regard this separation as especially important where a report may later appear in litigation. The scientific witness should testify to the evidence and its limits, not quietly convert a commercial or protective preference into an attribution or a claim of absence.

Sir David Cox, Cross-Peer Question to Abraham Wald: Mr. Wald, I should like you to distinguish a planned stopping rule from a retrospective explanation of why a survey ended. A team may have a predeclared protocol requiring a minimum observation duration, coverage of stated receiver bands, a closing calibration test and verification of storage continuity. In practice a receiver overload may invalidate a period, and the operator may elect to repeat that period or extend the visit. How can we preserve the validity of the survey while permitting sound engineering judgement in response to new observations? Conversely, suppose the same team sees an unusually quiet spectrum and decides to terminate early because nothing appears wrong. What would a responsible report say about the uncompleted tests and the evidence not acquired? I also ask whether sequential inference is practicable when the set of potentially relevant sources is ill-defined and the conditional probability of detection changes with the site geometry. What minimum information should the team retain so that an independent reviewer can assess its termination decision?

Copyright 2026, James M. Atkinson

Abraham Wald, Cross-Peer Answer to Sir David Cox: Sir David, the solution begins by recording the protocol before the observations influence the operator's choices. A protocol can define minimum eligible observation time, required antenna positions, frequency ranges, controlled source challenges and final acquisition integrity checks. It should also define exceptions: where overload, missing samples or another instrument fault invalidates an interval, the team must either repeat the affected test or explicitly declare the corresponding coverage requirement unmet. An extension in response to a fault may improve the scientific record without pretending that the original plan was perfectly executed. What matters is that the reason, timing and consequences of each change are visible to the later reviewer.

Early termination because the screen appeared quiet is a different form of adaptation. The team is using the outcome of the measurement to decide how much more evidence to collect, and may thereby change the inferential properties of any statistical procedure. If the original protocol required two hours and a closing challenge, a twenty-minute quiet observation cannot be reported as the completion of the two-hour protocol. It may be described as a negative observation over the twenty eligible minutes actually acquired. If a safety or legal restriction compelled termination, that fact also belongs in the report. The moral is not that judgement is forbidden, but that prospective design and subsequent deviation should not be merged into one invented history.

Sequential inference can be valid for a narrow, demonstrably specified source model, but it is not a universal substitute for understanding source activity. A likelihood ratio requires probability models under competing

Copyright 2026, James M. Atkinson

hypotheses, and those models must account for dependence and changing measurement opportunity. Without defensible source activation and receiver-response distributions, a numerical stopping boundary is no more authoritative than an unsupported fixed-sample calculation. The investigator may still use engineering completion criteria rather than a formal statistical stopping rule. The criteria should be chosen to expose known failure modes and to satisfy the intended evidential purpose, not merely to generate a reassuring number of screen captures.

The custody record should retain the original survey plan, versioned instrument configuration, receiver-native acquisition counters, the start and end of each eligible interval, operator actions, detected anomalies, retuning or overload events, and any changes to the planned schedule. It should also preserve reference test results before and after critical configuration changes. An independent reviewer can then distinguish a completed planned observation, an authorised adaptation and an incomplete test. This record permits practical decision-making without allowing post hoc selection of observation duration to masquerade as independent confirmation. The evidential effect of a negative result remains conditional upon the work actually performed.

Dr. James M. Atkinson, Moderator: Sir David has separated evidential validity from the later allocation of investigative resources. Sir Karl Popper, please conclude with the refutable claims that a responsible negative survey can sustain.

Copyright 2026, James M. Atkinson

Sir Karl Raimund Popper, Fifth Principal Contributor: Dr. Atkinson, I approach the report as a collection of propositions which must be exposed to possible refutation. The statement that no device exists anywhere in a building cannot be meaningfully tested by a finite RF search when the statement quietly includes every conceivable inactive or inaccessible mechanism. An adversary could always describe an invisible exception beyond the tested frequency, time, place or method. That capacity to evade a negative observation must not be mistaken for evidential proof of either presence or absence. Our task is to devise precise propositions whose failure conditions are plain, and then record whether the instruments actually exposed those propositions to a severe test.

A bounded claim might say that no authorised laboratory reference burst above a defined receiver-input level, with a stated occupied bandwidth and repetition schedule, was missed during the controlled trial. Such a proposition is testable because a missed burst would contradict it. A subsequent site observation can then say that no event meeting the corresponding criteria was recorded during eligible observation intervals. The first proposition concerns demonstrated test-system performance; the second concerns what the site instrument observed. One must not silently infer a third proposition, namely that there was no transmitter, because the third invokes assumptions beyond the measured evidence. The argument should show its inferential bridges rather than leap over them.

A severe test is one designed to expose a method's weakness, not one that arranges the conditions for an easy success. If a detector is evaluated only against powerful continuous carriers directly in front of its antenna, it has not been challenged for weak bursts arriving at inconvenient angles. If the

Copyright 2026, James M. Atkinson

receiver is tested after a noise-free instrument reset, the trial may fail to reveal overload recovery and gain-state memory. If all reference transmissions are scheduled at exactly the moments when the scanner is dwelling on the appropriate band, the demonstration may conceal significant blind time. An honest laboratory should deliberately include difficult but plausible conditions within the declared intended use, record failures and refuse to erase inconvenient outcomes from the analysis.

Falsifiability is not the same as universal exclusion. Even after a detector survives many well-designed tests, the result supports confidence in its behaviour within those conditions, not an unrestricted proof about unknown emitters. A client who asks for an assurance statement should be given both the observation and the circumstances in which it would have failed. For example, a silent observation would have been contradicted by a validated qualifying pulse in a monitored band while the receiver was functioning. It would not have been contradicted by a transmitter that never activated. These are different states of the world, even if they leave indistinguishable traces on the screen. The report must state which states remain observationally equivalent.

There is also a problem of alternative physical channels. A radio-frequency receiver cannot generally resolve communications which occur solely by conductive coupling along a protected cable, optical signalling outside the inspected method, or physical data transfer without electromagnetic radiation within the survey's observable envelope. Even where those channels produce incidental electromagnetic leakage, its level and appearance cannot be assumed without measurement. A negative RF result therefore does not eliminate all surveillance methods. The proper response

Copyright 2026, James M. Atkinson

is not to add a token phrase about limitations and then return to an absolute conclusion. It is to define the survey's discipline and note where another authorised examination, such as network, wireline or physical inspection, addresses a separate proposition.

The chain of custody helps preserve the test's refutability. If the laboratory retains only its final PDF and discards the relevant receiver states, acquisition records and negative controls, a later reviewer cannot determine whether a false assurance arose from the instrument, the interpretation or an unexplained omission. The preserved record should permit an independent examiner to reproduce the decision rule on the same samples, challenge the instrument with a comparable reference, and locate intervals which were not observed. Cryptographic hashes can help maintain the identity of preserved records after acquisition; they do not prove that the antenna was attached, that the operator set the right frequency, or that the unknown emitter was active.

An effective conclusion ought therefore to contain graded statements. The strongest may concern directly observed calibration results and documented acquisition states. A narrower negative statement may cover the absence of a qualifying feature in eligible records. An interpretive statement may indicate that certain risk scenarios are less consistent with those observations, conditional upon assumptions of activity and observability. The report should also identify hypotheses that were not meaningfully exposed to refutation, so that readers do not mistake an absence of scrutiny for an absence of risk. The language should preserve uncertainty without sacrificing practical relevance. The client should be able to act upon an honest account of what was tested.

Copyright 2026, James M. Atkinson

Finally, scientific humility should not be confused with paralysis. A properly bounded negative survey can be decision-useful even though absolute certainty is impossible. It can help justify changes in protective arrangements, identify areas requiring longer observation, and provide documentary evidence that certain authorised challenges were performed. What renders it useful is the severity and transparency of the test, not the flourish of an unqualified declaration. I would ask each of my colleagues whether the method could have failed under a credible alternative condition, and whether the report tells the reader how that possibility was examined. I pass the token back to Dr. Atkinson so that the peer challenges may test our proposed reporting standards rather than merely praise them.

Sir Karl Raimund Popper, Cross-Peer Question to Sir David Cox: Sir David, I ask that you place our proposed assurance report under a severe challenge. A team may truthfully state that it observed no qualifying RF emissions during its measured survey interval. It may also describe a set of reference tests which the receiver passed. Yet a nontechnical reader could still mistake those two true statements for proof that there was no concealed apparatus. Can we specify the precise proposition that was tested, the conceivable observation that would have refuted it, and the alternative source behaviours that remained outside the test? I would also ask how a graded conclusion should respond to a failed low-level calibration challenge or an unverified period of sample loss. Should one recalculate an optimistic detection probability from only the successful trials, or instead treat the failed control as a limitation on the entire claim? Finally, what language would you permit in a written report intended for a legal forum where small verbal exaggerations may acquire great significance?

Copyright 2026, James M. Atkinson

Sir David Cox, Cross-Peer Answer to Sir Karl Raimund Popper: Sir Karl, an assurance report should begin with the instrument's actual observational proposition. For example: during the documented eligible intervals, on the specified bands and antenna configurations, no stored event satisfied the predetermined classification rule. This proposition is refutable by identifying a qualifying stored event which was overlooked or misclassified. A second proposition might state that the equipment passed particular reference challenges with specified input conditions. That proposition is refutable by a documented failure during the challenge or by an error in the calibration record. The broader claim that no hidden apparatus exists is not implied by either proposition. The report should not rely upon the reader to supply that logical distinction unaided.

A failed low-level challenge is evidence about the measurement system and must remain in the record. It may require a revised operating envelope, a technical repair, repetition of the affected test or a limitation on the negative conclusion. It is not acceptable to discard the failed trial and recalculate a favourable detection fraction from a self-selected subset unless there is a prospectively justified exclusion criterion and the analysis discloses the decision. Even then, the rejected trial may reveal an important operational failure mode and deserves separate discussion. Similarly, an unverified sample interval cannot be counted as observed quiet time. The proper treatment is to identify it as uncertain or missing and examine the resulting sensitivity of any inferential statement.

A graded statement can distinguish direct observation from calibration evidence and scenario-based interpretation. The direct observation might be highly secure if the original record, software version and acquisition

Copyright 2026, James M. Atkinson

continuity have been preserved. The calibration evidence may be strong for some waveform classes and weak for others. The interpretive inference that a particular type of active transmitter was unlikely to have escaped detection depends upon tested activation, coupling and noise conditions. A different source operating intermittently outside those conditions may remain largely unexamined. Presenting this hierarchy is not equivocation. It is the natural consequence of identifying the propositions and their supporting evidence accurately.

For a legal audience I would recommend language that reports the test, not the investigator's optimism. It might state: 'No emission meeting the declared detection criteria was recorded in the eligible surveillance intervals. Controlled reference tests support the stated sensitivity and coverage for the specified waveform and input conditions. These findings do not exclude inactive devices, sources outside the surveyed envelope, unobserved periods or non-RF surveillance mechanisms.' Where the experiment contains a failed control or a notable acquisition gap, identify it expressly and describe its consequences. The witness should be able to explain each sentence by reference to a contemporaneous record. That is how a limited negative finding becomes both useful and defensible without being converted into an assertion of universal absence.

Dr. James M. Atkinson, Moderator: I am obliged to all contributors for maintaining courtesy while challenging the evidential scope of the negative survey. The panel concludes that silence is meaningful only within the independently evidenced observation envelope and tested source hypotheses. The token returns to the editor for technical verification and lawful-context review.

QUESTION 101

Copyright 2026, James M. Atkinson

Can parallel converter channels increase effective resolution without synthesising nonexistent physical bits?

Dr. James M. Atkinson, Moderator: Dr. Bardeen, I invite you to examine a claim sometimes made in discussions of wideband software-defined radio: that a collection of 12-bit or 14-bit converters receiving the same waveform may simply have their outputs combined to constitute a 24-bit, 32-bit or even higher-resolution analogue-to-digital conversion. Please distinguish independent noise averaging from statistical estimation of a common analogue value, and both from time-interleaving to achieve greater sample rate. Explain why converter bit depth cannot be concatenated in this way, and identify what might legitimately improve under carefully controlled conditions. I ask you to include a laboratory comparison using independent dither, correlated noise, gain and offset mismatch, aperture jitter, and a properly specified SINAD measurement.

John Bardeen, Principal Contributor: Dr. Atkinson, the first mistake is to regard a converter's nominal digital word length as an additive physical resource. A 12-bit quantiser maps an analogue input into one of 4,096 nominal codes under a defined input range. Two nominally identical 12-bit converters connected to the same analogue source each report a code related to that same physical input. If the two code words are appended to form a 24-bit string, the result may possess twenty-four storage bits, but the first twelve do not magically resolve the analogue amplitude uncertainty hidden beneath the second converter's quantisation interval. The physical information made available depends upon calibration, input noise, sampling instants, quantiser behaviour and the statistical relation of the errors, not

Copyright 2026, James M. Atkinson

the number of symbols in a larger register. A perfectly correlated error is reproduced by every added channel.

One must define the architecture before deriving any improvement. In a simultaneous-sampling array, each converter observes approximately the same analogue input at the same nominal time. The resulting digital values may be averaged, or processed as an ensemble, to reduce components of random error which vary independently between channels. In a time-interleaved array the converters instead observe successive sampling instants offset in phase; the primary purpose is to raise aggregate sample rate. Time interleaving can increase the accessible instantaneous bandwidth under an adequately band-limited analogue front end, but it creates sensitivity to aperture skew, gain mismatch and offset mismatch across channels. Both arrangements are useful, yet one should not claim that the bandwidth advantage of one is a resolution advantage of the other without separate evidence.

Consider an idealised simultaneous arrangement in which each converter measures a common scalar input plus an independent, zero-mean error with identical variance. Let the error variance of each channel be σ^2 and let the number of channels be N. The arithmetic mean of the N readings has error variance σ^2 divided by N when all off-diagonal error covariances vanish. Thus the rms error decreases with the square root of N, and the power signal-to-noise ratio improves by ten times the base-ten logarithm of N decibels if the signal term remains unchanged. In the conventional idealised relation between resolution and signal-to-noise ratio, doubling the number of independent channels yields only about half an effective bit, not a full word-length increase. Sixteen fully independent channels can ideally

Copyright 2026, James M. Atkinson

yield a two-bit improvement under those restrictive conditions. A measured result must be compared with those assumptions, not announced as sixteen times the nominal resolution.

The word independent requires particular care. Several ADCs may share the same analogue source noise, preamplifier distortion and power supply interference. They may also share a clock whose phase error moves the effective sample aperture of every converter together. These shared disturbances are correlated, and their common part does not average away merely because more digital words are available. For errors with nonzero covariance, the variance of the mean contains the sum of those covariance terms. A laboratory experiment should therefore measure cross-channel noise correlations, not only the individual channel noise floors. A quiet spectrum obtained from an averaging algorithm is not conclusive evidence of improved analogue accuracy if a common distortion component persists beneath the lower apparent random floor.

Quantisation creates another qualification. Ideal quantisation error is not always independent noise. For certain deterministic periodic inputs and sampling relationships, it can be correlated with the signal and with errors in other converters. Deliberately introduced, characterised dither may decorrelate some quantisation effects, after which suitably averaged measurements can yield finer estimates of certain analogue quantities. Yet dither introduces noise of its own and may worsen individual sample performance. It is not an incantation that turns any twelve-bit converter into a higher-bit instrument. The relevant comparison must fix the measurement bandwidth, input range, clock condition, dither spectrum and decision

Copyright 2026, James M. Atkinson

metric. A resolution claim without these specifications can refer to almost any convenient output number.

There is a difference, too, between an improvement in amplitude estimation over repeated observations and the resolution of a single instantaneous event. A receiver analysing a stable carrier over a long interval can exploit averaging and coherence that may not be available for a fleeting pulse. If a burst lasts only a handful of sample apertures, the number of independent observations relevant to its amplitude or phase may be small. Parallel channels sampling at the same instant can still help under suitable independent-noise conditions, but their shared analogue limitations remain. They cannot reconstruct a detail erased by common front-end clipping, a missing antenna-bandwidth component, or a jitter excursion recorded identically in every channel. The distinction matters acutely in defensive RF investigations where a transient cannot be repeated on demand.

An effective-number-of-bits figure must be treated as a measured performance metric, not a label for a digital container. Under the conventional full-scale sinusoidal SINAD relationship, ENOB is estimated from the measured signal-to-noise-and-distortion ratio after applying the appropriate bandwidth and test conditions. Distortion components, including mismatch spurs, matter. A system that reduces random noise but retains a large harmonic can exhibit much less ENOB improvement than the simple independent-noise calculation predicts. Equally, a wider receiver bandwidth integrates more noise and changes the scope of the measurement. One must not quote an ENOB obtained after narrow filtering as though it characterised a much wider instantaneous receiving band without explaining the change in conditions.

Copyright 2026, James M. Atkinson

The laboratory trial should compare at least four conditions using one accurately characterised input waveform and a second monitor. First, record each converter separately with its native gain, input range and clock state. Secondly, combine simultaneous channels without deliberate dither, measuring the actual covariance of their errors. Thirdly, apply independent controlled dither and repeat the estimate. Fourthly, introduce a shared disturbance or an intentional channel mismatch to test whether the claimed improvement disappears as predicted. The record should retain the original codes, calibration constants, sample counters and processing scripts, permitting another investigator to reproduce the arithmetic. At every stage distinguish numerical agreement between programs from physical accuracy of the analogue measurement.

I would insist on a further comparison with time interleaving, because a spectacular aggregate sample rate is easily mistaken for an equally spectacular gain in precision. Divide the clock phases among channels and measure the spectral spurs produced by small sampling-skew, offset and gain errors. Repeat the measurement as input frequency increases, because a fixed time error can become more consequential at higher frequency. This experiment may reveal a useful expansion of instantaneous bandwidth with a simultaneous deterioration of spurious-free dynamic range. A conscientious report can describe both results without contradiction. The receiver has gained access to more frequencies, but has not manufactured physical resolution by joining digital outputs together.

My conclusion is therefore conditional and quantitative. Parallel channels can improve selected estimators when their independent error components can be reduced and their shared limitations controlled. The improvement

Copyright 2026, James M. Atkinson

should be expressed through measured covariance, SNR, SINAD, ENOB and spurious-free dynamic range within a specified measurement bandwidth and over tested operating conditions. The naive addition of nominal bit widths is not a lawful engineering inference from the architecture. Nor should a demonstration on an easy continuous reference signal be treated as proof of equivalent performance against a single short burst. I pass the token to the remaining contributors to examine device nonlinearity, sample timing, information limits and error-aware digital combination.

Charles Hard Townes, Peer Question: Dr. Bardeen, I want to examine the assumption of independence at the physical source, not merely in the resulting sample arrays. Suppose sixteen converters have separate internal quantisers and separately seeded digital dither, but all receive their analogue input through one low-noise amplifier driven by a thermal environment and a strong neighbouring transmission. A spectral estimate may fall by twelve decibels after the outputs are averaged, while the distortion produced before the splitter remains unchanged. What experiment would persuade you that an observed gain belongs to genuine improved measurement of the weak test waveform rather than to the analyst's selective exclusion of shared disturbances? I am also concerned that measuring noise in one unoccupied FFT bin is not equivalent to measuring the integral noise and distortion in a declared receiver bandwidth. Would you insist on independent analogue monitoring, and how should the investigator explain a result when a sixteen-way array performs impressively with a clean laboratory sine wave but fails to discover a short low-level pulse under the same analogue blocker?

Copyright 2026, James M. Atkinson

John Bardeen, Response: Dr. Townes, the question identifies precisely the limit of an attractive averaging result. I would not accept a gain established only by showing a reduced baseline in a selected displayed spectral bin. The laboratory must establish a defined physical input, reference bandwidth, signal amplitude and independent estimate of noise and distortion. A single high-quality analogue monitor placed at an appropriate reference plane can confirm the applied stimulus, although the monitor's own uncertainty must be characterised; a second acquisition arrangement can test whether the observed weak pulse is a property of the source or of the converter chain. The central distinction is between measurement of a known controlled reference and inference about an unknown emission. If the test uses a known weak sine wave, the study can measure how well the array estimates its amplitude. It does not thereby validate an emission detector for all short bursts and interference conditions.

I would design a crossed experiment. Keep the same sixteen-channel hardware while varying, separately, the common amplifier, the independent channel noise, the dither correlation and the blocker level. In one run drive the channels from an exceptionally clean distributed reference; in the next inject a calibrated common-noise component; in the third introduce a non-linear shared stage. Predict beforehand which error terms should change under averaging. For independent unit-variance errors, the variance of the mean should approach one-sixteenth of one channel's error variance. If a shared term dominates, the improvement should collapse toward its irreducible floor. The acceptance test should compare predicted and measured covariance matrices rather than rely on one convenient number.

Copyright 2026, James M. Atkinson

Any failure should be retained as evidence about the instrument's true operating range.

The FFT question is equally important. Noise power is related to the selected filter or estimator's effective bandwidth. Decreasing the display resolution bandwidth can make a plotted floor appear lower without changing the physical converter or producing an equivalent instantaneous amplitude measurement. We should state whether the quoted metric is input-referred integrated noise, SINAD from a specified sine-wave test, amplitude-estimation variance or probability of detection for a declared burst. Each has a different experimental denominator. We should not transfer a twelve-decibel difference obtained in a narrowband estimate into a blanket two-bit improvement across the entire receiver's instantaneous passband. A lower plotted line is not a new datum about the analogue input until the measurement model is declared.

As to the failed short-pulse trial, I would report it prominently. The pulse might be masked by the shared amplifier's compression, by clock-aperture uncertainty, by the test detector's threshold, or by analogue band-limiting. We must use controlled fault isolation to distinguish those explanations; the failure itself does not identify one cause. It would demonstrate that the particular array and processing method did not achieve the specified sensitivity in that condition. A useful engineering outcome may be to add front-end preselection, change the gain distribution, or modify the observation schedule. Those are new designs requiring independent tests. It would be wholly indefensible to retain the clean-sine claim while quietly suppressing the inconvenient pulse result, for that is precisely how nominal specifications become misleading forensic assertions.

Copyright 2026, James M. Atkinson

John von Neumann, Peer Question: Dr. Bardeen, may I challenge the calculation of an ensemble mean when the converters have unequal calibration errors and unequal variances? A simple arithmetic average is optimal only under selected assumptions. Suppose one converter has an offset that drifts with temperature, another suffers occasional clipping, and a third has relatively low random variance but shares a reference disturbance with its neighbours. A computer can solve for weights that appear to minimise observed error on the training data. What safeguards prevent this optimisation from manufacturing an implausible claim of extra effective bits, particularly when the chosen weights depend on the same test waveform used to pronounce success? Would you insist upon a separate calibration set and a blinded confirmation set? I should also like to know whether weights are permitted to be negative, and what a forensic examiner should do when the mathematically optimum weighting dramatically magnifies sensitivity to a small drift in one channel's physical characteristics.

John Bardeen, Response: Professor von Neumann, unequal channels certainly invite weighted estimation, but the weights must be accompanied by a physical model and evidence that the model holds. If an array yields readings $y_i=x+e_i$ and the covariance matrix Σ of the error vector is known and suitably invertible, a conventional minimum-variance unbiased linear estimator for a common scalar may use weights proportional to $\Sigma^{-1}1$, normalised so that their sum is one. That expression is a mathematical result under the assumed model, not proof that a particular converter is truthful. A poorly estimated covariance matrix can produce exaggerated, unstable or even sign-changing weights. Negative weights are possible in

Copyright 2026, James M. Atkinson

some correlated-error models; their mere appearance is not a formal error. But they should be treated as a warning to examine model sensitivity and noise amplification, particularly if the instrument must operate outside the calibration conditions.

The calibration and confirmation datasets must be separated. The laboratory should characterise channel gain, offset, covariance and clipping before choosing its combination rule. The algorithm, weights, validity rules and acceptance thresholds should then be frozen for an independent confirmatory set whose physical inputs and nuisance conditions were not selected to favour that algorithm. If an investigator chooses weights after inspecting the very weak signal whose presence is in dispute, a claimed detection gain cannot be evaluated as though the weights had been chosen in advance. The resulting exploratory finding may still be useful for designing another test, but its evidential weight must be qualified. Separate monitoring of the applied analogue input is also necessary because an optimisation can fit the shared distortion rather than remove it.

For drift, I would require a sensitivity experiment. Vary the temperature, clock and input power independently, perturb the calibrated gains and offsets within their uncertainty ranges, and recompute the estimate. If a nominally optimum weight set produces widely differing results under small plausible perturbations, its formal variance advantage is not operationally robust. A more conservative estimator, or a subset of well-characterised channels, may be preferable. Report the stability as a function of operating state and bandwidth, not merely a favourable scalar ENOB at one temperature. A dropped or clipped channel should not be silently assigned

Copyright 2026, James M. Atkinson

its nominal weight; the validity mask and weighting revision must be explicit and preserved.

Above all I would retain the raw independent streams, their calibration records and a reproducible processing manifest. An independently checked output that is numerically identical to the original combined stream shows that the same computation can be repeated, but it does not by itself show that Σ was appropriate or that the reference clock behaved correctly. The final report should state which errors were directly measured, which model parameters were estimated, and which alternative explanations remain viable. The weighted algorithm earns its authority through challenged experiments, not through the elegance of the matrix formula or the impressive number of digits printed by the computer.

Dr. James M. Atkinson, Moderator: Dr. Kroemer, I thank Dr. Bardeen and the first peer interlocutors. I invite your examination of the analogue distribution network, correlated gain and timing errors, and nonlinear behaviour under strong neighbouring signals. The token is yours.

Herbert Kroemer, Second Principal Contributor: Dr. Atkinson, I would begin at the transistor and sampling switch rather than at the digital word. The array has a physical front end, and every channel is ultimately subject to an analogue transfer characteristic. That characteristic is not specified by the number of bits written at the output. If twelve- or fourteen-bit converters share one splitter, preamplifier, reference rail and timing source, they inherit common-mode effects before any computation begins. The first instrument question is therefore which noise terms are statistically independent at the sampling aperture, which errors track the signal, and which mechanisms are common to the entire assembly. The impressive

Copyright 2026, James M. Atkinson

diagram of sixteen parallel paths may conceal one common weakness. In particular, a small common nonlinearity can create an apparently repeatable spectral line which averaging preserves rather than attenuates. A receiver forensicist should welcome that persistence as diagnostic information, not hide it behind a higher-resolution claim.

Let each channel be represented by $y_i(t)=g_i x(t+\delta_i)+b_i+c(t)+\varepsilon_i(t)+d_i(t)$, where x is the analogue input, g_i is its gain, b_i its offset, δ_i its sampling-time error, c is a disturbance shared by all channels, ε_i is independent noise, and d_i collects channel-specific distortion. I use this as a first-order descriptive model, not as a universal characterisation of a real converter. Gain, offset and skew will themselves vary with frequency, temperature and source impedance. If the analyst computes a simple mean of the channels, the independent components may be reduced, but the average contains the common disturbance c unchanged. Any gain and offset correction must be justified by calibration, and a timing correction requires a reference traceable to the actual aperture. Calling the result twenty-four-bit is conceptually mistaken because its lower numerical bits may be dominated by an uncorrected physical error.

It is possible to calculate the limitation without the romance of ideal components. Imagine sixteen channels each presenting an rms independent error of one arbitrary unit and a shared rms error of one unit, all zero-mean and uncorrelated between the shared and independent terms. Before averaging, the total error variance of one channel is two units squared. After averaging, the independent variance is one-sixteenth, whereas the common variance remains one. The combined variance is therefore 1.0625, not one-eighth. The rms error falls from the square root of

Copyright 2026, James M. Atkinson

two to the square root of 1.0625, an improvement of only about 2.75 decibels in power SNR, assuming the signal gain and bandwidth are fixed. No assertion about absolute converter resolution follows without testing its distortion and reference accuracy. Merely reporting the ideal twelve-decibel improvement for sixteen channels would conceal the measured common noise.

A second experiment should vary the analogue distribution network deliberately. A power splitter may have amplitude imbalance, frequency-dependent phase shift, reflections and changing isolation between branches. If the investigator compares the output codes of channels that have not been independently calibrated at each test frequency, differences in their apparent noise may reflect the splitter rather than converter silicon. The source must be accurately characterised and operated below its own distortion threshold. The measurement is also sensitive to the amplifier's recovery after a strong blocker. Suppose a weak laboratory tone is present beside a high-amplitude signal. The front-end amplifier may compress all sixteen branches, and the array average will faithfully reproduce a distorted observation. It does not regain information that the shared analogue stage destroyed. An examination of blocker tolerance, not merely low-level sine-wave noise, is indispensable in a wideband defensive receiver.

The sampling aperture matters particularly for rapidly varying signals. For a sinusoid $x(t)=A \sin(2\pi f t)$, a small timing error δt produces an approximate voltage error $\delta x \approx 2\pi f A \cos(2\pi f t)\delta t$. The approximation is local and fails for sufficiently large jitter or non-sinusoidal excursions, but it correctly shows the growth of the sensitivity with frequency. A shared clock-jitter event can shift every converter's observation coherently, so adding simultaneous

Copyright 2026, James M. Atkinson

channels will not generally reduce it. A channel-specific aperture disturbance may be partly averaged if its correlations and distribution permit it. Yet an average of samples nominally simultaneous is not necessarily equivalent to a true simultaneous sample if the apertures are misaligned. A short RF burst can develop a false leading edge or an attenuated peak when the array's samples are combined without alignment.

For time interleaving, the same timing parameter appears in a more conspicuous form. Suppose four channels each operate at one hundred million samples per second, their ideal apertures separated by 2.5 nanoseconds within a ten-nanosecond cycle. Under suitable analogue and digital conditions the assembly produces four hundred million output samples per second, raising the ideal real-signal Nyquist boundary to two hundred megahertz. It has not changed any individual channel's nominal code count. Offset errors can create a comb of spurs linked to the channel cycle; gain and timing mismatches can generate images whose positions depend upon the input tone and interleaving pattern. For a short transient those imperfections may mimic multiple pulses. The legal and scientific reporting question is whether the combined record preserves the physical event with a calibrated uncertainty, not whether its aggregate sample-rate label looks commercially persuasive.

I recommend a calibration sequence in which the same array is exposed to a low-frequency sine wave, a high-frequency sine wave, a short independently monitored pulse and a two-tone blocker test. Each test probes a different weakness. The first checks offset and gain; the second raises the consequences of aperture skew; the pulse challenges transient fidelity; the two-tone test reveals nonlinear mixing and recovery. Repeat the sequence

Copyright 2026, James M. Atkinson

before and after thermal cycling, after replacing the reference clock, and after changing the splitter. If a correction algorithm improves SINAD at one frequency but worsens phase fidelity for the short pulse, the system's report must preserve both outcomes. No single average performance figure can excuse a failed use-case measurement.

I would also keep the engineering vocabulary disciplined. Resolution can mean code step size, effective amplitude estimation precision, spectral resolution after a chosen observation time, or the ability to discriminate two adjacent frequencies. These are different quantities. A twelve-bit converter has 4,096 nominal quantisation codes; a sixteen-channel ensemble may provide an estimator with reduced random variance; and a four-channel interleaver may increase sampling throughput. None of those facts alone establishes a twenty-four-bit or thirty-two-bit equivalent physical input resolution. The proper claim is accompanied by a traceable reference plane, specified bandwidth, input range, controlled state and uncertainty statement. I pass the token to Dr. Nyquist to examine how sampling theory constrains the interleaved architecture.

Dennis Gabor, Peer Question: Dr. Kroemer, I ask how an array that gains average amplitude precision might nonetheless lose information about a very brief waveform. Your timing-error model uses a local derivative and describes the change in a sine wave for a small aperture displacement, but a short pulse may include rapidly changing components which an analogue input filter has already dispersed. If the channels have slightly different analogue group delays, averaging their samples at equal nominal indices can blur an edge even when each channel's separate capture is informative. What evidence would distinguish that physical smearing from random noise

Copyright 2026, James M. Atkinson

reduction, and how might an examiner avoid treating a narrower post-averaging amplitude distribution as proof of improved transient accuracy? I would also challenge the traditional reliance on one coherent sine wave in converter demonstrations. Could a multi-tone or calibrated pulse response reveal errors which an optimised sine-wave ENOB number conceals? Please describe the necessary controls without overstating the ability of a finite-bandwidth instrument to reconstruct an arbitrarily abrupt event.

Herbert Kroemer, Response: Dr. Gabor, the time-domain problem is not interchangeable with a scalar variance problem. If separate channels produce differently delayed versions of a pulse, the pointwise average can reduce the measured peak and widen the apparent pulse without adding noise in the ordinary sense. Such an average may have a lower sample-to-sample variance than any individual capture while being less faithful to the true pulse shape. A strong test would record an independently monitored reference waveform, characterise each channel's impulse response and group delay, and compare calibrated alignment with naïve index-based averaging. The response of the analogue path is part of the measurement. A digital post-processing operation cannot restore spectral components which the entire analogue distribution network suppressed below the information needed for reliable reconstruction.

One could quantify the first-order problem with a Gaussian test pulse whose timing and bandwidth were independently specified, while carefully acknowledging that this is a model waveform rather than every possible radio transient. Inject it at several amplitudes and positions within the interleaving clock cycle. Save separate captures, the array mean before alignment, the mean after traceable alignment and the independent

Copyright 2026, James M. Atkinson

reference. For each, compute peak amplitude error, time-of-peak error, pulse-area difference and an appropriately windowed spectral residual. A gain in one metric may be accompanied by a loss in another. The report should preserve all of them if the forensic question concerns both amplitude and timing. A high ENOB derived from a long continuous sine does not certify that a brief burst has been recorded without time smear.

The distinction becomes important in a channel array containing dissimilar analogue filters or transformers. A group-delay mismatch that depends on frequency cannot always be corrected by one constant time shift. The engineer must measure the actual phase response and, if a compensation filter is proposed, evaluate whether its numerical inversion amplifies noise or creates ringing. When the input is close to an unknown saturation condition, linear response methods may also fail. The correct record should identify which state-dependent assumptions were tested and which are extrapolations. More channels can improve a well-defined estimator, yet more physical paths can also introduce a larger set of calibration uncertainties. Neither fact negates the other.

A two-tone and a pulse test would be useful companions to the sine-wave specification. The two-tone stimulus challenges intermodulation and shared front-end compression; the pulse challenges aperture alignment, transient response and the effect of finite analogue bandwidth. Each should be repeated with the channels individually and in combination. I would especially inspect whether a new spectral line moves when the channel order or interleaving phase changes. Movement tied to receiver configuration may indicate an instrument-generated product, not an external emitter, although the conclusion still requires control experiments.

Copyright 2026, James M. Atkinson

For technical-surveillance evidence the report should state the limited observation: the array reproduced the specified reference within the tested uncertainty, or it did not. It should avoid claiming universal transient fidelity from an attractive noise-floor display.

Lord Rayleigh, Peer Question: Dr. Kroemer, I would like the panel to resolve a distinction among noise reduction, distortion and calibration uncertainty. An experiment may show that sixteen channel outputs have noisy residuals whose arithmetic mean fluctuates less than any one channel. Yet if a shared gain error of one per cent persists, the ensemble can be very precise while remaining inaccurate. Under what conditions may an investigator infer improved ability to separate a small signal from background, and when must that inference be limited to repeated readings of a known reference? I ask particularly about the difference between rms signal-to-noise ratio and the spurious-free dynamic range of a wideband receiver. Could a lower random floor coexist with a more conspicuous deterministic spur from interleaving mismatch? Finally, please state which uncertainty components should be attributed to the common input path rather than counted independently for each converter when constructing the final measurement budget.

Herbert Kroemer, Response: Lord Rayleigh, a precise ensemble may indeed be consistently wrong. If all channels share a gain error, averaging reduces independent scatter but does not remove the calibration bias. The proper uncertainty budget should contain a term for the common gain model and its uncertainty, a term for shared clock and front-end disturbances, and terms for independent channel effects. One cannot divide a common calibration uncertainty by the square root of sixteen merely because sixteen

Copyright 2026, James M. Atkinson

readings were taken. Some shared components may be estimated and corrected using traceable references, but the residual uncertainty of that correction remains. The report must distinguish an applied correction, its uncertainty and a merely assumed offset. A narrow scatter plot alone is not evidence of absolute accuracy.

The two dynamic metrics answer different questions. SNR ordinarily quantifies signal power relative to noise under a specified measurement procedure; spurious-free dynamic range addresses the ratio between a desired signal and the largest relevant spur within the test conditions. A system can reduce broadband random noise by averaging while retaining a strong correlated harmonic or interleaving image. In that case the weak signal may still be hidden by the spur, and the improvement implied by a lower noise floor may have little operational benefit near the spur's frequency. A calibrated sine-wave SINAD test incorporates distortion according to its specified procedure, whereas a displayed SNR reading may exclude selected tones. We must report precisely what was included or excluded rather than transferring one number into another metric.

For an example, suppose the per-channel uncorrelated noise power is the reference unit, and the common distortion at a selected bin has power one hundred times greater. Ideal sixteen-channel averaging would reduce the independent-noise power to one-sixteenth, a twelve-decibel reduction of that part. It would not reduce the common distortion if the channels reproduce it coherently. At the selected frequency the total impairment would change from 101 to approximately 100.0625 reference units, a negligible system-level improvement. This elementary arithmetic is a warning against observing one part of the spectrum and claiming a general

Copyright 2026, James M. Atkinson

converter enhancement. The actual system may have further nonlinear interactions which require measurement rather than extrapolation.

The ability to detect a small signal must be demonstrated under a stated operating environment, observation period, receiver bandwidth, false-alarm rule and signal model. I would include a controlled weak source adjacent to a blocker and vary the blocker level to reveal compression and spur development. A long coherent tone is a legitimate test, but not a substitute for a short emission near a retune gap or after a strong-signal overload. A defensible result should describe the tested class of signals and levels and the degree of confidence supported by repeated independent challenge trials. The instrument's calibration record should disclose all common components so that a later examiner does not count the same uncertainty sixteen times as independent or, worse, divide it away sixteenfold.

Herbert Kroemer, Cross-Peer Question to Harry Nyquist: Dr. Nyquist, I invite you to challenge an assumption that sometimes appears when converter channels are time-interleaved. An engineer may state that four channels, each sampling at one hundred million samples per second, automatically create an instrument with four hundred million samples per second and therefore double the usable real-signal observation bandwidth of a two-hundred-million-sample arrangement. Yet the analogue channels may differ in anti-alias filter phase, their aperture clocks may have unequal delays, and their output data may be stitched together using a presumed timing map rather than one supported by experiment. Could you distinguish the mathematically ideal increase in sampling opportunities from the empirically defensible increase in usable RF bandwidth? I am especially concerned about strong out-of-band emissions folding into the new

Copyright 2026, James M. Atkinson

channel, producing spurs that resemble an external transmitter. What tests should an independent investigator demand before accepting the expanded-bandwidth claim, and how might the result be presented without implying that greater sampling throughput has also delivered extra amplitude bits?

Harry Nyquist, Cross-Peer Answer to Herbert Kroemer: Dr. Kroemer, the asserted four-hundred-million-sample rate is credible only if the physical apertures genuinely occur at the intended staggered times and the resulting record preserves their order and values correctly. A schedule printed by digital firmware is not an observation of analogue aperture timing. The engineer must establish the actual timing offsets, including their frequency and temperature dependence, with an independently appropriate reference. The analogue input response should also be characterised for every branch, because a uniform high-rate output sequence cannot reconstruct a frequency component which the common or individual input networks failed to convey. We should distinguish an arithmetic data rate from the verified passband in which defined signal amplitudes, phases and timing can be measured within the declared uncertainty.

A suitable challenge begins with known tones swept through the intended band and through the transition regions beyond it. The independent reference should establish what was applied, while the converter array reports what appeared in its output spectrum. The examiner should vary channel order, interleaving clock phase and input attenuation while retaining raw data, then determine whether spurious lines follow the predicted mismatch pattern. An external source's field at the antenna does not normally acquire a different physical frequency merely because software

Copyright 2026, James M. Atkinson

changes a multiplexing order, although the receiver's interpretation may change; this is a useful but not solitary discrimination test. A second receiver using materially different sampling architecture can provide corroboration. The test needs a suitably strong out-of-band challenge because a clean in-band tone does not prove sufficient anti-alias rejection.

The ideal real-valued Nyquist limit of a four-hundred-million-sample-per-second uniformly sampled system is two hundred megahertz, but that ceiling is not a certificate of flat amplitude response, immunity to aliasing or adequate dynamic range. A tested useful bandwidth may be smaller, and the lower edge of any uncertain transition should be disclosed. The result must also be conditioned on actual acquisition continuity. A high data rate can overwhelm the host pipeline, producing missing samples despite perfectly functioning ADC clocks. The investigator should include verified sample counters and overflow flags so that a supposed short RF pulse is not silently altered by concatenation after a loss. Frequency coverage is therefore a chain property, not the arithmetic product of channel number and catalogue sampling rate.

Finally, the voltage measurement remains constrained by each converter's noise, linearity and calibration. Time interleaving provides different sample times rather than independent simultaneous readings of one physical amplitude. It may improve a reconstruction problem by supplying more temporal information, but it does not imply the independent-error reduction of an ensemble average. A proper report might state that a four-way interleaved array demonstrated usable coverage up to a specified frequency at a specified SINAD and spurious-free dynamic-range threshold, with recorded aperture uncertainty. Such a statement is stronger scientifically

Copyright 2026, James M. Atkinson

than claiming fourfold frequency coverage and a fictitious collection of extra resolution bits without a reference experiment. I return the token in gratitude for the important distinction between throughput and measured fidelity.

Dr. James M. Atkinson, Moderator: Dr. Nyquist, please distinguish greater temporal sampling coverage from improved amplitude resolution, and qualify the limits imposed by analogue filtering and mismatch. I pass the token to you with thanks.

Harry Nyquist, Third Principal Contributor: Dr. Atkinson, the seductive phrase more bits obscures two distinct questions. How finely may an amplitude be estimated, and what time variation may be represented without ambiguity? An array of simultaneous converters aims principally at the first question under conditions of independent error. An array with staggered apertures addresses the second by producing more time samples. If the channels are rearranged digitally, one must identify which physical instants were sampled and whether the analogue input satisfied the assumptions required for subsequent reconstruction. An unverified high aggregate sample rate cannot repair spectral content already removed by a common filter, nor can it guarantee accurate amplitude if the channels have poor linearity. I would therefore put an acquisition-time diagram beside every proposed processing architecture before evaluating a bits-per-sample calculation.

Consider two channels, each sampling at one hundred million samples per second. If they are driven by the same sampling edge, they provide two estimates of each ten-nanosecond instant; their combined output is not a two-hundred-million-samples-per-second time series of distinct instants. If

Copyright 2026, James M. Atkinson

the second is delayed ideally by five nanoseconds, the interleaved record provides samples every five nanoseconds, which is a different physical experiment. The ideal real-valued reconstruction boundary then changes from fifty to one hundred megahertz, provided the band-limiting and interleaving assumptions hold. A system that alternates two simultaneous samples without actually staggering the physical apertures merely repeats information. A plot whose time axis is assigned after acquisition cannot turn those repeated values into valid intermediate observations. The laboratory should verify actual sample aperture timing, not the rate reported by a software buffer.

The original sampling theorem requires careful assumptions, and I would resist using it as a slogan in expert evidence. A mathematically band-limited waveform, sampled uniformly above twice its highest frequency, can in principle be reconstructed under ideal conditions. A laboratory receiver operates with filters whose attenuation is finite, jitter and mismatch, and a real analogue front end which may be driven by signals outside its nominal band. Strong out-of-band energy can alias into the digitised channel if the anti-aliasing filter does not suppress it sufficiently. Interleaving does not remove this danger; it can complicate the pattern of images. A converter array may display a weak spectral feature which belongs to a remote interferer folded into the measured band rather than the supposed external source of interest. Preselection and substitution tests remain essential.

Now consider an ensemble whose individual channels are twelve-bit quantisers. The nominal ideal signal-to-quantisation-noise ratio for a full-scale sine is approximately 6.02B+1.76 decibels under the usual uniform, appropriately decorrelated quantisation assumptions, where B is the

Copyright 2026, James M. Atkinson

number of bits. At B=12 the ideal figure is about seventy-four decibels. A sixteen-way statistically independent ensemble could in an ideal noise-limited case improve the relevant error power by twelve decibels, corresponding to roughly two additional effective bits. But that improvement is conditional on the error model and on how SINAD is measured. An ideal quantiser may exhibit signal-correlated error for some deterministic inputs, and a real converter includes nonlinear components which do not behave as independent white noise. Thus the arithmetic supplies a testable upper benchmark, not a warranty.

There is another conceptual danger. A narrowband Fourier estimate accumulates evidence across time, and a digital receiver may display a spectral noise floor far below the apparent quantisation step of one raw sample. This does not imply that each instantaneous analogue sample acquired an equal number of new intrinsic amplitude bits. Processing gain, coherent accumulation and reduced resolution bandwidth can all alter the uncertainty of a parameter estimate. An investigator should state whether the claimed improvement concerns one sample, one estimated carrier amplitude over a stated interval, a detected transient event or a reconstructed continuous waveform. For short signals, extending the averaging interval may be impossible without mixing observations of different states. A performance demonstration should include a specified transient as well as a continuous tone.

The sample-rate and bandwidth claims should also be conditioned on temporal covariance. A commonly distributed sampling clock may introduce correlations between channels; a nominal time shift can be imperfect, and the error may change with temperature. In a two-way interleaver a fixed

Copyright 2026, James M. Atkinson

skew of one hundred picoseconds is a small fraction of a five-nanosecond ideal offset, but its effect on a high-frequency sine can be material. At an input frequency of one hundred megahertz, a one-hundred-picosecond differential shift represents approximately 0.0628 radians of phase, or 3.6 degrees. This is not a universal specification of system performance. It is a simple illustration that a small absolute timing error can become noticeable in a measurement near the expanded band edge. The correction and its uncertainty must be verified independently.

I would insist that the test report preserve the precise analogue bandwidths of the individual paths as well as the digital multiplexing pattern. Some arrays are assembled from converters whose front-end response falls sharply near the intended upper frequency. Although a calculated aggregate sample rate may permit wider sampling, the analogue front-end may not deliver an adequate signal at that edge. The report should include input-referred noise, gain flatness, phase response and spurious-free dynamic range across the useful passband rather than only a single sample-rate statement. For technical-surveillance work the strongest interference, not the weakest signal, may determine the practical dynamic range. One cannot certify discovery of a minuscule emission merely by enlarging the number of output samples.

Finally, the investigator should keep the distinction between sampling redundancy and timing diversity visible in the saved evidence. If successive channels sample distinct instants, record which channel acquired each point and the actual sample times or calibrated offsets. If simultaneous channels are averaged, retain the raw separate streams and the weights used to combine them. Reprocessing with another calibration model should be

Copyright 2026, James M. Atkinson

possible. This discipline avoids retrospectively altering the apparent event when a correction algorithm is revised. The defensible description may be modest: the interleaved receiver expanded tested instantaneous coverage under a known spur and jitter envelope; the simultaneous array improved a specified estimator by a measured amount under a covariance model. Neither description needs an imaginary bit count. I pass the token to Dr. Shannon for the statistical account of how much information the array actually yields.

Karl Guthe Jansky, Peer Question: Dr. Nyquist, in a practical spectrum survey the environmental signal seldom resembles the ideal isolated sine which appears in textbooks. Suppose several converters share a wideband antenna and front end while strong broadcast signals, switching transients and unintended reflections change through the day. A time-interleaved arrangement claims a doubled or quadrupled instantaneous sample rate, but the practical observation may exhibit combs of periodic spurs linked to the channel sequence. How should a field investigator separate a genuine faint external signal from an image generated by analogue mismatch or clock timing, especially when only one particular receiver configuration produces the feature? Would you regard a controlled antenna substitution, attenuation changes and an independently constructed receiver as more informative than a display of astonishingly fine digital frequency bins? Please also explain what evidence is necessary before asserting that no unobserved band exists between the nominal frequency limits of the array.

Harry Nyquist, Response: Dr. Jansky, the first task is to map the observation apparatus against its asserted frequency coverage. An interleaved sampler's aggregate clock does not automatically make its analogue front end

Copyright 2026, James M. Atkinson

uniform across the corresponding Nyquist interval. The investigator should measure or otherwise establish the useful analogue passband, anti-alias attenuation, gain response and clock-related spur behaviour. A spectral feature seen only in one interleaving mode is a reason to challenge that mode, not immediate proof that the feature is artificial or genuine. Change the number and order of active channels, the clock phases where authorised and the reference source, then observe whether the apparent spectral component follows predicted instrument-generated aliases. An independent receiver with a materially different architecture can offer a useful check, provided its own overload and calibration states are recorded.

Attenuation and antenna substitution are particularly revealing when interpreted carefully. A genuine external input ordinarily changes with a controlled input attenuation in a manner consistent with the calibrated receiver chain, subject to its detection threshold and noise regime. An internal spur downstream of the attenuator may not respond in the same way. But an upstream overload product may change nonlinearly with attenuation, and an antenna substitution can alter the load impedance and disturb a marginal front end. Thus no single change is conclusive. The value lies in a controlled pattern of results across independently understood configurations. A field note must record the actual attenuation, gain and preselector state, not merely the operator's conclusion that a suspicious line disappeared.

The frequency-axis question also matters. Digital FFT bin spacing is determined by sample rate and transform length; it is not a promise of independent physical resolution at every printed frequency. Windowing, acquisition duration, oscillator accuracy and the analogue transfer function

Copyright 2026, James M. Atkinson

affect a valid conclusion. If the interleaving changes the effective sample rate, the entire data pipeline must update its metadata and frequency mapping. An incorrect sampling-rate field can place a genuine narrowband reference at the wrong displayed frequency even when the raw data are unchanged. This provides a simple falsification test: inject an independently monitored tone at several known frequencies, including near the nominal band edges, and verify both its spectral location and amplitude under each mode.

A claim of gap-free coverage requires more than the aggregate sampling theorem. The analogue response and filter transition regions must be documented, and relevant alias products must be bounded for the expected external environment. Observation scheduling, storage throughput and processing gaps can also create blind periods. The array may be sampling continuously in hardware while the host drops blocks, or it may record every sample but lack sensitivity in a sub-band due to a filter notch. The responsible statement is that the tested system monitored a declared band with specified sensitivity and continuity limitations, not that every conceivable signal would necessarily have been detected. A short weak burst can escape a receiver with an excellent sample-rate specification if acquisition state or receiver dynamic range makes it unobservable.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, I ask you to examine a commonly overlooked inference from the law of large numbers. An array may gather many observations of the same analogue source, and the resulting average may converge numerically with considerable apparent stability. Suppose, however, that every observation shares an offset in the analogue reference, while channel-specific noise

Copyright 2026, James M. Atkinson

remains independent. A practitioner may claim that enough converters will eventually overcome all uncertainty because the residual scatter decreases. Could you present a statistically defensible limit to that reasoning, specifying what assumptions permit a one-over-N variance improvement and what happens when pairwise correlations persist? Please also consider the word effective in ENOB: is the conventional conversion of measured SINAD to an equivalent bit count a statement about the number of independent physical facts learned, or merely a useful benchmarking convention under its own stimulus and measurement assumptions? I request an explicit numerical example which exposes the difference.

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Dr. Nyquist, the relevant proposition is conditional. If N observations each equal a common signal plus zero-mean independent errors with variance σ^2, then the variance of their arithmetic mean is σ^2/N. But if the errors have equal marginal variance and pairwise correlation ρ in an exchangeable covariance model, the variance becomes $\sigma^2[\rho+(1-\rho)/N]$. The correlated term remains as N grows. The calculation demonstrates why a larger register cannot suppress an unknown shared analogue offset. In actual hardware, the covariance may not be exchangeable, and a more general expression $w^T\Sigma w$ is required for a weighted combination. These are models which must be compared with measurements, not declarations that all converter arrays behave alike.

For a numerical illustration take N=16 and pairwise correlation ρ=0.25. The variance ratio relative to an individual channel is 0.25+0.75/16=0.296875, not 1/16. Under a fixed signal-power assumption, the SNR gain of this mean is 10log10(1/0.296875), approximately 5.27 decibels, equivalent to about 0.875

Copyright 2026, James M. Atkinson

of the ideal six-decibel-per-bit benchmark. With truly independent noise the ratio would be 0.0625, the gain about 12.04 decibels, or two ideal effective bits. The correlated example therefore falls substantially short. We must be careful that correlation can also arise from measurement procedures and that any estimated gain has its own uncertainty. More channels can improve some estimators but cannot eliminate a shared disturbance through repetition alone.

The conventional ENOB figure is a useful test-dependent way of expressing dynamic converter performance relative to a model of ideal quantisation. It is not an integer count of uniquely recovered facts and not a statement about the information capacity of a communication channel. Its value depends on input waveform amplitude and frequency, measurement bandwidth, noise and distortion treatment, calibration and the adopted test method. We should not treat a fractional ENOB improvement measured with a particular sine wave as a universal guarantee that a single brief radio pulse will be sampled with an equivalent number of accurate amplitude bits. Independent test scenarios must establish whether the estimator's real task benefits from the change.

I would communicate the result as a hierarchy of claims. First, the array had a specified number of nominally twelve-bit or fourteen-bit conversion channels and a documented operating arrangement. Secondly, within a declared laboratory condition its averaged estimator exhibited a measured reduction in variance, with uncertainty and cross-channel covariance records. Thirdly, a conventional dynamic metric such as SINAD or ENOB was measured by a stated standardised procedure, while timing fidelity and strong-signal performance were tested separately. There is no need to

Copyright 2026, James M. Atkinson

create a fictitious twenty-four-bit or thirty-two-bit converter. The science becomes clearer when the independent observations, shared assumptions and numerical representations are explicitly separated. I return the token to our moderator with respect for the distinction you have drawn.

Dr. James M. Atkinson, Moderator: Dr. Shannon, I invite the panel to distinguish information in independent observations from additional symbols in the output representation. Please examine covariance and a reproducible quantitative limit.

Claude Elwood Shannon, Fourth Principal Contributor: Dr. Atkinson, I would distinguish the number of digits in a file from the uncertainty of a proposition inferred from that file. A digital register can be made arbitrarily wide by padding its output with zeros. The register then contains more bits as a syntactic object but no additional information about the analogue source. Parallel converters do provide separate observations, and independent observations can refine an estimate. The relevant inquiry is not how many bits can be written but how distinguishable the resulting observations are under competing analogue inputs. This is fundamentally a question about the conditional distributions of measurements given the physical signal and the nuisance parameters. A useful experiment must characterise those distributions, including errors shared between channels.

Suppose N channels observe the same scalar amplitude x, yielding $Y_i=x+E_i$. If each E_i has zero mean, independent variance σ^2 and no covariance with the others, then the arithmetic mean has variance σ^2/N. The corresponding standard deviation scales as $1/\sqrt{N}$. If errors share correlation coefficient ρ, equal marginal variance and a valid exchangeable covariance model, the mean variance is $\sigma^2[\rho+(1-\rho)/N]$. This expression exposes the limit of

Copyright 2026, James M. Atkinson

indiscriminate optimism. As N becomes large, the independent term vanishes but the correlated term remains. It would be a mistake to conclude that a hundred channels necessarily provide a hundredfold reduction in error variance. With a common covariance fraction of one quarter, the asymptotic variance is one quarter of the individual-channel variance regardless of the size of the array.

The ideal equivalent-bit improvement follows from an assumed doubling of signal-to-noise power for each doubling of independent observations. In a noise-limited system with fixed signal power, averaging N independent channels ideally raises SNR by 10log10N decibels. Dividing by 6.0206 decibels per ideal bit gives approximately 0.5log2N additional effective bits. For N=4 the increase is one bit; for N=16 it is two; for N=64 it is three. It does not follow that N=64 produces sixty-four independent bits of analogue amplitude. Moreover, the calculation does not establish an ENOB gain if distortion and shared clock noise dominate SINAD. It describes a statistical error-reduction result under explicit conditions. The correct report should keep both the theoretical ceiling and the measured departure from it.

An important distinction arises between nominal quantisation step size and information that can be inferred through dither. Imagine that several quantisers have identical thresholds and that their common input lies within one code interval. If all channels have exactly the same deterministic mapping and no independent perturbation, they may return the same code every time. Their average carries no new sub-code evidence. If each channel experiences a separately characterised perturbation, the observed distribution of codes may convey information about the input's position within the nominal interval, provided the perturbation distribution is known

Copyright 2026, James M. Atkinson

and the reconstruction estimator is appropriate. This is not the same as a single converter suddenly acquiring physically exact extra bits. It is a probabilistic estimate that has its own variance, possible bias and finite-data limitations.

Information must also be judged against the signal's bandwidth and the experimental objective. A stable test sine observed for many cycles supplies repeated opportunities to estimate phase and amplitude. A brief impulsive RF event may not. If the pulse is distorted by a common preamplifier, additional digitiser channels provide independent records of the same distortion. If the pulse amplitude exceeds full scale, all converters can saturate simultaneously. The processing algorithm cannot reconstruct the unclipped peak without separate valid measurements or assumptions which must be declared. The analyst should never equate a reconstructed plausible waveform with a preserved observation. Such restraint is especially important when a narrow conclusion, such as a threshold crossing, is later used to allege a particular transmitter's presence.

I would formulate the controlled experiment using two distinct information tasks. In the first, estimate the amplitude of a known stable reference with a repeated simultaneous array. In the second, classify whether a brief independent reference pulse occurred within a specified time window. For each task generate positive and negative test instances, record the true input through an independently calibrated monitor, and compare the individual channels with the combined estimator. Vary independent error, common error, dither and clock state separately. An observed reduction in amplitude variance in the first task may not translate into improved detection probability in the second because the processing algorithm and

Copyright 2026, James M. Atkinson

nuisance conditions differ. The result should not be generalised beyond the experiments actually performed.

The relationship between SNR and resolution has an important caveat: ENOB is a conventional converter performance metric measured under specified dynamic test conditions, often derived from a full-scale sine-wave SINAD relationship. It is not a direct measurement of Shannon channel capacity, nor a certificate that every amplitude code is accurate to a fraction of one nominal least-significant bit. A converter can have a large nominal number of codes and a poor effective dynamic result due to harmonics and spurs. Conversely, narrowband processing may produce a precise estimate of one tone from data whose individual samples have much lower nominal resolution. The meaning of the precision claim is inseparable from its measurement procedure.

My concluding recommendation is to document the full likelihood structure, or at least a controlled approximation to the covariance and error model, when presenting the benefit of parallel channels. The analyst should publish separate traces for common-mode and independent disturbances, specify any dither injected, and report the uncertainty of the final estimator on the actual test waveform. If the observed improvement is less than the ideal bound, that is not a failure of the experiment. It identifies which physical limitations govern the hardware. The scientific failure occurs when the output word is enlarged and then described as though the analogue input has been observed with an equivalently enlarged number of independent bits. I pass the token to Dr. Hamming for a discussion of numerical representation, error detection and the integrity of the digital combination.

Copyright 2026, James M. Atkinson

William Redington Hewlett, Peer Question: Dr. Shannon, the panel has derived an attractive covariance formula, but an engineering laboratory must decide how much statistical modelling is warranted before a product passes its acceptance test. Suppose a vendor presents sixty-four nominally independent converters, along with one narrowband noise reduction demonstration and a plot headed thirty-two-bit performance. How should a purchaser specify a falsifiable requirement which avoids rewarding an invented output word length? Would you use measured SINAD, ENOB and spurious-free dynamic range at several operating points, and a separate short-burst detection test? How should the laboratory guard against combining sixty-four channels whose noise is visibly correlated through a common clock or power system, particularly when the vendor claims that more averaging will eventually suppress every remaining impairment? I would also like the report to state whether a measured gain in one selected estimator constitutes a system-wide dynamic-range improvement. Please specify whether the independent laboratory should repeat the trial after thermal cycling and under a deliberately strong adjacent-channel blocker, even when the narrowband test has passed.

Claude Elwood Shannon, Response: Mr. Hewlett, I would make the purchasing requirement observable and scenario-specific. An array may be required to achieve a measured amplitude-estimation uncertainty below a specified threshold for a known input waveform, temperature range and bandwidth. It may separately be required to detect a class of short laboratory bursts at a declared false-alarm rate under specified blocker levels. Such requirements can be tested without making a declaration about nominal effective word length. If an ENOB claim is made, the stimulus

Copyright 2026, James M. Atkinson

amplitude and frequency, test bandwidth, SINAD method and equipment configuration must be specified, as the applicable converter-test framework demands. The claims for simultaneous averaging and interleaving should be separate because they concern different physical operations.

The covariance measurement is not an academic decoration. Before approving a sixty-four-channel noise-reduction claim, the laboratory should record individual-channel residuals under a common calibrated input and estimate cross-channel correlations under multiple independent test conditions. A common clock perturbation or reference-rail disturbance may yield a nonzero covariance structure. The ideal σ^2/N expression assumes away those correlations; it may be a useful limiting benchmark, but it is not a fit-for-purpose acceptance rule when the observed residuals have substantial common structure. Introduce an independent controlled common disturbance and see whether the reported gain degrades as the model predicts. If the vendor instead treats every residual as uncorrelated by assumption, the demonstration has not tested the central assertion.

The phrase thirty-two-bit performance should be unpacked until it has an operational meaning. It may mean the software exports thirty-two-bit floating-point numbers, that an accumulator uses thirty-two fixed-point bits, or that a narrowband estimator exhibits a variance approaching the value associated with a high ideal-bit benchmark. Those are not equivalent. The buyer should ask for the actual number of nominal ADC codes, the measured ENOB at the relevant input frequencies and amplitudes, and the confidence interval for any claimed ensemble gain. An improved amplitude estimate for a stable tone does not automatically confer increased instantaneous dynamic range for multiple interfering signals. If a shared

Copyright 2026, James M. Atkinson

analogue stage clips under a blocker, the output's many decimal places may merely give a precise number for distorted input data.

A useful acceptance report should be designed to survive an unfriendly independent laboratory. It should include raw per-channel streams, equipment configurations, timebase and reference-plane records, source uncertainty, dither conditions, combination weights and versions of all processing code. The test should explicitly include a condition selected to challenge correlation, a condition selected to challenge distortion, and a condition selected to challenge temporal fidelity. A failure in one condition does not erase a genuine improvement in another; it limits the scope of the claim. The strongest report will therefore say exactly where the array helps and where it does not. That is more valuable to a forensic practitioner than a universal proclamation of thirty-two effective bits which no physically independent experiment can substantiate.

Claude Elwood Shannon, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, suppose an SDR application receives sixteen streams of nominal twelve-bit converter codes, applies a calibrated set of weights and writes a thirty-two-bit floating-point stream. A later forensic report describes the output as thirty-two-bit sampled RF evidence. The computation may be bitwise reproducible from the saved files, yet the recorded precision can substantially exceed the physical confidence justified by the source waveform and analogue calibration. What controls can a digital processing pipeline implement to prevent the output word format from becoming an evidential claim about amplitude resolution? I would also ask how to protect the distinction between raw observations and derived estimates when a firmware upgrade changes the arithmetic rounding policy. Please explain

Copyright 2026, James M. Atkinson

how sample masks, source hashes and calibration revisions can be used without suggesting that cryptographic integrity can authenticate the analogue waveform or fix a defective original measurement.

Richard Wesley Hamming, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, the first safeguard is an explicit data model with distinct fields for native ADC code width, storage representation, arithmetic accumulator precision, combined-output representation and measured performance. If an application writes thirty-two-bit floating-point values derived from twelve-bit inputs, it should state exactly that. The output type is a software choice. It has no authority to represent the original analogue amplitude uncertainty, which must be assessed separately. Reproducibility means that an independent implementation can trace the transformation from preserved inputs to derived output under specified rules. Scientific validity requires further evidence that the analogue source was properly measured. A technically accurate interface should make this separation visible rather than bury it in a footnote.

The processing pipeline ought to save a versioned manifest describing channel ordering, input signedness and endianness, sample rate, clock epoch, calibration coefficients, averaging weights, missing-data policy and numeric rules. A firmware upgrade which changes rounding or scaling should create a new identified processing revision, not silently overwrite the historical interpretation of the file. Where the original code streams are retained under appropriate authority, protected digests can help detect subsequent changes to those bytes. A separate protected manifest and custody ledger describe the acquisition and later transformations. A file hash tells us about continuity from the reference hashing event, not the

Copyright 2026, James M. Atkinson

truth of the acquisition claim. A converter could hash an inaccurate measurement as faithfully as an accurate one.

I would add machine-checkable invariants. In simultaneous mode every combined output must identify the acquisition epoch and valid contributing channels; weights must be applied in the declared order and sum to the intended value within a specified numerical tolerance. In interleaved mode the sequence must reflect actual distinct apertures, not a convenient post hoc timestamp assignment. Every overflow, saturation flag and sample gap should be exposed to the analysis code. A software process that removes a clipped channel without retaining the validity mask may change apparent signal amplitude in exactly the interval the investigator is attempting to interpret. Each derivative must state the data discarded and the reason for discarding it.

For acceptance I would require an independent implementation, boundary-value arithmetic tests and physical reference captures. First show that the stored code words are interpreted correctly; next show that the algorithm reproduces the intended mathematics; finally show that the overall apparatus measures the test waveform within the declared uncertainty and dynamic operating limits. Passing one step is not passing the others. The final report should publish a narrow, useful result such as a measured one-bit improvement in a specified stable-signal estimator, while retaining the warning that the analogue observation did not become a thirty-two-bit physical sample. That phrasing is both technically useful and robust under critical forensic questioning.

Dr. James M. Atkinson, Moderator: Dr. Hamming, we now turn to the digital representation and the integrity of the combining algorithm. I invite you to

Copyright 2026, James M. Atkinson

challenge claims based on nominal word length rather than tested analogue performance.

Richard Wesley Hamming, Fifth Principal Contributor: Dr. Atkinson, I shall examine how an array can create a misleading appearance of precision after conversion. A floating-point accumulator may represent a mean to many decimal places, and a fixed-point signal processor may assign thirty-two bits to a result formed from twelve-bit inputs. Neither output format establishes that the physical estimate has thirty-two bits of accuracy. Digital arithmetic offers range, scaling and rounding control; it does not erase the uncertainty introduced before the data reached the processor. I would teach investigators to separate three layers: the recorded code words, the processing representation, and the physically supported measurement. If those layers are conflated, a perfectly reproducible computation can yield an overconfident statement about a hidden radio source.

Consider sixteen twelve-bit signed input codes in a simple averaging algorithm. Summing sixteen positive raw magnitudes can require additional accumulator bits to avoid overflow; division by sixteen may then yield fractional results if a fixed-point scaling convention is used. The accumulator's extra bits describe arithmetic headroom and representational detail. They are not themselves evidence that each converter identified an extra set of analogue thresholds. If all sixteen channels return the same code due to common-mode error or identical quantisation, the mean returns that same code even if the software writes it with twenty-four or thirty-two bits. The file's resolution field should therefore distinguish physical code width from processing word width, and neither should be used as an unqualified statement of ENOB.

Copyright 2026, James M. Atkinson

The numerical combination needs its own error budget. An implementation can overflow, silently saturate, round too early or use weights which cease summing to unity after fixed-point quantisation. Channel order may be altered during file loading, or complex I/Q samples may be averaged after one channel has its quadratures reversed. A small systematic defect can generate a smooth spectrum with plausible detail. The appropriate controls include known input patterns, boundary cases at full scale, negative and positive signed extremes, missing sample flags, endian conversion, and comparison with a higher-precision independent implementation. A successful bit-exact repeat of the same faulty routine is reproducibility, not validation. The test must reveal why the result is physically correct under stated assumptions.

I would also distinguish averaging from error correction in communications coding. Redundant digital codes can detect or correct some storage or transmission errors under a specified code and fault model. But a parity check on digitised sample words does not reveal an analogue voltage which the converter measured inaccurately. If two digitiser channels disagree, it may be because their analogue gains differ rather than because one stored a wrong bit. A coding-theory routine can protect the custody of recorded bytes, yet it cannot infer the missing analogue truth merely by checking a checksum. Those propositions have different evidential foundations. In a forensic workflow the original byte records, clock and calibration logs, processing code and evidence-transfer hashes should be preserved as distinct items.

The algorithm should also report how many genuinely valid samples contributed to each output. A naïve mean may divide by sixteen even if four

Copyright 2026, James M. Atkinson

channels clipped or lost a buffer. That result is biased unless the missing-data rule and estimator account for the resulting selection. An algorithm that silently discards saturated channels can make a transient appear weaker than it was, especially if saturation is linked to high amplitude. Conversely, a majority vote across converters with a common disturbance provides no protection against the common event. I propose a validity mask per channel and sample epoch, a count of accepted contributors, and a reason code for every exclusion. Where the mask changes rapidly, the investigator should check whether the apparent waveform feature belongs to the physical source or to the adaptive composition of channels.

Calibration coefficients introduce further numerical hazards. A gain table stored with a limited precision may create discontinuities when the input crosses a frequency or temperature boundary. An update to firmware can change coefficient interpretation, numeric scale or rounding behaviour while retaining the same apparent channel count. Thus, the reproducibility manifest must specify converter identity, sampling mode, analogue gain, calibration revision, software and firmware versions, processing order, input data types, numeric precision and rounding rules. If a later analyst recomputes the output using a revised table, the resulting difference should be recorded as a derivative and not silently substituted for the original. Computational accountability is particularly important when the report's conclusion depends on a weak feature near the detection threshold.

A controlled demonstration can expose errors that a single smooth spectral trace conceals. Feed a stable authorised reference waveform, deliberately reverse one channel's I and Q ordering, introduce one saturated block, and change the gain of another channel by a small known factor. A correct

Copyright 2026, James M. Atkinson

evidence pipeline should flag each anomaly, maintain the original records and report the consequences for the mean and the measured SINAD. Next, switch from simultaneous acquisition to time-interleaving without changing the reporting template. If the template continues to print an invented twenty-four-bit physical resolution, the fault lies in the interpretation layer as well as the software. The instrument must describe which hardware experiment occurred before it can describe what the numerical result means.

I should insist on an independent set of acceptance tests. The engineer who writes the combining algorithm should not be the only person who selects the examples on which it succeeds. Blind laboratory cases should include correlated noise, coherent spurs, input frequencies near the analogue bandwidth boundary, clock skew, clipping and deliberate dither. The outcome should be compared against predefined amplitude, spectral and timing tolerances. The engineer may quite properly improve a processing routine after seeing a failure, but that adjustment creates a new version requiring a new confirmatory test. A cryptographic hash can establish that the tested file has not changed since a trusted digest was made; it does not certify that the algorithm or analogue model was sound.

My final answer is that a parallel ADC array can be a valuable receiver technique, but its output must be labelled with epistemic restraint. Use the full arithmetic word length needed to avoid numerical errors, and measure the actual uncertainty and dynamic performance of the physical acquisition chain. If the apparatus uses sixteen nominal twelve-bit converters, report that architecture accurately. If an appropriately calibrated simultaneous ensemble achieves an empirically verified gain of, say, one or two effective

Copyright 2026, James M. Atkinson

bits for a particular narrowband estimator, report that conditional result and its uncertainty. If time-interleaving increases tested coverage, report its bandwidth and distortion limits instead. No conjunction of code words should be mistaken for a new physical measurement. I pass the token to the peer investigators to test these claims under the least convenient conditions.

Grace Brewster Murray Hopper, Peer Question: Dr. Hamming, the preserved samples may be as sound as the hardware permits, yet software can invent a resolution claim by repackaging data. An instrument might deliver signed twelve-bit samples stored in sixteen-bit containers, then combine sixteen channels into a thirty-two-bit floating-point stream with an automatic gain correction. The user interface might display thirty-two bits beside a beautiful waterfall, concealing that some channels were discarded after clipping or that the sampling mode changed without updating the metadata. What exact machine-readable fields and software acceptance tests would you insist upon before a later investigator can reproduce and interpret that result? How should the file distinguish an original recorded code from a derived estimate, and how would you respond when a vendor offers only the combined data rather than the individual channels and the calibration history? Please consider the possibility that a bit-exact output can remain scientifically false.

Richard Wesley Hamming, Response: Admiral Hopper, I would insist on a versioned acquisition contract as well as a versioned processing contract. The acquisition record identifies each converter channel, its native nominal code width, signedness, storage packing, sample rate, aperture relation, analogue gain, input range, clock reference state, calibration identifier and

Copyright 2026, James M. Atkinson

any overflow or invalid-sample conditions. It also records whether the channels sampled simultaneously or were deliberately staggered for interleaving. The processing record identifies the transform from source streams to output values, including weights, validity masks, numeric representation, rounding, clipping rules and software or firmware version. A thirty-two-bit floating-point output should be labelled as such, but never substituted for a physical ENOB claim. The metadata should make it possible to tell whether extra storage digits represent arithmetic detail, a calibrated statistical estimate or merely zeros appended to a narrower code.

I would make the original separate-channel records immutable once captured for a legally authorised test, calculate protected cryptographic digests at a documented custody point, and record all subsequent derivatives with their own identifiers. A laboratory that receives only a combined data file may be able to reproduce the vendor's final numerical output, but it cannot necessarily inspect whether one contributing channel clipped or whether a common reference disturbance affected all channels. That limitation must appear in the report. Where privacy or storage restrictions make full preservation impossible, the test plan must define a defensible minimal dataset and record precisely which independent verification questions can no longer be answered. We cannot treat absent information as though it were silently available.

The acceptance suite should include bitwise fixtures that detect signedness and endian mistakes, arithmetic fixtures at minimum and maximum code values, tests for overflow, and deliberately introduced sample gaps. It should also contain physical laboratory references at more than one amplitude and frequency so that numerical correctness and analogue

Copyright 2026, James M. Atkinson

validity are challenged separately. The software must reject an impossible operating mode rather than quietly assign a new sample rate to old data. It should preserve an audit log if an algorithm discards a clipped channel or changes its weight. A correct output for a nominal case is not sufficient when the system fails exactly on the high-amplitude transient the investigator most needs to understand.

A bit-exact repeat does have evidential value, but its value is narrow. It shows that the recorded input and a specified computation can yield the same output under the controlled environment, if the provenance claims are trustworthy. It does not show that a clock was stable, that the converter possessed the asserted analogue resolution, or that the alleged RF emitter existed. The scientific validation uses independent reference measurements and falsifiable performance criteria. The provenance record explains what the software did; it does not grant the instrument infallibility. I would encourage the report to present raw-code width, processing width and measured effective dynamic performance in separate fields, ensuring that a reader never confuses a thirty-two-bit file format with a thirty-two-bit physical observation.

Richard Wesley Hamming, Cross-Peer Question to John Bardeen: Dr. Bardeen, I should like to return from numerical software to the hardware claim that began our discussion. If an engineer assembles two nominal fourteen-bit ADCs on one input, advertises their combined output as twenty-eight-bit resolution, and then points to a narrowband averaged spectrum as proof, what minimum set of experiments would allow us to issue a precise corrective conclusion rather than a merely rhetorical objection? The architecture might use simultaneous apertures, deliberately staggered

Copyright 2026, James M. Atkinson

sampling, independent dither or some mixture of those modes. How should the investigator classify each, measure the actual improvement and report the limitations imposed by common noise, gain mismatch, quantiser correlations and jitter? I would also ask how the conclusion should change when a customer is chiefly interested in brief low-level signals next to strong blockers, rather than a stable sinusoid for which elaborate averaging has been optimised. Please state how you would avoid turning a failed test into a universal statement that parallel ADC systems can never help.

John Bardeen, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, the corrective conclusion should be expressed positively as a tested physical relationship. First, document the actual sampling architecture. Two simultaneous converters on one input supply redundant estimates at approximately the same aperture; two staggered converters may instead produce a higher aggregate temporal sample rate if the analogue and timing conditions permit. If the apparatus switches between modes, each mode requires independent acceptance criteria and provenance. The advertisement twenty-eight-bit resolution is unsupported unless the seller defines a specific statistical or dynamic measurement by which it could be challenged. It should not be inferred by concatenating two fourteen-bit output strings, because the number of storage symbols is not the number of analogue thresholds actually distinguished.

I would begin with individual-channel characterisation using a traceable input and documented test conditions. Measure each converter's gain, offset, noise, distortion, effective dynamic performance and sample-aperture behaviour across the relevant bandwidth and temperature range. Then test the combination. In simultaneous mode estimate cross-channel

Copyright 2026, James M. Atkinson

covariance and compare the measured error reduction with the prediction under independent and correlated noise models. In staggered mode verify actual aperture offsets, anti-alias response, timing-skew spurs and end-to-end acquisition continuity. For either mode, deliberately introduce a shared clock disturbance, a common blocker and a channel-specific mismatch, and verify that the outputs respond in a physically explicable way. Preserve all original streams and the processing version for independent reconstruction.

The two-channel ideal gain is modest. For two independent channels whose relevant errors have equal variance, an equally weighted mean halves error variance and ideally improves power SNR by 10log10(2), approximately 3.01 decibels. In the simplified effective-bit convention this is about half a bit. It is not fourteen additional bits. If the errors are fully correlated, the mean offers no reduction of that shared component. A laboratory can verify those predictions in a controlled scenario without pretending that they cover every possible input. One should also report whether SINAD improved, because distortion and common jitter may prevent the simple SNR reduction from becoming an ENOB improvement.

For short signals near blockers, the test objective must be changed accordingly. Inject known low-level pulses next to controlled strong signals, record the input with an independent reference, and vary observation timing, pulse width and front-end gain. Compare sensitivity and false alarms against the single-channel baseline, while retaining saturation, recovery and clipping records. An improved stable-tone amplitude estimate may coexist with poor pulse detection after overload. If the combined array fails a particular test, report that operating limitation; it does not establish that all parallel converter designs are worthless. The scientifically defensible

Copyright 2026, James M. Atkinson

conclusion is that some forms of independent-noise averaging or time interleaving can provide measured benefits under explicit assumptions, whereas arithmetic addition of nominal bit widths does not itself establish a higher-resolution physical measurement. I return the token respectfully.

Dr. James M. Atkinson, Moderator: My thanks to the panel for its attentive and respectful examinations. We have distinguished simultaneous noise averaging, time interleaving, digital accumulator width, effective converter performance and lawful evidential conclusions. The principal engineering result is conditional. Independent errors can be reduced under a validated covariance model; common analogue distortion, clipping, reference uncertainty and unmeasured aperture defects are not abolished by joining converter outputs. The expert witness should describe the tested receiver, waveform, bandwidth, uncertainty and limitations rather than announce a synthetic 24-bit or 32-bit physical converter.

SCHOLARLY RECONSTRUCTION AND REFERENCES. The foregoing modern exchange is an explicitly fictional pedagogical reconstruction involving deceased historical specialists and is not a quotation, transcript or attribution of contemporary knowledge to those individuals. Technical background for separate source-to-claim review includes IEEE 1241-2023, IEEE Standard for Terminology and Test Methods for Analog-to-Digital Converters (https://standards.ieee.org/ieee/1241/6797/); Behzad Razavi, Problem of Timing Mismatch in Interleaved ADCs (IEEE Custom Integrated Circuits Conference, 2012, public manuscript https://www.seas.ucla.edu/brweb/papers/Conferences/BRCICC12.pdf); and the general sampling, estimation and quantisation principles. A later independent source review must establish precise correspondence, editions

Copyright 2026, James M. Atkinson

and rights before publication. No claim of field-detected external emissions or verified operation of a particular hardware array is made.

EDITORIAL QUALIFICATION. All apparatus, observations and numerical examples in this discussion are hypothetical educational exercises, not measured results. The ideal averaging equations assume zero-mean errors, a stated covariance structure, fixed signal power and appropriate frequency-dependent measurement conditions. ENOB requires a defined test waveform and procedure; reference, dither, clock, analogue overload and software limits must be measured on the actual apparatus.

QUESTION 102

Copyright 2026, James M. Atkinson

How should ultrawideband SDR capture balance instantaneous bandwidth and usable dynamic range?

Dr. James M. Atkinson, Moderator: Dr. Kroemer, I invite you to consider the contemporary desire to capture several hundred megahertz, or even wider swathes, of radio-frequency spectrum in one observation. The bright waterfall and large sample-rate numeral may suggest comprehensive technical-security coverage, yet a modest signal may be eclipsed by analogue overload, a poorly controlled noise floor, finite dynamic range or a disk recorder which silently loses samples. Explain how a lawful defensive survey should define the usable instantaneous bandwidth of the entire measurement chain, rather than accept the converter clock and storage specification in isolation. Please consider the weakness of nominal ENOB as an all-purpose sensitivity promise, and propose a controlled experiment in which a faint authorised signal is presented beside a much stronger interferer.

Herbert Kroemer, Principal Contributor: Dr. Atkinson, I would distinguish spectral access from physical knowledge. The capacity to produce a digital sequence containing a wide band of frequencies is a real engineering achievement. Yet the proposition that every relevant signal within that band can be detected, characterised and supported by defensible evidence is quite another assertion. From the antenna terminal through the last digital decision, the system contains amplifiers, switches, filters, converters, clock trees and software resources that determine what can actually be observed. A wide digital display is only the visible end of that physical chain. We should first declare the reference plane at which a signal level is specified and the test conditions under which the claimed performance applies. A receiver

Copyright 2026, James M. Atkinson

connected to a mismatched antenna in a strongly reflecting room is not equivalent to the same receiver driven by a calibrated coaxial reference, however similar their graphical interfaces may look.

At the analogue front end I would begin with the strongest plausible environmental signal rather than the smallest one. A very sensitive preamplifier can be admirable when the electromagnetic environment is quiet. Place a substantial blocker within or near its passband and that same amplifier may compress, generate intermodulation products or recover slowly after a large excursion. The small signal sought by a technical-security investigator may then disappear, and a spurious product can appear elsewhere in the spectrum. An increase in nominal instantaneous bandwidth may worsen the risk if the preselector becomes broad enough to admit more energetic interferers into the same nonlinear stage. The question is not whether greater bandwidth is intrinsically bad. The question is whether the front end preserves the weak authorised reference under a specified set of stronger signals, with measured limitations rather than convenient assumptions.

The digitiser adds another layer of qualification. A converter's advertised sample rate describes how often its aperture operates, under stated conditions. Its full-scale input range, analogue bandwidth, sample clock quality, linearity and effective number of bits determine what those samples mean. For a full-scale sine test, the traditional idealised resolution relationship provides a useful comparison, but it does not grant the same effective sensitivity to a pulse alongside a blocker. The strong signal can consume much of the converter's available range, leaving a small disturbance represented by only a few uncertain codes or masked by

Copyright 2026, James M. Atkinson

distortion. If a converter clips, the excess amplitude is not restored by later software precision. If a time-interleaved converter uses multiple channels, interchannel skew and gain error may create images that survive even an attractive digital filter. I would therefore ask for SINAD and spurious-free dynamic range across input frequency, amplitude and operating mode, not just a catalogue bit-depth label.

A simple thermal-noise calculation illustrates the trade-off when other influences are temporarily set aside. The ideal input noise power in a matched bandwidth B at temperature T is proportional to kTB, where k is Boltzmann's constant. If the effective measurement bandwidth increases by a factor of ten while the relevant noise spectral density remains approximately flat and all other conditions fixed, the integrated noise power increases by ten decibels. That relationship does not mean that every detector becomes ten decibels worse. Narrow sub-band filtering, coherent integration and suitable detection statistics can recover sensitivity for a known signal model, but those operations must be disclosed as processing conditions. A statement about a wide instantaneous capture and a statement about narrowband post-processed detection sensitivity should not be fused into one unqualified instrument specification. They refer to different stages of the inference.

Storage and transport are equally material. Suppose one complex IQ sample is stored as a sixteen-bit signed I component plus a sixteen-bit signed Q component, and the receiver produces one hundred million complex samples each second. Each complete sample occupies four bytes, yielding a nominal data rate of four hundred million bytes per second, or 400 decimal megabytes per second, before headers, timestamps, metadata, error-

Copyright 2026, James M. Atkinson

correction records or file-system overhead. If four such channels are simultaneously recorded, the nominal raw rate is 1.6 gigabytes per second. An apparatus with a fast converter and an inadequate sustained recorder may produce the appearance of continuous wideband surveillance while dropping blocks during the busiest intervals. The investigator needs hardware sample counters, queue-overflow flags and a verified definition of missing data. A later gap in the file is a gap in observation, not evidence that the spectrum was silent.

One might propose an adaptive recording scheme that stores the wideband stream only when an anomaly detector raises an alarm. That may be practical within lawful authority and carefully designed retention rules, but it changes the scientific sample. The preserved dataset then overrepresents conditions under which the detector was already inclined to alarm. We cannot estimate the true frequency of weak non-alarm emissions from the saved alarms alone without knowing the observation schedule, detector miss probability, triggering logic and any unrecorded blind intervals. This selection problem belongs beside the storage equation. A lower data rate is not a free gain in evidential certainty. The system should preserve a protected event ledger identifying when the receiver was active, its configuration, its detection rule and what was or was not saved, while limiting retention of unnecessary communication content.

My proposed laboratory comparison has an independent reference generator producing two authorised signals. The first is a weak controlled waveform whose frequency and duration can be varied, while the second is a much stronger blocker which moves through the input passband and its adjacent regions. A separate monitor, whose own limitations are

Copyright 2026, James M. Atkinson

characterised, records the actual applied reference. The receiving apparatus is tested with several preselector settings, gain distributions, bandwidth modes and recording loads. We should determine whether the weak signal is recovered, whether its measured amplitude and timing remain within specified uncertainty, and whether a new spur follows receiver configuration rather than the external generator. Each trial must retain the actual front-end state and the raw validity flags. The test should include a brief low-level pulse, because the easy case of a continuous tone does not settle the harder problem of intermittent surveillance emissions.

I would repeat that experiment at several temperatures and at the boundaries of the claimed band. In a wideband arrangement the antenna, filters and converter input may have substantially different gain and phase responses near the edges than near the centre. A calibration taken at one frequency cannot simply be projected across the full span without evidence. Similarly, a gain setting that is safe with the blocker absent may overload when the blocker appears. The result should be expressed as a performance envelope: input levels and frequencies for which detection and measurement are supported under stated noise, distortion and acquisition-continuity limits. Outside that envelope the system may still be useful for exploratory observation, but the operator must not transform an untested region into an assertion of complete coverage.

I would insist upon a final distinction between the visible waterfall and the underlying evidence. A spectral display may show an orderly field of colours after decimation, averaging, clipping or automatic scaling, while the raw acquisition contains saturations, changing masks or missing intervals. An independently reviewed report needs the processing recipe, colour-to-

Copyright 2026, James M. Atkinson

power transformation, window and bandwidth settings, and a way to reproduce the numerical estimates from retained data. If the claim concerns a rare pulse, the file must preserve a meaningful record of the temporal region around its alleged appearance or disclose why it was unavailable. A digital drawing can inform an investigator, but it is not an independent substitute for a calibrated, complete and legally maintained measurement.

My preliminary conclusion is therefore one of engineering discipline rather than technological pessimism. Greater instantaneous bandwidth can be valuable when it reduces retune blind time and allows observation of signals whose frequencies were not known in advance. Its benefit must be balanced against analogue blocker tolerance, dynamic range, preselector response, clock integrity, sustained data throughput and the detector's operating characteristics. The same design may be excellent for discovering the presence of broad spectral activity yet poorly suited to accurately measuring a weak transient next to a large adjacent signal. I would invite Mr. Hewlett to develop the acceptance specification, Dr. Bardeen to examine converter noise and front-end dynamic range, Dr. Nyquist to review sampling and aliases, and Dr. Slepian to challenge the detection and finite-time inference. Each should confront the instrument with a test likely to expose its limitations rather than a demonstration selected to flatter its nominal specifications.

Lord Rayleigh, Peer Question: Dr. Kroemer, a receiver engineer may proudly report a spectrum that appears flat across an enormous frequency interval while the actual electric field at an antenna terminal is neither flat nor easily known. The practitioner might then compare the coloured height of peaks at distant frequencies as though each had been transformed through an

Copyright 2026, James M. Atkinson

identical transfer function. How would you separate a genuinely weaker field from different antenna factors, cable losses, filter ripple and gain calibration, especially where the tested frequency lies near a preselector transition band? I should also like you to examine whether a large integrated noise figure provides any useful guarantee about a narrow transient observed in one channel. Please describe a test that could reveal a failure of this supposed equality without requiring the examiner to reconstruct every unknown emitter in the environment. The difficulty is one of measurement, not merely signal display. A physically honest answer ought to expose which variable is a reference quantity, which is the instrument's response, and which remains uncertain.

Herbert Kroemer, Response: Lord Rayleigh, the first task is to reject the assumption that the colours on a waterfall share a universal calibration merely because one software programme painted them. The antenna presents a frequency-dependent response involving effective aperture, polarisation and geometry; the interconnecting network adds insertion loss and mismatch; and the receiver contributes transfer gain, noise and distortion that may change with configuration. Even a laboratory injection at a calibrated receiver connector proves only the response from that plane downstream. A field-strength conclusion demands separate evidence about the receiving antenna and its environment. The controlled measurement should therefore identify the reference plane and provide an uncertainty budget appropriate to that plane. A result reported at the receiver input must not quietly become a result at an unknown physical point in a room.

I would use a set of laboratory reference signals whose frequencies traverse the claimed operating span, concentrating more densely near filter

Copyright 2026, James M. Atkinson

boundaries, gain-transition points and known spurious regions. The sources should be independently measured, attenuators and cables characterised, and receiver gain states fixed for each run. By calculating the difference between known input levels and recorded numerical estimates, we obtain a response map that can reveal ripple, abrupt transitions and compression. Repeat at several levels, including one approaching the detector threshold and another that tests large-signal linearity. If the response is nonlinear, a single gain-correction curve cannot be applied without qualification. If changing the nominal bandwidth changes the response map, both configurations require separate documented states.

The antenna question requires a distinct trial. Compare known radiated reference fields under controlled geometry where lawful and practical, using a traceable reference instrument and sensible allowance for reflections and polarisation. Such a test may establish performance in the chosen geometry, but it cannot guarantee equivalent reception in every furnished room with metal structures and standing-wave nulls. A negative observation should therefore be limited to positions, polarisations, frequencies, detector settings and time intervals actually investigated. Antenna substitution or displacement can be a powerful challenge to a suspected artifact, but the substituted antenna must itself be understood. An unexplained change between antennas is evidence requiring diagnosis, not automatically a proof of external origin.

As for integrated noise figure, it is useful only when the applicable model and measurement conditions are stated. A noise figure measured in one bandwidth and frequency region does not establish the detection performance of an arbitrary transient after filtering, windowing, gain

Copyright 2026, James M. Atkinson

changes or overload. A short burst may have energy distributed across many bins and time samples, so a detector chosen for a persistent tone may fail despite an attractive baseline. I would present frequency-dependent calibration and a separate family of transient detection trials. Each trial would preserve failures, clipped events and uncertain records. Thus the answer to your physical question is not a single grand number but a measured performance surface which a second examiner can reproduce and challenge.

Karl Guthe Jansky, Peer Question: Dr. Kroemer, broad observation tempts the investigator to equate a large photographed spectral span with comprehensive listening. But many natural and industrial radio environments change during the very minute in which a screen is being recorded, and the receiver itself may switch gain, filters or clock states. Suppose a short source occurs only once during a long shift. What records would you demand to decide whether that source lay outside the usable receiver range or simply inside an unobserved interval? Would you retain a time-frequency exposure mask for each channel and identify all receiver restarts, gain transitions, transfer overruns and user adjustments? I ask you also to distinguish a measurement at a fixed antenna position from a claim about an entire building. A careful survey must be able to explain the conditions under which an absence of detection is informative and the cases where it is merely silence from the instrument.

Herbert Kroemer, Response: Mr. Jansky, a comprehensive visual frame is not evidence of comprehensive exposure. A receiver that tunes through a wide range may ultimately show many frequencies, but the time during which any one frequency was actually observed depends upon dwell, retune

Copyright 2026, James M. Atkinson

latency, filter switching, acquisition reset and the detector's processing window. I would record a time-frequency exposure map indicating when each frequency interval was acquired under a valid configuration, separately from the map showing detected energy. Where the sample stream has a gap, a flag should say unavailable, not zero signal. That requirement remains even for a nominally simultaneous wideband system, because transport loss and recording saturation can interrupt observation without obviously changing the waterfall.

The operating log should include the oscillator and clock state, preselector position, analogue gain, temperature when relevant, ADC overflow indicators, sample counters, start and stop timestamps linked to the acquisition clock, and the exact decision statistic used for alerts. An operator's manual adjustment is an event in the evidence record. If an automatic gain controller operates, the gain history is a physical part of the measurement. If an alarm detector suppresses recording until an internal threshold is crossed, a later reviewer needs to know what happened to data below threshold and whether the alarm itself can be replayed. A bounded statement of opportunity is more defensible than an assertion of permanent watchfulness.

A single short event poses a severe inference problem because we do not have repeated observations from which to estimate all probabilities. The survey can nevertheless be tested using independently scheduled laboratory pulses at many start phases and frequencies, including times immediately before and after anticipated transitions. Measure the proportion recovered under stated signal levels and environmental conditions, and do not present the trial frequency as the probability of

Copyright 2026, James M. Atkinson

detection for all possible unknown devices. The result is conditional upon the tested signal family and the observed environment. I would also require deliberate overload trials, since a receiver can be fully running while its front end is so desensitised that the intended signal is effectively invisible.

A building-level claim introduces spatial uncertainty. The receiving location, antenna polarisation, shielding, reflections and potential coupling paths influence what reached the instrument. Moving the antenna or employing an independently monitored reference can test some of those limitations but cannot abolish all possible blind spots. My desired report would say exactly which rooms or positions were sampled, with which antenna and detector configuration, and which periods were valid. If the instrument failed during part of the shift, the examiner should say that it was not observing then. That modest acknowledgement can prevent a much larger professional error: turning a beautiful empty chart into an unjustified statement that a hidden source could not exist anywhere on the premises.

Dr. James M. Atkinson, Moderator: Dr. Kroemer, thank you for defining usable bandwidth against the calibrated receiver and the observed environment. Mr. Hewlett, I pass the token to you for an engineering acceptance specification that distinguishes brief demonstrations from sustained recording.

William Redington Hewlett, Second Principal Contributor: Dr. Atkinson, an acceptance specification is a promise concerning performance under specified conditions, not a decorative collection of maximum values taken from incompatible laboratory trials. The procurement officer may ask for a very broad capture aperture, the radio engineer may seek a high spurious-free dynamic range, and the forensic examiner may need defensible

Copyright 2026, James M. Atkinson

amplitudes for short signals. These requirements cannot responsibly be combined by choosing the most flattering number from each catalogue line. A receiver is a chain of physical transformations. An acquisition claim must identify the antenna or calibrated input reference plane, the frequency region, the installed analogue filters, the gain state, the sample-rate and clock state, the ADC input scale, the digital channeliser, the selected analysis bandwidth, the duty cycle and the condition of the storage path. Only then does the word usable acquire a testable meaning.

I would write separate pass criteria for detection and measurement. A receiver may reliably raise a timely alarm when a signal of known class appears, yet its amplitude estimate may be biased by filter ripple, an uncorrected antenna factor or the automatic gain-control response. In the detection trial I would specify a family of authorised laboratory bursts and noise conditions, then evaluate the empirical probability of detection against a fixed false-alarm policy. In the quantitative trial I would use calibrated steady sources and independently characterised short pulses to determine amplitude error, timing uncertainty and distortion under explicit operating states. A single successful sighting of an injected signal says little about a rare-event detector's actual miss probability. Conversely, failing an exact amplitude tolerance does not always make a receiver useless for exploratory detection. The report must state which narrower claim remains justified.

The blocker test is indispensable. Place a faint reference emission at several frequencies across the proposed capture span, and add one strong blocker whose level and separation are controlled independently. Repeat with two blockers to search for intermodulation, and with a pulsed blocker to examine overload recovery. A seemingly improved sensitivity resulting from

Copyright 2026, James M. Atkinson

more front-end gain may reverse as soon as the strong signal appears. There may be a useful gain state in which the weak reference is visible and the converter avoids clipping; that operating point need not be the state with the lowest displayed noise floor in the absence of a blocker. A calibration table should therefore be multidimensional. Frequency, gain setting, blocker amplitude, blocker separation and temperature may all matter. The manufacturer should disclose enough to distinguish a tested envelope from a merely plausible extrapolation.

I would insist that the strongest interferer be monitored by a separate measurement instrument during the trial. If the blocker generator silently compresses, the instrument under examination may appear to have admirable immunity through a failure of the test source. Similarly, the faint generator must not be coupled into the receiver through an unmeasured leakage route. Splitters, attenuators and cables require appropriate characterisation, especially at the edge of a very wide band. A laboratory should retain uncertainty estimates for source level and frequency, and repeat conditions that expose calibration drift. A change of laboratory temperature, reference clock or preselector configuration can invalidate a performance promise without any change in software version. The recorded provenance should tell us which version of the measurement chain was actually tested.

Storage performance is not a secondary clerical matter. Suppose a recorder accepts one channel of complex samples at one hundred million samples per second, each sample represented by two signed sixteen-bit components. Four bytes per complex sample imply four hundred million bytes per second before metadata or file-system overhead. A ten-minute

Copyright 2026, James M. Atkinson

uninterrupted capture would contain two hundred and forty billion raw sample bytes, conventionally 240 GB in decimal units. Several such channels multiply the sustained requirement. A host may write briefly at the requisite rate into a cache while its physical storage fails to maintain that rate over a long run. Therefore the acceptance test must measure sustained writes, not only peak throughput, and must confirm with independent sample counters that all samples arrived. A plausible file length does not prove that zero padding, repeated buffers or hidden clipping were absent.

The duty-cycle calculation must include receiver configuration. A system described as observing a huge aggregate tuning range may spend considerable time switching filters, resetting gain, flushing pipelines or writing metadata. If two simultaneous front ends cover distinct spans, they may offer genuine continuous coverage of both spans, but only if their per-channel performance and recording integrity are demonstrated. If one front end scans between spans, the brochure's union of tuning ranges says little about the probability of catching a brief burst. An acceptance schedule should include short, randomly timed test pulses placed near tuning transitions and record the missed opportunities. One cannot claim continuous observation simply by drawing adjacent rectangles across a frequency chart.

There is a further distinction between a numerical result and a presentation. The analyst who changes an FFT length, window, overlap or colour scale may make a trace look more prominent without improving the instrument's fundamental sensitivity. I would preserve the raw capture where lawful and necessary, the manifest of signal-processing parameters, the calibration factors, and the detection threshold established before the test. A

Copyright 2026, James M. Atkinson

subsequent processing change should generate a new derivative and an explicit reason for the change. This requirement does not forbid exploration. It ensures that exploratory settings are not covertly substituted for the pre-specified confirmatory method. The client should receive conclusions tied to the actual test conditions and the uncertainty that remains.

In summary, an ultrawideband receiver can be a magnificent means of avoiding the blind time inherent in retuning. Its purchase specification should nevertheless require an operating envelope for weak-signal detection under blockers, calibrated measurement across the passband, time and frequency integrity, and storage continuity. I would reject a specification that simply adds sample rate, bit depth and nominal span as though these were interchangeable guarantees. The appropriate system is the one that passes the relevant adversarial trials with documented limitations. Mr. Jansky may legitimately prefer long observational consistency; Dr. Bardeen may require disciplined converter tests; Dr. Nyquist will demand rigorous alias analysis. Their objections should be welcomed because a challenge test that finds a real limit has performed more useful work than a flawless promotional demonstration.

Grace Brewster Murray Hopper, Peer Question: Mr. Hewlett, an instrument builder may prove that a converter can deliver the required sample rate for a short laboratory demonstration and that the host can write a very large file. Yet neither achievement necessarily establishes that every sample in the file came from a continuous acquisition. How would you define a verifiable end-to-end contract among the ADC, FPGA, transport driver, acquisition application and storage medium? Please consider buffer duplication, out-of-order packets, counter reset, cached writes and an operating system whose

Copyright 2026, James M. Atkinson

visible file timestamp marks the close of the archive rather than the first sampling instant. I would welcome a test capable of distinguishing a true RF quiet interval from zeros inserted during a recorder failure. Finally, which elements would you require to be immutable primary records, and which might responsibly be recorded as later interpretations or working derivatives without altering the original evidence? A successful end-to-end test should explicitly distinguish ordinary network congestion from a damaged RF acquisition record, rather than hide them in one error label.

William Redington Hewlett, Response: Admiral Hopper, the most reliable contract begins with the event at the acquisition device rather than the application window. Where the hardware supports it, each buffer should carry an acquisition sequence identifier, a start sample counter, the count of valid samples, a clear indication of any lost or invalid samples, a status record for saturation or clock loss, and an identifier for the currently installed processing configuration. The driver may add transport identifiers, but these must remain distinguishable from the device-native counters. The host application may add receipt and file-write timestamps, but they do not replace sample-aperture timing. A later reviewer should be able to reconstruct the difference between the chronology reported by the acquisition device and the chronology of host processing.

The acceptance trial should deliberately inject one failure at a time. Force a USB or network transfer omission while leaving the ADC running. Simulate a buffer repeated by a faulty driver. Restart the device clock and verify that a new acquisition epoch is recorded. Saturate the file writer under a prolonged load, not merely for a burst shorter than a cache can absorb. Introduce zeros at a controlled software stage in a test branch, and confirm

Copyright 2026, James M. Atkinson

that the final record marks them as synthetic rather than as real measurements of a quiet antenna. The necessary controls should be verified against an independent laboratory recorder driven by a known test waveform. A system that fails to distinguish these cases must disclose that limitation rather than extrapolate continuity from file size.

The immutable primary object comprises the bytes actually exported by the hardware, or the closest supported raw representation, accompanied by preserved native headers and a contemporaneous acquisition manifest. A cryptographic digest can provide strong evidence that those bytes have not changed since the protected reference digest was created, assuming sound implementation and custody. It cannot prove that the ADC originally sampled the correct signal or that its clock and analogue path were calibrated. Working derivatives, such as decimated extracts or corrected time axes, deserve new identifiers and documented transformations. A correction to a processing script must not rewrite the record of what the equipment actually emitted in the earlier session.

I would document the recorder's operating envelope as a matrix of sustained throughput, channel count, storage latency, data format and worst-case acquisition duration. Compression changes the average byte rate, but a variable-rate compressor can produce bursts that overwhelm a transport link even when the mean appears acceptable. One should preserve a per-interval loss register and compare its counts with source-side sample expectations. Finally, the file system's creation and modification times belong to administrative custody, not to the RF emission's physical arrival time. This separation permits a competent examiner to say that the stored sequence has continuity under defined assumptions while

Copyright 2026, James M. Atkinson

recognising that the chronology of the external source remains an independent, testable proposition.

Claude Elwood Shannon, Peer Question: Mr. Hewlett, your sustained-throughput example gives four hundred decimal megabytes per second for a single complex channel, but I want to challenge the temptation to treat that rate as an information-theoretic necessity independent of data representation. If a signal is band-limited, the recording may be decimated after an adequate filter; if its statistical structure is compressible, a lossless encoder may reduce its stored size. How should an engineer separate those possibilities from an unsupported claim that one may discard samples or precision without harming later forensic questions? Can a receiver be specified with a bounded event-preservation guarantee while recording only a subset of its wideband data? I ask particularly about unknown future questions involving weak bursts, and about a protocol that stores alarm-triggered IQ segments but loses the negative evidence needed to assess false negatives and the proportion of time actually observed. The independent monitor and retention policy should therefore be treated as part of the experiment, not administrative conveniences added after the event.

William Redington Hewlett, Response: Dr. Shannon, the arithmetic describes the uncompressed representation chosen in the hypothetical example, not an absolute lower bound on storage for every possible waveform or processing objective. A filter followed by decimation can legitimately reduce the number of samples required to represent a narrower band when the analogue and digital filtering assumptions are satisfied. Lossless coding can represent the same original data exactly in fewer bytes if exploitable

Copyright 2026, James M. Atkinson

regularities exist. But the compression ratio is input-dependent, and neither technique supports the proposition that an arbitrarily unknown future investigation will retain everything it might need. The relevant question is which scientific and legal claims the record is intended to support, and whether the chosen transformations preserve the information those claims require.

I would make the retention architecture explicit before procurement. For certain authorised detections, the instrument may need only event time, frequency, approximate amplitude and a short raw extract with protected configuration metadata. For phase or transient characterisation, longer unaltered IQ may be required. A lower-rate statistical record may support a population-level occupancy estimate but not prove that every short event was captured. The operator should identify the class of claims that can survive each storage mode and avoid claiming equivalence merely because two files lead to similar-looking waterfall pictures. Where a transformation is irreversible, the chain-of-custody record should mark the point at which exact reconstruction became impossible.

Alarm-only preservation requires special caution. If the trigger is generated by the same detector later being evaluated, the saved examples form a selected population. They can tell the examiner about the signal shapes the detector retained, but not, without additional observations and assumptions, how many events it missed. The recorder might preserve periodic random audit windows, aggregate exposure statistics and independent calibration trials while limiting capture of sensitive communications content. Such choices can improve scientific accountability and proportionate retention, but the policy must be lawful and technically

Copyright 2026, James M. Atkinson

justified. The audit scheme must not silently be described as full raw-spectrum continuity if it is not.

Finally, throughput must be verified in the worst credible operating state. Lossless coding may produce poor compression on noise-like data, and a data stream rich in unexpected transients may exceed the performance observed on smooth test tones. A reference file generator can exercise the full storage pipeline under high-entropy input, concurrent channels and prolonged operation. Compare source-side sample counters against received records and log any discontinuity. It is entirely appropriate for a project to choose constrained retention rather than indefinite wideband raw capture. What is inappropriate is to erase the distinction between what was genuinely sampled, what was later selected, and what the remaining bytes can still demonstrate.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, thank you for confronting the recorder with continuity and load tests. Dr. Bardeen, the token passes to you to examine analogue input limits, aperture uncertainty and the use and misuse of converter performance figures.

John Bardeen, Third Principal Contributor: Dr. Atkinson, the broadness of the sampled spectrum does not remove the analogue limitations that precede quantisation. Even a direct-RF ADC receives a continuous electrical signal through a finite-input-bandwidth circuit. Its track-and-hold behaviour, input matching, reference distribution, clock jitter, nonlinear transfer characteristics and electrical protection stages govern whether a modest signal is represented faithfully in the vicinity of a strong one. A broad preselector may grant a large range of accessible frequencies yet expose the input stage to energy from many unrelated services. That energy

Copyright 2026, James M. Atkinson

contributes to voltage swing and to nonlinear products. The ADC's nominal code width cannot recover the part of a waveform that an earlier stage has compressed, nor can any digital algorithm restore amplitudes clipped to full scale without independent, restrictive assumptions.

I would begin with a distinction among several figures often conflated. The quantisation step describes the ideal spacing between adjacent digital codes for a specified input range. Effective number of bits is conventionally inferred from SINAD for a sinusoidal test under stated conditions. Spurious-free dynamic range compares a fundamental tone with the largest relevant spurious component over a declared spectral search region. Noise figure characterises degradation relative to a reference thermal-noise model, when its conditions apply. Blocker tolerance asks whether a wanted weak emission remains detectable or measurable as a stronger unwanted signal is introduced. These metrics are connected through architecture, yet they are not synonyms and should never be interchanged in a technical report. One figure measured at low intermediate frequency cannot simply be transferred to the top of the ADC's analogue input band.

Aperture uncertainty is particularly serious as RF frequency increases. For a hypothetical full-scale sinusoid, a commonly used idealised jitter-limited signal-to-noise relationship is SNR_jitter = minus twenty times log base ten of two pi f sigma_t, provided the small-jitter assumptions apply. Here f is input frequency in hertz and sigma_t is RMS aperture timing uncertainty in seconds. The approximation makes plain why clock purity becomes more demanding at higher frequencies. If sigma_t remains one hundred femtoseconds, the corresponding idealised jitter bound at one gigahertz is about 64 decibels. The same approximation at two gigahertz yields about 58

Copyright 2026, James M. Atkinson

decibels. This is neither an instrument's measured SINAD nor proof that all other noises disappear; it is an illustrative limit that must be combined carefully with other contributions, including uncertainty in the clock specification itself.

Consider a modest narrowband signal that is twenty decibels above the receiver's unloaded displayed noise floor. Add a much stronger blocker. The desired signal could disappear for three very different reasons: actual analogue compression, reciprocal mixing of the blocker against clock or local-oscillator phase noise, or a changed processing threshold that responds to the elevated apparent floor. A digital capture with a thousand frequency bins may make these mechanisms look similar on one heat map. The experiment should therefore record input power, full-scale utilisation, overload indicators, independent reference measurements and changes in gain state, while varying blocker separation in a controlled sequence. If the weak signal reappears when a physically appropriate preselector attenuates only the blocker, that is evidence favouring an overload or mixing mechanism; it is not yet proof of a unique cause without further controls.

The ADC input network itself may create frequency-dependent error. A sample-and-hold stage can have finite linearity and bandwidth, while termination imperfections produce reflections. In direct sampling, analog input bandwidth exceeding the Nyquist interval is not a licence to admit every signal without care. Out-of-band energy can alias into the measured interval, sometimes masquerading as an in-band emission. Bandpass sampling can deliberately exploit aliasing under carefully designed analogue filters, but the sampling plan must prove that undesired bands do not fold onto the wanted one at levels relevant to the investigation. It is a question of

Copyright 2026, James M. Atkinson

filter rejection and known spectral occupancy, not just arithmetic with the sampling clock. The spectrum visible at the digital output must be traced back through those assumptions to a defined analogue input band.

A useful test report should plot a performance envelope rather than one symbolic number. For each of several input frequencies, characterise the minimum detectible calibrated reference in a specified analysis bandwidth, the largest usable blocker level and any spurious components that exceed a chosen threshold. Repeat with different front-end gains and preselector states. Add a short-pulse test whose duration exercises overload recovery and buffer continuity, because sustained-tone ENOB does not settle transient performance. Repeated measurements should permit an uncertainty evaluation, while conditions that produced invalid data must be recorded as such. A report that excludes inconvenient clipped trials will overstate usable dynamic range even if its published measurements are otherwise calculated correctly.

Multi-converter arrays do not escape this discipline. Parallel, simultaneous ADCs receiving the same input may support averaging of independent error components, but correlated front-end distortion and common clock jitter do not vanish merely because the digital words are combined. Time-interleaving several converters can increase aggregate sample rate, but mismatches in offset, gain and aperture delay can create characteristic periodic spurs. Both arrangements require detailed calibration and have different theoretical benefits. It would be improper to announce that four nominal fourteen-bit converters produce a fifty-six-bit converter. A higher accumulator width is merely a numerical representation; effective analogue

Copyright 2026, James M. Atkinson

resolution must be established through measured estimator performance and stated input assumptions.

I would finally warn against treating a high dynamic range measured with an ideal coherent sine source as a guarantee against extremely brief unpredictable bursts. A short event occupies different time-frequency uncertainty conditions, may strike during gain recovery or recording blind time, and can be destroyed by averaging selected for steady carriers. Detection probability must be assessed under a representative event family. That family should include low-level pulses, burst trains, changes in phase, and controlled blocks adjacent in frequency. The independent reference should measure what entered the receiver before we draw conclusions from its output. The conclusion is not that ultrawideband capture must be abandoned. It is that every reported gain in bandwidth must carry an explicit statement of the physical performance lost, retained or untested elsewhere in the chain.

Alan Mathison Turing, Peer Question: Dr. Bardeen, suppose a laboratory's reference test shows a weak carrier below a strong neighbouring tone in one software version but not in another. The FPGA bitstream, digital filter coefficients and FFT routines have changed, while the front-end gain control claims to remain the same. What experiment would separate a legitimate processing improvement from a new instrumental artefact or an overfitted detector? Would you require blind trials whose stimulus identities are not disclosed to the analyst, and would you freeze the decision threshold before comparing versions? Please also address a subtle case: a colour display appears more favourable in the revised version, but the underlying numerical detection statistic remains unchanged. Can the institution claim

Copyright 2026, James M. Atkinson

better sensitivity? I seek a method of falsification that identifies a particular receiver or processing state rather than assuming that repeatable computer output necessarily measures the external field accurately. Please identify which test result could genuinely falsify the claimed improvement, rather than merely disagree with the programme designer's preferred image.

John Bardeen, Response: Dr. Turing, the first step is to separate the source of evidence from the appearance of its display. If the numerical detector output remains unchanged and only a colour map has been altered, the revised picture supplies no evidence of improved physical sensitivity. A shift in display range can improve readability, but one should not misdescribe it as a lower instrument noise figure, improved SINAD or higher probability of detecting short bursts. A genuine processing improvement should be tested against raw data of known provenance, using fixed detector criteria and an independent set of cases that were not used to select the algorithm. The laboratory must state whether it seeks better amplitude estimation, lower false-alarm probability, improved timing, or greater detection sensitivity for a specified waveform class.

I would run a factorial trial in which hardware configuration and software revision vary independently where practical. Record one raw sequence from a controlled front end, then process it with both software versions without changing the acquired bytes. That reveals differences attributable to computation. Separately acquire new data with each hardware or FPGA configuration under independently monitored input conditions. This second experiment can expose changes in analogue timing, input scale or buffering that a software-only replay cannot detect. When the ADC or FPGA itself performs filtering before storage, an apparently identical file format may

Copyright 2026, James M. Atkinson

represent different physical operations. Its processing lineage must therefore include firmware identity and a reproducible description of the operations actually applied.

Blind trials can be valuable if their design is sound. Prepare a balanced family of weak tones, short bursts, blockers, no-signal controls and deliberately induced overload cases, with randomised trial order. Freeze the detection decision rule before revealing which trials contain which signal. Estimate detection and false-alarm rates by condition, including the effects of blocker separation and sample continuity. A detector tuned on the same data used to advertise its performance gives an optimistic estimate unless the selection process is incorporated into the statistical evaluation. Hold-out data or independently conducted confirmation is necessary for a defensible claim about generalisation.

A failure should be investigated at the appropriate layer. If both software versions produce a spurious in-band peak from an unfiltered strong out-of-band tone, aliasing or analogue nonlinearity is a stronger initial concern than FFT implementation. If the raw file is stable but one version produces a shifted frequency estimate, examine sample-rate interpretation, FFT bin mapping and decimation metadata. If the event disappears only after averaging changes, examine the observation window against event duration. No single test proves every hypothesis, but the combination can falsify careless claims. I would report the improvement only when the independent controls demonstrate the specific performance metric, not when the user prefers the appearance of the newer waterfall.

William Redington Hewlett, Cross-Peer Question to John Bardeen: Dr. Bardeen, you have explained why the converter cannot be evaluated

Copyright 2026, James M. Atkinson

independently of the analogue input and clock. I would like to make that explanation operational for an engineering acceptance team. Suppose two candidate systems have equal advertised instantaneous bandwidth, but the first uses a broad direct-sampling input and the second uses segmented analogue preselectors with lower sensitivity to powerful out-of-band sources. The broad system performs better in a quiet room yet fails to detect a faint reference beside a blocker. Which controlled measurements distinguish a failure of analogue headroom from a failure of clock phase noise, and what evidence would justify selecting one system over the other? Please explain whether a 14-bit nominal converter can outperform a nominally higher-resolution converter under the relevant test conditions, and how the report should use ENOB, SFDR and blocker-dependent detection results without pretending that one figure is a complete measure of investigative utility.

John Bardeen, Cross-Peer Answer to William Redington Hewlett: Mr. Hewlett, the first comparison must keep the input stimulus and the reference plane common while avoiding a shared failure in the monitoring equipment. Characterise both systems with known weak tones across their stated bands, initially without blockers, to establish frequency-dependent transfer gain and noise. Then introduce a strong signal with adjustable level and offset. Monitor the input with an independent instrument capable of handling the imposed amplitudes, and observe the receiver's full-scale occupancy, saturation flags, new spectral products and residual noise near the reference. An abrupt increase in distortion products or suppression as the blocker rises may support a nonlinear-headroom explanation; a spreading noise skirt that changes systematically with frequency separation

Copyright 2026, James M. Atkinson

may favour reciprocal mixing. Neither pattern is conclusive alone, so alternate clock reference, filtering and attenuation states to challenge the proposed mechanism.

A converter with more nominal bits can perform worse when its analogue front end or clock is inferior at the operating frequency. Nominal resolution describes the output code width. Its dynamic behaviour depends on noise, nonlinearity, aperture uncertainty, input frequency and the complete receiving chain. A fourteen-bit converter with robust clock distribution and carefully managed gain could preserve a weak wanted signal more faithfully in some blocked conditions than a nominal sixteen-bit part forced close to overload. Conversely, the larger code width may be valuable in a sufficiently quiet and accurately calibrated architecture. Neither proposition is a universal ranking. They require measurements at the intended frequency, signal level and interference state.

ENOB can provide a convenient sinusoidal performance summary when the test is specified, but I would not use it as a surrogate for the probability of detecting a millisecond burst. SFDR reveals the relative size of spurs under a stated spectral condition and search bandwidth, yet a strong blocker may activate new nonlinear pathways absent from the single-tone trial. Blocker-dependent detection results directly address the operational question, provided the false-alarm threshold is fixed and missed trials are counted. I would offer the procurement officer a matrix showing valid operation by frequency, gain configuration, blocker level and duration class, with separate columns for calibration error, dropouts and uncertain findings. The decision then becomes transparent: which failure modes matter to the authorised survey, and what performance has actually been demonstrated?

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Bardeen and Mr. Hewlett, I appreciate the careful distinction between nominal codes and demonstrated dynamic behaviour. Dr. Nyquist, I invite you to examine sampled frequency representations, aliasing and the limitations of digital channel boundaries.

Harry Nyquist, Fourth Principal Contributor: Dr. Atkinson, the phrase instantaneous bandwidth carries a precise mathematical danger when used without the word signal. Sampling theory connects a continuous-time band-limited function to a sequence under ideal conditions. A rate greater than twice the highest frequency is the familiar sufficient condition for reconstructing an ordinary low-pass real-valued signal with an appropriate reconstruction filter, provided the specified band limitation and ideal sampling assumptions hold. Engineers also exploit complex baseband representations and intentional bandpass sampling. None of these theorems alone characterises the sensitivity, overload tolerance or completeness of a practical surveillance receiver. They explain where spectral components can be represented without ambiguous folding, not whether those components were preserved accurately before the aperture.

I would require a written frequency plan that distinguishes the analogue passband, the converter sample clock, the digital frequency axis and the exact spectrum later displayed. A real sample stream at a nominal rate of 200 million samples per second is often associated with a first Nyquist interval of one hundred megahertz, but the usable span is less than or otherwise qualified by transition bands, filter attenuation, analogue input response and the chosen mixing architecture. In quadrature systems complex samples permit a different convenient frequency representation, with signed baseband frequencies extending on either side of zero. The

Copyright 2026, James M. Atkinson

numerical sample rate and the visually labelled bandwidth therefore cannot be equated without specifying the representation, the filtering and the exact frequency translation. The defence against misunderstanding is a recorded signal-path diagram and independent injection tests at frequencies near every relevant boundary.

For a concrete example, imagine a converter sampling at two hundred million real samples per second while a strong unfiltered tone exists at one hundred and thirty megahertz. In an elementary idealised low-pass sampling description, its alias can appear at seventy megahertz. Whether an actual instrument produces that apparent component at a detectable level depends on analogue input bandwidth and anti-alias filtering. If a tested preselector rejects the external tone sufficiently, the alias may be insignificant. If its rejection is poor, software could display a plausible in-band peak that never existed at the nominally labelled input frequency. The investigator should vary sample rate or analogue filtering, where authorised, to test the interpretation. A peak that moves according to the alias equation rather than remaining fixed in absolute RF frequency is evidence favouring a sampling-origin explanation.

Window functions and decimation require equal care. A wideband digitiser can yield many narrow channels through polyphase filter banks, each with finite stopband rejection and transition bandwidth. A strong signal near a channel boundary may leak into an adjacent display, and a very short pulse may be smoothed or partially suppressed by the selected averaging. The detector's result must therefore name the particular digital filter coefficients or verified implementation version, sample rate, decimation ratio and window or analysis kernel. A spectrogram with attractive rectangular

Copyright 2026, James M. Atkinson

frequency boundaries may conceal finite leakage and delays. If the user relies on the display to assert a negative finding, the laboratory must establish which events could have been missed or displaced by the processing chain.

Bandwidth trades can sometimes be made to our advantage. A system might capture a wide band continuously at modest raw sensitivity, preserve the raw samples, and later apply a narrower matched or energy detector to test a specified waveform family. Provided the original recording has not clipped, aliased or lost the event, the later analysis may improve its evidential usefulness. But an averaging or integration operation cannot undo the absence of the original samples. Nor does a sharply reduced resolution bandwidth automatically improve the probability of detecting a pulse whose energy is spread in time or frequency differently from the filter model. A powerful detector is one whose assumptions and error rates are calibrated against relevant controls, not one whose chart shows the deepest coloured background.

There is a special risk at tuning boundaries. A frequency-agile receiver may advertise enormous coverage over time, but the band was not observed continuously if the analogue front end retuned, changed filters or re-established a clock. A brief burst can occur entirely in an unobserved interval. Combining the successive screenshots into a single wide waterfall is a form of presentation, not evidence that all frequencies were simultaneously sampled. I would retain a timeline mask indicating precisely which frequencies were being observed at each instant. Any period that lacks samples must be marked unknown, not quiet. For simultaneous multi-channel capture, one must additionally establish that all channels share a

Copyright 2026, James M. Atkinson

known clock relation and that their data streams have no silent discontinuities.

As to practical acceptance, use a comb of authorised test tones with known frequencies and controlled separations, then add short bursts at selected times and a movable strong blocker. Vary the front-end preselector, analogue gain, centre frequency, sample rate and digital channel plan. The analyst should pre-register expected alias mappings and channel-edge attenuations before seeing the outcome, rather than adjust a favourable interpretation afterwards. Repeat with an independent spectrum reference to detect calibration or stimulus errors. Report any unexplained component as an unresolved observation until an alternative experiment distinguishes external RF energy from an internally created product. There is no shame in recording the limits of the apparatus; the scientific error is to let a numerical frequency label exceed the evidence.

I would conclude that instantaneous bandwidth is a joint property of the analogue filters, mixing architecture, converter and coherent digital processing, constrained by performance tolerances. A nominal sampling rate tells us something essential about representation but not everything needed for a lawful defensive survey. If the goal is to discover extremely rare, narrow emissions, continuous wide acquisition may be valuable because it avoids scanning gaps. If the goal is to measure a faint emission in the presence of a large nearby carrier, a narrower analogue preselection and carefully calibrated gain distribution may yield stronger evidence. These approaches are complementary tools, not rival schools of thought. The correct balance depends on the stated signal hypothesis, the site's actual electromagnetic environment and the validated test conditions.

Copyright 2026, James M. Atkinson

Marvin Lee Minsky, Peer Question: Dr. Nyquist, the investigator may use an adaptive software system to direct wideband observation towards features that appear anomalous. The software could retune a front end, modify channel bandwidth, change processing gain, or prioritise storage of certain spectral regions. Its proponents may call the result an intelligent expansion of coverage, while a sceptic sees a moving and potentially selective observation window. How would you specify the boundary between a physically observed frequency-time interval and a model-generated prediction? Should a system be permitted to interpolate a visually continuous waterfall over gaps caused by retuning or data loss, and if so how ought those pixels be labelled? I also ask how to evaluate a classifier whose training set includes examples produced by the same aliasing or phase-noise artefacts that it later purports to recognise as external emissions. The acceptance report ought to disclose the controller’s observation policy, not merely the apparently successful events it chose to save.

Harry Nyquist, Response: Mr. Minsky, the crucial distinction is between the signal that entered the instrument during a defined acquisition interval and the numerical constructions applied afterwards. An adaptive controller may provide operational benefits by allocating receiver resources towards a region with apparent activity, but it does not enlarge the physical interval during which unobserved frequencies were actually sampled. Its retuning decisions should be recorded with sufficient timing information to reconstruct the coverage mask. A display can interpolate for a clearly marked navigational purpose, but those interpolated pixels must not be used as observations or treated as evidence of a quiet band. If the

Copyright 2026, James M. Atkinson

application cannot distinguish native measurements from model-generated values, it is unsafe for evidential reporting without additional controls.

I would retain a ledger of configuration transitions. Each transition should identify the old and new centre frequencies, analogue filter states, sample rate, decimation mode, software revision, the effective time at which valid acquisition resumed, and any uncertain transition interval. The coverage record must be independent of the detector that triggered the transition; otherwise the system may explain away its own blind spots by presenting only the portions it chose to inspect. For a statistical assessment of overall occupancy, some deliberately randomised observation intervals or a validated sampling scheme may be needed. Adaptive observation is not automatically biased for every objective, but a claim about all frequencies and all times requires assumptions that the raw capture alone may not support.

The aliasing question is equally direct. If a strong out-of-band carrier creates a folded spectral image, a classifier trained on those images may become impressively consistent while learning the instrument's own response rather than the external emitter's characteristics. Change the sampling rate, insert a suitable preselector or substitute an independent receiver, and examine whether the supposed emitter feature behaves like an absolute RF source or a sampling-origin product. Also vary the independent source level and blocker conditions. A robust classifier should disclose its response to these perturbations. Confidence numbers generated by a model are not automatically calibrated probabilities of external origin.

Where the algorithm directs storage, evaluation must include the acquisition decisions it did not make. An audit might inject known pulses

Copyright 2026, James M. Atkinson

into frequencies that the controller initially judged unimportant, then measure how often they were missed during retuning or load shedding. The experiment should count time-frequency opportunities, not only true positives among saved alarms. An attractive adaptive heat map may be useful for navigating a crowded environment, but it must preserve the distinction between observation, inference and prediction. If the controller changes rules after each successful detection, the confirmation tests must be carried out on independently prepared cases. Mathematical sampling conditions still govern the physical data; no intelligent label can repeal them.

Herbert Kroemer, Cross-Peer Question to Harry Nyquist: Dr. Nyquist, I want to test a frequent misunderstanding about raw ADC sample rate. An engineer may place an extremely fast converter directly behind a nominally broadband coupling network, then assume that every RF emission in the displayed band is genuinely external and fully captured. Yet analogue input bandwidth, anti-alias filtering and periodic conversion artefacts may each interfere with that conclusion. Suppose the user sees a stable peak inside a nominal two-hundred-megahertz observation window while an independent receiver sees no such peak at the labelled frequency. What precise changes in sampling rate, analogue filter configuration or input termination would discriminate an alias from a true input signal? Would the same experiment support conclusions about rare transient sources? I should also like you to clarify why digital channelisation can create apparently neat frequency edges even when the analogue preselector's stopband rejection remains inadequate. I would also expect a frequency-plan diagram identifying which input bands were deliberately excluded rather than merely absent from the recorded graph.

Copyright 2026, James M. Atkinson

Harry Nyquist, Cross-Peer Answer to Herbert Kroemer: Dr. Kroemer, the numerical label is the beginning of the inquiry rather than its conclusion. For a real-valued sampler, a continuous input sinusoid at a frequency above the first Nyquist interval can map to a lower apparent frequency according to its relation to the sampling frequency. Changing the rate changes that mapping for many out-of-band inputs, while an actual in-band carrier, after correct frequency-axis recalibration, remains at its absolute RF frequency. This diagnostic requires a known and appropriately stable source or independent reference, because an unknown frequency-agile emitter might itself move during the experiment. Changing the analogue preselector can further test whether the component arises from energy outside the claimed passband; if a suitably characterised filter strongly suppresses the external candidate and the displayed peak disappears, the alias hypothesis gains support.

Input termination and gain tests supply other controls. A receiver-generated spur may persist with a properly terminated input, though some products depend on the magnitude of incoming signals and can vanish when the input is disconnected. A peak that scales with an externally injected test tone can still be a harmonic or intermodulation product, not necessarily an independent RF source. Therefore the laboratory should combine several perturbations rather than demand that one yields a universal answer. Exact filter response and test conditions must be recorded. A change of sample rate can affect clock phase noise, processing workload or converter operating mode as well as the alias mapping; the analyst must not assume that all other variables remain fixed unless the architecture permits them to be measured or controlled.

Copyright 2026, James M. Atkinson

The short-pulse case needs special caution. A transient occupies a broad spectrum and can overlap filter transitions, while the time-domain impulse response of an analogue or digital filter may distort its duration and apparent arrival time. A false peak in one Fourier frame may arise from leakage, a transient overload or a decimation artifact. Repeated controlled pulses of known shape, with randomised timing relative to processing windows, provide a means to characterise what the receiver would produce. One cannot apply the narrowband tone diagnosis uncritically to an arbitrary unknown impulse. Its cause may remain unresolved even after the frequency-axis tests.

Digital channelisation creates rectangular-looking regions because software assigns output channels finite names and grid boundaries. The actual filters have passbands, transition regions, stopband leakage and phase responses. Strong energy admitted by an analogue stage can leak or fold in ways not apparent on the simplified diagram. Consequently the usable bandwidth must be defined by measured rejection, distortion and detection criteria. A visually continuous array of channels does not prove the analogue chain is immune to aliases, nor does it establish that all frequency bins carry equally accurate amplitude information. I would preserve both the frequency plan and the empirical boundary-test results, leaving any untested interval explicitly qualified.

Dr. James M. Atkinson, Moderator: Dr. Nyquist, the panel is obliged to you for separating a sampling theorem from an assertion of a complete field measurement. Dr. Slepian, please accept the token and test the detectability of rare signals under finite observation windows and changing storage conditions.

Copyright 2026, James M. Atkinson

David Slepian, Fifth Principal Contributor: Dr. Atkinson, I would examine this question as a problem of finite observations and inference. A spectrum of extraordinary width provides opportunities to see events that a narrow scanner might miss, but the investigator's conclusion is not determined by the fraction of the tuning scale painted by the screen. The relevant quantities are the observation process, the family of possible signals, the noise and interference model, and the decision procedure. A receiver can collect enormous quantities of data while remaining ineffective against a rare event if its detector was optimised for persistent tones or if its storage collapses during the decisive interval. Conversely, a modest receiver can provide strong evidence about a restricted class of signals when the test conditions and observation opportunities are demonstrably controlled.

The relationship between time and frequency resolution is unavoidable. A short observation interval cannot yield arbitrarily fine discrimination of nearby stationary frequencies without assumptions beyond that interval. Narrowing a spectral analysis bandwidth ordinarily requires a longer effective observation window. Yet a burst shorter than the window may be diluted in an estimator that averages power across the longer interval. It is therefore misleading to optimise a display solely for a beautiful noise floor when the target hypothesis concerns signals lasting a fraction of a millisecond. An analysis procedure should specify the waveform family and duration range against which its detection probability is evaluated, and should preserve enough raw temporal information to test whether a displayed peak arose from one brief excursion or a persistent carrier.

For a detector with a fixed threshold, false-alarm probability and detection probability depend on its test statistic and the distributions under the

Copyright 2026, James M. Atkinson

competing hypotheses. These quantities cannot be read directly from an ADC's bit depth or the width of its captured span. If the receiver searches a million correlated spectral time-frequency cells, even a low per-cell false-alarm rate may create many apparent events, and overlap among FFT windows complicates the count of genuinely independent opportunities. The appropriate laboratory should examine families of injected events at predetermined strengths and randomised start times, retain trials in which the receiver fails, and evaluate both false positives and misses. A detector whose threshold was adjusted after seeing the desired test burst requires a new independent validation dataset before confirmatory error rates can be claimed.

The independent observation opportunity is particularly important for pulsed signals. Consider an authorised laboratory source emitting short bursts with a randomised start phase relative to the receiver's buffer and retune schedule. If the receiver genuinely captures the full relevant band without gaps, the distribution of start phases should not produce unexplained systematic misses. If a scanner's dwell leaves a blind interval, some bursts will land wholly within it. A nominal 100 percent coverage statement based on the union of frequency spans does not measure temporal opportunity. We should report time-frequency exposure as a tested function or mask, and distinguish a valid observation with no detection from an interval in which the receiver did not acquire usable samples. The distinction is essential to any negative survey report.

Data compression offers a difficult trade-off. A recorder confronted with hundreds of megabytes per second may be tempted to save only alarm-triggered excerpts or to apply irreversible quantisation. That choice may be

Copyright 2026, James M. Atkinson

operationally necessary and lawful, but it creates an asymmetric record: positive candidates are retained while silent or below-threshold intervals may disappear. It then becomes harder for a later expert to estimate an unbiased event prevalence or to challenge the detector's false-negative behaviour. A defensible system can preserve lower-volume observation logs, random audit samples, calibration summaries, dropout masks and hashes of critical configuration files while limiting sensitive content retention. Where raw IQ is retained for a narrow legal and scientific purpose, access, duration and disposal controls should be explicit. More recorded content is not automatically better evidence.

The validation matrix should therefore span three dimensions independently: signal strength and morphology, interfering-signal conditions, and acquisition continuity. For example, use weak narrowband tones, short gated carriers and wideband bursts; test them in quiet and blocked conditions; repeat under low and high recorder load. This gives a structured account of failure, rather than one all-purpose detection percentage. The operator should not collapse successful quiet trials and failed blocked trials into a single number that conceals the condition of interest. If the detector remains accurate over one restricted subset, state that subset as the validated envelope. The most scientifically interesting outcome may be a limit surface showing exactly when extra bandwidth ceases to compensate for reduced dynamic range.

One must be attentive also to correlated evidence. Two wideband receivers sharing the same antenna distribution, clock or preamplifier can exhibit the same spurious component. Agreement between them is not necessarily independent corroboration. A well-designed experiment includes an

Copyright 2026, James M. Atkinson

independently powered reference with a distinct front-end chain, alternate preselection or an attenuated input test, and, where feasible, a different antenna position or polarisation. Changing the suspected signal strength while leaving a receiver artifact invariant can illuminate the causal distinction. Without those controls, a coincident mark in two waterfalls may be nothing more than a shared distortion mechanism. The report should describe the correlation assumptions rather than simply count instruments.

My closing position is that a usable wideband capability should be defined as an empirically validated region in frequency, amplitude, interfering environment, event duration and observation time, not as the geometrical area occupied by a displayed spectrum. The error rates and uncertainty of each inference must be stated in terms of the actual conditions. If the instrument is excellent for finding anomalous energy but poor for attributing it, the report should keep those conclusions separate. If it cannot guarantee uninterrupted recording, the analyst should disclose where no valid observation exists. An appropriate conclusion may be modest but durable: a particular reference burst was detected under documented conditions, with an estimated miss rate and calibration limits; broader claims about unidentified emitters or absolute absence were not tested. Such restraint is a strength of technical evidence, not an admission of professional inadequacy.

Edsger Wybe Dijkstra, Peer Question: Dr. Slepian, a system acceptance report sometimes gives one detection probability for an instrument regardless of frequency, event duration, strong-signal environment and recorder load. I suspect that such a scalar hides more than it reveals. Could you define a finite and auditable test suite whose cases cover the principal

Copyright 2026, James M. Atkinson

ways a wideband survey might fail, without pretending that any finite set proves universal absence of unknown emitters? Please describe a record that makes every failed case reproducible: the injected signal, the relevant observation opportunity, the programme state, and the declared reason the test was invalid or unsuccessful. How should the institution distinguish a genuine detector miss from an unobserved interval, and how should it prevent staff from deleting difficult trials after seeing the outcome? The objective is a narrow, trustworthy assertion rather than a grand, untestable assurance. An explicit test oracle would make it harder for the operator to rename a failure as a success after the captured evidence has been inspected.

David Slepian, Response: Dr. Dijkstra, I would treat the acceptance protocol as a specification of conditional claims. Partition the intended operating range into documented frequency regions and representative input conditions, then select distinct signal families: a continuous carrier, a short gated tone, a frequency-agile burst and a wideband transient. For each, vary signal strength, blocker amplitude and separation, duration, receiver gain state and recording load. Include controls with no injected event and with known overload artefacts. The protocol should record what the independent reference says was presented, what the receiver actually observed, and what the pre-specified decision rule reported. The cases must be designed before the principal evaluation so that the experimenter cannot quietly narrow the sample space around favourable outcomes.

A valid observation opportunity requires more than a row in a test schedule. The device must be in a known state, the relevant input band must be acquired, the sample interval must be continuous enough for the statistic

Copyright 2026, James M. Atkinson

being tested, and the reference source must have operated as intended. If the recorder loses samples, mark that trial as an acquisition failure rather than a negative detection, while preserving it in the overall operational reliability assessment. If valid samples are present but the detector fails to alert for an injected test signal, that is a detector miss under the tested conditions. If an injected reference is not independently confirmed, the stimulus validity is uncertain. The laboratory should not conflate these outcomes or erase any from the experimental ledger.

For a finite trial count, even an observed success rate of one hundred percent has uncertainty. Ten successful observations do not justify a universal guarantee that every similar event will be detected, let alone that any unknown hidden transmitter would necessarily be found. The frequency of success should be reported with a suitable statistical interval under an explicit sampling model. Correlation among trials, especially shared gain state, blocked conditions or common storage failures, reduces the amount of independent information. A full survey report should describe the range of conditions investigated and the remaining plausible gaps. If a client requires a particular risk threshold, the decision procedure can be designed accordingly, but the resulting statement must remain conditional on its hypotheses.

The failure record should be immutable in its primary form, with a controlled amendment trail for later interpretation. Include the source programme and calibrated level, trial time, receiver and firmware configuration, sample counters, detection statistics, raw or appropriately minimised supporting data, and a reasoned disposition. If a run is invalid, the disposition should state a demonstrated reason rather than merely

Copyright 2026, James M. Atkinson

noting that its result was disappointing. Re-run cases with a blinded sequence where feasible and retain both original and repeat outcomes. The purpose is not to produce perfect numbers; it is to learn which region of the instrument's performance envelope is fit for its intended investigative use. A wideband system that reports these limits accurately may be more valuable than one promising everywhere-at-once certainty.

Harry Nyquist, Cross-Peer Question to David Slepian: Dr. Slepian, the laboratory has offered a remarkable wideband capture that avoids retuning, but its analysts then average many overlapping Fourier frames to produce a quiet and apparently sensitive waterfall. I am concerned that the observation interval and the detection question have become confused. Suppose a brief authorised burst occupies only a small portion of a long analysis window. How should the survey compare a short-window energy detector with a longer-window spectral estimator, especially if they have different false-alarm characteristics? Can one report a single probability of detection across all burst durations, and what documentation would permit later verification of a negative result? Please distinguish the actual number of independent opportunities from the number of correlated display pixels, and examine what should be said if the storage chain lost samples within the interval where a pulse could have occurred. The challenge must be independently reproducible, with the reference event time and the receiver’s sample validity established in advance of classification.

David Slepian, Cross-Peer Answer to Harry Nyquist: Dr. Nyquist, one detector cannot be called superior without specifying the hypothesis against which it is tested. A long spectral window can offer narrow frequency discrimination for a sufficiently persistent source, whereas a shorter energy

Copyright 2026, James M. Atkinson

window may preserve evidence of a brief event that the long average dilutes. The threshold for each detector should be set according to a declared false-alarm objective and validated on independent cases. If an analyst compares them only at equal numerical thresholds or by the height of their displayed peaks, the result has little scientific meaning. We must account for different degrees of freedom, noise correlation, window response and the signal energy each statistic retains.

I would design a grid of laboratory trials that varies pulse duration and amplitude independently of its start time relative to the analysis frames. Randomise start phases, include events near frame boundaries and retain genuine no-event controls. For each duration class, report the empirical detection rate together with uncertainty and the fixed false-alarm rule. Where trials are correlated by common environmental conditions or overlapping samples, the analysis must not count every heat-map cell as a separate independent replicate. The effective number of independent opportunities depends on the actual estimator and observation design, not the pixel count. Any modelling shortcut to this quantity should be justified by either analytic covariance or a suitable independent calibration experiment.

A single overall probability could be quoted only for a clearly specified mixture of pulse durations, input levels, conditions and opportunities. It should not be advertised as the probability of detecting any unknown transmitter at any time. A future signal may have a duration or morphology absent from the calibration family. For a negative survey result, I would retain the detector configuration, valid observation intervals, tested pulse family, chosen threshold and response curves so that an independent

Copyright 2026, James M. Atkinson

examiner can assess the actual limits. A confidence statement must concern what the experiment tested, not the metaphysical possibility that a source might exist somewhere outside its observation envelope.

If sample loss occurs in an interval that could contain the pulse, the observer did not acquire the evidence necessary to decide whether the event happened. The case must be represented as missing observation, not as a negative detector output. Where a recorder inserts synthetic zeros, the derived data must identify them so that a subsequent spectral estimator does not mistake them for physical silence. Repeating the trial may test the corrected instrument, but it does not retroactively recreate the missing event in the original record. Such disciplined distinctions make a wideband system more scientifically useful precisely because they prevent the attractive appearance of continuity from exceeding the underlying physical evidence.

John Bardeen, Cross-Peer Question to Herbert Kroemer: Dr. Kroemer, I should like to return the discussion from digital outputs to the physical receiver entrance. In a quiet laboratory, the survey team finds a faint reference with generous margin using a broadband LNA. At a site with powerful nearby transmissions, however, the same nominal gain produces spurious signals and suppresses the reference. Should the team immediately increase attenuation, insert narrow preselection, or choose another antenna? Each action changes the effective observation and risks making the before-and-after spectra incomparable. What controls are needed to determine whether the improvement reflects release from overload rather than simply a different calibration factor? Please include the possibility that the stronger signal enters through cables, power distribution

Copyright 2026, James M. Atkinson

or the receiver enclosure rather than the intended antenna terminal. How should such coupling alter the wording of an RF survey finding when the suspected source cannot independently be identified? The same protections must distinguish a genuine environmental signal from a spurious component created within the survey apparatus itself.

Herbert Kroemer, Cross-Peer Answer to John Bardeen: Dr. Bardeen, one should avoid treating attenuation, preselection and antenna substitution as interchangeable remedies. Each perturbs a different part of the chain and can provide discriminating evidence if its consequences are measured. Increasing input attenuation tends to reduce both the wanted signal and the blocker before downstream stages, and may release an overloaded amplifier or converter at the cost of sensitivity. A narrow preselector can preferentially reject the blocker when the desired frequency is sufficiently separated and the filter is suitable. Antenna substitution changes the electromagnetic coupling to the environment as well as the matching and frequency response. These operations must be accompanied by a calibration or a careful relative comparison at a defined plane, otherwise the observer may mistake an ordinary gain change for improved dynamic range.

I would begin by recording the original configuration with a protected observation log and an independently verified weak reference where lawful. Repeat with a known attenuation increment and examine whether the suspect spur changes in a way consistent with intermodulation. A third-order product, under its ideal small-signal assumptions, may change more steeply with input level than a fundamental component, but practical saturation and gain-controlled operation can invalidate simple slopes.

Copyright 2026, James M. Atkinson

Alternate preselection and compare the input-band response using a reference generator. If the weak target reappears while the blocker is suppressed, the evidence favours a receiver impairment in the original broad configuration. It does not alone prove whether the impairment occurred in the first amplifier, the converter or an earlier device without further isolation tests.

Unintended coupling requires separate investigation. A strong nearby signal can enter through an imperfectly screened cable, a power lead, a clock distribution path or the instrument enclosure. Terminating the intended antenna port while the apparent component persists is a valuable clue, although termination itself may alter loading. Moving and shielding the receiver, changing cable routing, substituting an independent supply or employing a second instrument can help isolate the ingress path. Such tests belong to lawful defensive engineering; they need not involve decoding or intruding into another party's communication. The written record should distinguish which paths were demonstrated, which were only suspected and which were not tested.

A report may properly conclude that an observed spectral feature was instrument-dependent under defined perturbations and therefore cannot be accepted as independent evidence of an external source at its displayed frequency. If an independent antenna system and separate receiver subsequently confirm a real field, the finding may be strengthened, but even that does not automatically establish the identity or intent of an emitter. The broader lesson is that dynamic range is a property of a configured chain in an environment, not a fixed virtue stamped on a component. An honest conclusion will say where attenuation or preselection

Copyright 2026, James M. Atkinson

made the measurement valid, which sensitivities were thereby sacrificed, and what uncertainty remains about the unexplained observation.

Dr. James M. Atkinson, Moderator: My thanks to the five principal specialists and to each peer who has challenged the underlying assumptions with appropriate professional courtesy. This fictional educational roundtable distinguishes usable instantaneous bandwidth from catalogue span, calibrates dynamic range under blockers, tests the converter and sampling chain, and treats data continuity and non-observation as evidential constraints. No result here identifies an unknown emitter or authorises collecting protected communication content. The token passes to the editorial team for independent verification, rather than to a premature claim of publication readiness.

QUESTION 103

Copyright 2026, James M. Atkinson

When is compressive sampling of rare RF emissions defensible without a validated sparsity model?

SCHOLARLY RECONSTRUCTION. This moderated dialogue is original fictional academic exposition using deceased historical specialists. It is not an actual meeting, quotation, endorsement, testimony or claim that these individuals discussed modern compressive RF receivers. The experiment numbers are illustrative rather than observed results.

Dr. James M. Atkinson, Moderator: Dr. Slepian, proponents of compressive acquisition rightly draw attention to the efficiency possible when a signal belongs to a class admitting a sparse representation, yet forensic acquisition cannot assume away the exceptional signal it has been commissioned to discover. A technical-security survey may be concerned precisely with unknown rare pulses, broadband transients and emissions which have never been observed by its detector. Please distinguish the mathematical conditions for sparse recovery from the physical guarantee that every relevant RF event has entered a reliable evidence record. I should like a controlled experiment in which the model is deliberately violated, and a reporting rule that prevents a reconstructed empty spectrum from becoming a declaration that no signal existed.

David Slepian, Principal Contributor: Dr. Atkinson, I would begin with the role of the model. Compressive acquisition can be powerful when an observation y is related to a signal representation x by a sufficiently well-characterised operator A, with an appropriate noise term. A formal recovery theorem then needs assumptions about x, A and the reconstruction procedure. Sparsity may refer to a small number of nonzero coefficients in a

Copyright 2026, James M. Atkinson

chosen basis or dictionary; it does not mean that a radio environment is necessarily empty most of the time in every representation. The operator may be a mathematical design on paper, while the real RF chain includes analogue filters, jitter, saturation, unknown coupling, gain drift and finite-word-length arithmetic. A theorem concerning an ideal operator is not automatically a certificate of any one physical recorder. Its hypotheses must be challenged by measurement.

I would distinguish a reconstruction from an observation. A conventional recorder may preserve sample values closely linked to the instrument's acquisition process. A compressive system preserves a lower-dimensional set of measurements and employs further assumptions to infer a candidate waveform. That inference may be excellent for a stipulated sparse family. However, different physical waveforms can produce indistinguishable or nearly indistinguishable compressed measurements when the acquisition operator lacks the necessary discriminating properties for the actual signal class. A display portraying one smooth reconstructed waveform should not conceal the fact that a different waveform may also be compatible with the measurements. In a forensic report, the observable quantities, the assumptions and the reconstructed hypotheses should occupy distinct fields.

An operator can correctly state that an algorithm recovered a set of authorised laboratory tones. Yet that achievement is narrower than a claim that it will recover every brief or unknown emission. Consider a controlled trial with sparse continuous carriers well separated in frequency. Such a family may match a selected dictionary, making reconstruction comparatively straightforward under favourable calibration and noise. Add a

Copyright 2026, James M. Atkinson

short broadband discharge with energy distributed across many dictionary elements, or combine several moving sources whose spectral support evolves unpredictably. The original sparsity premise may fail. Even if the reconstruction produces a graph with no apparent event, that absence may reflect the model's preference for a sparse explanation rather than a lack of electromagnetic energy in the real input. The laboratory must establish its miss characteristics using deliberately unfavourable signal families rather than flattering examples alone.

The forward operator requires scrutiny at the analogue reference plane. If the acquisition architecture uses a set of mixing functions, filters and sampling intervals, each must be characterised for frequency response, timing and linearity. A powerful blocker that drives one analogue stage into compression invalidates a simple linear measurement model. Interchannel phase error can corrupt a matrix assumed to be known exactly. A clock discontinuity can change the relation between measurements even though the software continues to apply an old operator. One should not respond to such failures by changing the reconstruction regularisation until the chart looks credible. The appropriate response is an acquisition-state record and a separate calibration study that determines whether the mathematical model remained applicable during the event.

A low residual is not sufficient proof of physical truth. The equation A times the reconstructed x approximates the recorded y is a necessary consistency check for some models, but it may be satisfied by more than one candidate signal. If the measurements omit distinctions essential to the forensic question, a reconstruction algorithm can return a plausible spectrum while excluding an event not represented by its prior assumptions. The examiner

Copyright 2026, James M. Atkinson

should test uniqueness or stability over a relevant model family, report the sensitivity to regularisation choices and preserve the original compressed measurements. If later developments permit a better reconstruction, the retained raw measurement vector and acquisition manifest will allow a new analysis without pretending that the earlier representation was a direct full-rate observation.

The experiment I would require uses an independently monitored RF source programme in a shielded and authorised environment. Prepare held-out cases involving sparse tones, frequency-agile bursts, short chirps, pulsed interferers and deliberately non-sparse events. Vary amplitude, event duration and start time independently of the compression schedule. Include powerful out-of-band sources to provoke analogue failures, and introduce controlled clock or matrix-calibration perturbations. Each trial should retain what the full-rate independent reference measured, what the compressed acquisition recorded and what the reconstruction reported. The predeclared acceptance criteria must distinguish successful detection, waveform reconstruction error, falsely inferred energy and invalid acquisition. The analyst should not discard trials merely because the algorithm's assumptions were violated. Those are precisely the trials that reveal its real limits.

One might add a blind comparison with a conventional receiver, though both systems must be independently calibrated. The comparison should account for any difference in analogue front end, gain and bandwidth. Otherwise, a superior preselector could make one arrangement look better for reasons unrelated to compressive mathematics. A defensible result might be that compressed capture detects a specified sparse family within

Copyright 2026, James M. Atkinson

measured error limits at reduced storage cost, while its performance for unmodelled impulsive events remains unknown or unacceptable. That is useful engineering knowledge. It does not entitle the surveyor to describe a quiet reconstruction as proof that no emitter was active in an unobserved region.

Finally, there is the evidence-preservation and privacy question. A compressed record may require less storage and can be attractive for lawful minimisation, but it is not automatically a privacy guarantee. The transform may still retain information about protected communication content, depending on its design and the relevant authority. Retained measurements, operator identity, configuration, processing revision, clock state and custody history should be protected in accordance with the specific lawful purpose. A later working reconstruction is a derivative, with its own algorithm parameters and digest; it should never replace the original measurements silently. I would ask Dr. Shannon to examine informational non-identifiability, Dr. Kolmogorov to challenge the stochastic assumptions, Dr. Hamming to investigate numerical error and Dr. Turing to formulate a falsifiable validation programme. Their analysis must preserve the distinction between what the hardware measured and what the mathematician's preferred model permits the computer to imagine.

Herbert Kroemer, Peer Question: Dr. Slepian, I wish to confront the analogue assumption on which the mathematical elegance rests. In an RF receiver the acquisition operator is not a static matrix suspended in a vacuum. Semiconductor gain, junction temperature, input protection, matching networks and blocker-induced changes can alter the relationship between incident electromagnetic fields and the samples from which a

Copyright 2026, James M. Atkinson

compressed vector is formed. Suppose a shielded laboratory demonstrates accurate reconstruction of isolated low-level tones. We then introduce a strong adjacent-band source which changes the operating point of the low-noise amplifier but is largely rejected by the final digital display. The compressed reconstruction still produces a clean narrow tone. What measurements would establish whether its amplitude and timing remain trustworthy? I would also ask what becomes of a proposed sparse-recovery guarantee after a front-end device exhibits memory, recovery delay or intermodulation. Must the operator be re-estimated for every gain state, or can one justify a bounded approximation? Please give an acceptance test that would detect a false quiet interval created before digitisation.

David Slepian, Response: Dr. Kroemer, your example demonstrates why one must distinguish a mathematical sensing matrix from the physical forward measurement map. If a front-end transistor changes gain or phase under strong blocking, a fixed linear operator may no longer describe the entire path. A reconstruction can fit the digitally retained compressed measurements yet incorrectly describe what entered the antenna. The first defence is an independent analogue measurement of the receiver's response across the declared input power and frequency envelope, including combinations of weak target and strong blocker signals. A single-tone calibration at a comfortable operating point cannot bound the response under all relevant two-tone or pulsed conditions. The operator's validity is an experimentally determined region, not a property of a data sheet slogan.

One could maintain a family of operator calibrations indexed by observed gain state and temperature, but that approach is defensible only if the state

Copyright 2026, James M. Atkinson

is recorded at the time of acquisition and the interpolation uncertainty has been tested. If the hardware enters a nonlinear regime, the linear model y=Ax+e should be regarded as invalid until a more suitable forward model has been validated. An engineer may use a local linear approximation within a measured neighbourhood, but must state the maximum perturbation and its consequences for the detection decision. The fact that an optimisation converges does not make the approximation true. It is preferable for a system to flag invalid measurement conditions than to hide the failure behind a plausible reconstructed line.

I would arrange a paired trial with a broadband independent reference recorder connected to a calibrated split of the authorised laboratory source, with each branch's gain and delay measured. Keep the weak target burst constant while varying blocker amplitude, centre frequency, phase relation and temporal overlap. Record the analogue stage's compression indicator if available, its actual gain state, recovery interval and output into the compressive sampler. Repeat the trial with the blocker absent. Compare not simply a reconstructed magnitude peak but an event-detection decision, onset time, amplitude estimate and declared uncertainty. A burst absent from the compressed result but present in the independent reference is a direct observed miss under that condition. It should remain in the statistical denominator, even if the operator specification originally excluded the blocker.

A false quiet interval can also arise when the analogue stage recovers after overload. The trial should therefore schedule events during the recovery period, not only in steady state before and after it. If the system does not monitor or log that period, its report must describe the resulting coverage

Copyright 2026, James M. Atkinson

gap. This is true irrespective of whether we use a sparse dictionary, direct full-rate capture or any other acquisition architecture. The distinguishing point is that compressed sampling requires an additional assumption to infer the unmeasured waveform. We should document that inference separately from what the hardware genuinely acquired. Your proposed challenge would be a strong qualification test and, if failed, a reason to narrow the claimed operating envelope.

Dr. James M. Atkinson, Moderator: Dr. Slepian has distinguished recovery assumptions from directly observed samples. I thank him and pass the token to Dr. Shannon to examine what information the measurement operator can and cannot distinguish.

Claude Elwood Shannon, Second Principal Contributor: Dr. Atkinson, the first mistake would be to treat the numerical size of a compressed record as though it supplied a universal certificate concerning the original electromagnetic environment. A finite collection of measurements partitions the set of possible waveforms into equivalence classes. When an acquisition matrix has fewer independent measurements than the number of unknown coordinates, its null space is generally nontrivial. Two inputs that differ by a vector in that null space can generate the same ideal measurement vector. A constraint such as sparsity may select one candidate from that class, but the selection is a hypothesis about the signal family, not an observation of every possible waveform. In a lawful technical-security survey the question is not whether the reconstructed spectrum is pleasingly sparse. It is whether the observation process retained evidence capable of separating the authorised hypothesis from competing physical events that would materially change the reported conclusion.

Copyright 2026, James M. Atkinson

A specified sparsity level can make a recovery problem tractable when the sensing operator has appropriate properties relative to the basis in which sparsity is assumed. The words 'when' and 'appropriate' carry the burden of the proof. In a textbook, we may show that an ideal random projection preserves relevant geometry for a selected model class with high probability under clearly stated conditions. An actual RF receiver has deterministic filters, nonlinear amplifiers, timing errors, quantisation, channel mismatch and potentially unknown gain changes. Those features mean that the implemented operator may differ from the ideal matrix. A guarantee for the first is not a guarantee for the second. It is especially hazardous to apply theoretical recovery bounds calculated for additive independent noise if the field noise is correlated, impulsive, cyclostationary or dominated by receiver-generated products.

We should distinguish three levels of evidence. First, an analogue instrument generated measurements according to a recorded acquisition configuration. Second, a reconstruction algorithm returned one or more signal candidates using a declared objective function, solver and assumptions. Third, an examiner inferred that some external event did or did not occur. Each transition requires an additional evidential argument. An algorithm that minimises an objective while fitting the measurements does not certify that every relevant alternative has been excluded. Even a zero residual may be compatible with nonunique reconstruction if the sensing operator has a nontrivial kernel. A small residual may merely show internal agreement between a measured vector and the model chosen to explain it. The original measurement vector must therefore be preserved along with a representation of the operator and its calibration uncertainties.

Copyright 2026, James M. Atkinson

The relevant outcome may be detection rather than waveform recovery. Suppose a survey seeks short RF bursts from a known laboratory emitter class. It may be possible to make a reliable hypothesis test on compressed measurements without reconstructing the waveform, provided the detector has been validated on independent test conditions and the false-alarm and miss behaviour are established. But the detection family must be described precisely. If a different, non-sparse short pulse passes through the apparatus during a period when the test is insensitive, an absence of an alarm cannot mean an absence of RF activity. We should test the system on deliberately adverse inputs, including off-model pulses and combinations of emitters, not merely on the examples the reconstruction dictionary already represents.

A concrete counterexample can be constructed without invoking any mysterious transmitter. Let A be a hypothetical 64 by 128 linear measurement matrix, let x be a 128-component representation, and let z be a nonzero element of the kernel of A. Then A(x+z)=Ax. The measurement system cannot distinguish x from x+z on the basis of those 64 values alone. If x is sparse and x+z is not, the sparse solver may select x and dismiss the energy represented by z. Whether z corresponds to a physically admissible analogue waveform is a further question, determined by front-end bandwidth, finite amplitude, temporal support and the actual implementation. The exercise establishes the logical limit of an unqualified no-signal claim; it does not prove that every conceivable kernel vector is physically realisable in a particular receiver.

It would be an error to move the ambiguity into a vague claim about privacy. Fewer samples do not automatically mean that the recording contains no

Copyright 2026, James M. Atkinson

protected information. Depending on the transform and signal family, compressed measurements can preserve enough information for successful reconstruction of content or other sensitive characteristics. Storage minimisation is a valuable engineering option, but lawful scope must be determined separately from transform dimension. An engineer should record the purpose of acquisition, authority, retained data type, access controls and rules for creating derivatives. We should avoid the fashionable belief that a clever mathematical mapping can substitute for the institution's evidential and legal responsibilities.

There is an additional complication when the measurement apparatus adapts to its own observations. If a detector changes its sensing matrix after each tentative trigger, the resulting record is conditional upon earlier data. The saved vector and the final matrix are not enough if the path of adaptation is omitted. One must preserve the configuration history, update rules, clock sequence and any periods during which the equipment did not observe the portions of the spectrum later described as surveyed. A report that preserves only successful reconstructions selectively hides the very conditions under which the process did not produce evidence. I would require a pre-registered experimental design and an explicit classification of successful reconstruction, missed event, false event and invalid acquisition.

Finally, the proper engineering conclusion may be circumscribed yet useful. A particular compressive receiver can be qualified for a defined frequency range, amplitude interval, occupancy model, pulse duration family and environmental envelope. Within that validated envelope, the cost of recording can be reduced while maintaining an agreed detection probability. Outside it, performance may be unknown. Such modest

Copyright 2026, James M. Atkinson

conclusions are not a retreat from mathematics. They are the only faithful translation of mathematical assumptions into scientific evidence. I return the token to Dr. Atkinson with a request that our colleagues press hardest upon the system's behaviour where its assumed signal class fails.

Marvin Lee Minsky, Peer Question: Dr. Shannon, a modern reconstruction system may use a learned sparse dictionary or a generative prior instead of the simple fixed mathematical basis described in many early explanations. Its output can look exceptionally realistic, even when important parts of the signal were not directly observed. How should we explain to a technically sophisticated tribunal the difference between a candidate signal produced by a prior and a directly measured RF waveform? If the model was trained using examples from related instruments, could its apparently successful reconstruction reflect knowledge of that training environment rather than the unknown source? I ask particularly whether presenting one convincing waveform image risks concealing a multitude of alternatives that agree equally well with the retained compressed vector. What controls would demonstrate that a machine-generated reconstruction has predictive rather than merely aesthetic validity, and which conclusions should the expert withhold when the inputs fall outside the model's training domain?

Claude Elwood Shannon, Response: Mr. Minsky, a powerful learned prior does not eliminate the information deficit created by the measurement process. It selects plausible waveforms according to a model acquired from earlier examples. That can be useful for denoising or estimating parameters within a familiar class, but it cannot create independent measurements that were never collected. If several physically different inputs produce the same retained measurement vector, the prior may choose the one it regards as

Copyright 2026, James M. Atkinson

most likely. The result may be visually persuasive without being uniquely supported by the evidence. An examiner must distinguish that conditional model selection from a claim of direct waveform observation. The distinction is as fundamental for a neural reconstruction as for a classical sparse optimisation.

I would preserve the compressed observations and the entire model identification record. That includes training-data provenance, architecture, weights or authenticated weight identity, preprocessing, version, input normalisation and any conditioning variables. A model trained extensively on one antenna, receiver or site might internalise the nuisance characteristics of that environment. Success on captures from the same hardware and room can therefore exaggerate performance in a genuinely different environment. Independent receivers, physical environments and signal generators should appear in a held-out study, with no leakage of highly correlated examples between training and validation sets. The model should also be tested on classes deliberately absent from training and permitted to abstain when it has no adequate evidential basis.

A useful validation should compare reconstructed parameters against independently acquired truth, not against the perceived quality of a displayed trace. Choose quantities relevant to the forensic conclusion, such as onset time, burst duration, centre frequency and phase continuity, each with calibrated uncertainty. Predeclare acceptable error bounds. Introduce controls where training priors favour a signal that is absent, and where the actual event belongs to a rare unfamiliar class. Measure false creation of events as well as omission of true events. If the system returns a single waveform, its report should disclose whether other candidates fit the

Copyright 2026, James M. Atkinson

measurement vector comparably well. Where the problem is nonidentifiable, no choice of attractive output can substitute for new measurements or a narrower inference.

It is also necessary to examine where training or tuning decisions have used the validation results. An algorithm repeatedly adjusted until it passes a particular laboratory test no longer offers an independent assessment on that test set. A final held-out evaluation, controlled by investigators who did not tune the model, can mitigate that problem. Even then the validity applies to the tested domain; it is not a guarantee about all possible unknown emissions. A tribunal should receive an explanation of the assumptions, observed failures and feasible alternatives. A reconstructed waveform may be presented as a model-derived hypothesis, never as an authenticated trace of an event solely because it is coherent or familiar in appearance.

Claude Elwood Shannon, Cross-Peer Question to Andrey Nikolaevich Kolmogorov: Professor Kolmogorov, I should like you to examine the difference between a mathematically defined sparsity assumption and a statistical assertion about the signals likely to occur in a real technical-security survey. Suppose an engineer validates a compressive receiver on a sequence of narrow laboratory carriers, estimates a very favourable recovery rate and then claims that the apparatus provides near-complete monitoring of a building where emitter types are unknown. The engineer may say that sparse occupancy is probable because the observed spectrum usually appears quiet, but the quietness itself is reported by the apparatus being evaluated. How could one avoid reasoning in a circle? I ask also how the conditional distribution of rare broadband impulses should enter the

Copyright 2026, James M. Atkinson

estimate of missed events, and how to report the result when the test population does not represent the field population. Can one give a rigorous bound without pretending that untested signal classes have known probabilities? The answer should separate empirical support from an attractive but unvalidated population model.

Andrey Nikolaevich Kolmogorov, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, the circularity is direct: the compressed instrument's quiet output is being used to establish the sparsity condition that was assumed in interpreting that same output. A valid assessment requires information independent of the candidate recorder. In a controlled laboratory the reference source and its schedule are established by a separate system, and an independently qualified monitor records whether events reached the designated RF reference plane. The candidate's output is then compared to events it did not choose to generate or retain. Where the actual field population is unknown, the laboratory can estimate performance for specified event classes, but it cannot use that estimate as a universal environmental guarantee.

The model must include the probability of an event entering the observation interval, the physical response of the front end and the conditional probability of detection by the compressed algorithm. An event with sparse support may have a favourable detection probability under one calibrated regime, while a broadband impulse may have a much poorer probability. If the population contains an unknown mixture of those classes, an unconditional success rate from a narrow laboratory mixture does not transport without assumptions about that mixture. The report should provide class-conditional performance, the tested envelope and a statement

Copyright 2026, James M. Atkinson

that broader performance is unknown. This may be less rhetorically satisfying, but it is more precise.

A rigorous bound may still be available for a carefully defined quantity. If a physical constraint supplies a known bound on amplitude, frequency support or temporal structure, one can use that constraint in an explicitly limited inference. If no such constraint exists, one should not manufacture a numerical miss bound out of the wish that the environment is sparse. The uncertainty has an epistemic component because the event class itself may be unobserved. Repeating the same selected tones reduces sampling uncertainty for those tones but does not resolve model mismatch for untested waveforms. More repetitions do not cure a defective experimental population.

The survey report should also state the mechanism of its missing observations. An event may be missed because its measurement vector is ambiguous, because it occurred during receiver downtime, because the analogue chain saturated or because a reconstruction prior suppressed it. Each is a different limitation. The institution can improve coverage by changing the experiment, introducing independent observation methods and documenting the exclusion of unqualified intervals. It cannot responsibly transform a statistical model's preference for sparse signals into a categorical declaration about every event that might have existed. That is the boundary between warranted inference and an unsupported assertion of assurance.

Dr. James M. Atkinson, Moderator: Dr. Shannon and Professor Kolmogorov have distinguished mathematical ambiguity from stochastic assumptions. I

Copyright 2026, James M. Atkinson

invite Professor Kolmogorov to develop the problem of unrepresentative rare-event populations.

Andrey Nikolaevich Kolmogorov, Third Principal Contributor: Dr. Atkinson, it would be profitable to begin by exposing the difference between a probabilistic model and the world from which the data are taken. A receiver engineer may say that an RF scene is sparse with high probability. The assertion is incomplete until the probability space, sampling mechanism, observation interval, joint distribution and conditioning information are specified. Sparse at an arbitrary instant is not the same as sparse over a block, nor is sparse occupancy in frequency the same as a sparse sequence of pulses in time. A narrow transmitter that changes frequency rapidly may have few active bins in one short snapshot and many active bins in a longer observation. A broad transient may be rare in time yet distribute its energy across nearly every frequency coefficient. One must not move silently between these descriptions as though the same theorem governed all of them.

An especially dangerous convenience is to estimate the sparsity model using the very records selected by an alarm system. If a detector retains only the compressed measurements that yield plausible sparse reconstructions, then the data available to fit the model have already been conditioned on the desired outcome. The unretained records and the times when the receiver was unavailable become invisible. A statement that most retained captures were sparse may thus be a tautology concerning the selection rule. To infer occupancy or missed-event rates one must know the number and duration of observation opportunities and the conditional probability of retention for the signal families of interest. When the selection mechanism is unknown,

Copyright 2026, James M. Atkinson

the investigator should not report an unbiased environmental frequency distribution.

For rare events the distinction between average and tail behaviour has practical importance. A model may reproduce the mean spectral occupancy or average reconstruction error while missing infrequent broadband impulses. The rare impulse may be precisely the object of the investigation. We should therefore evaluate conditional error given event duration, amplitude, initial time, frequency support, interference and device state. A single averaged success percentage is incapable of describing those dependencies. In a shielded trial, the generator schedule should be randomised independently of the sensing pattern, so the instrument cannot benefit from an accidental synchronisation. Otherwise a demonstration can be successful because of the alignment of two laboratory clocks rather than because the sensing architecture retains the event.

I would add the distinction between epistemic uncertainty and genuine stochastic variability. Some departures from the sparsity model may be observed among many randomly chosen events; others concern an unknown family that has never entered the validation study. One may estimate the former under a proper experimental design. One cannot claim a meaningful population miss rate for the latter merely by repeating known sparse tones. Calibration uncertainty in the realised matrix is a separate matter again. It may be quantified from repeated measurements of reference inputs, yet those measurements may not cover a rare thermal state or nonlinear regime. A proper uncertainty statement should say which uncertainty sources were measured, which were modelled and which remain untested.

Copyright 2026, James M. Atkinson

I suggest an intentionally simple numerical experiment. Consider a hypothetical reference source emitting 1,000 independently scheduled test events, 900 in a predeclared sparse class and 100 in a broad transient class. Suppose a given recorder detects 891 of the sparse events and 20 of the broad events. Its detection fraction for the overall laboratory mixture is 911/1,000, or 91.1 percent. That number conceals the 20 percent success rate for the broad class. If the real survey's mixture of event classes is unknown, the overall laboratory fraction cannot be transported uncritically into an environmental detection probability. The example is an arithmetic illustration, not a measured performance claim. The appropriate table should retain outcomes by class and condition, including the observations that were dropped or invalid.

The investigator must also distinguish the existence of a stable statistical model from the question of whether its parameters can be identified with the available observations. A few good reconstructions can be compatible with many different sparsity rates and event-duration distributions. Prior distributions, regularisation strengths and assumed dictionaries often strongly influence the recovery of low-amplitude components. Their sensitivity should be reported. If changing a plausible model parameter transforms an apparent quiet interval into a plausible burst, the final account should not pretend the quiet interval was an invariant fact. We may report a family of compatible reconstructions and the conditions under which each appears.

I would put model stress-testing into the acquisition qualification process. We should introduce artificially correlated support patterns, transient combinations, intentionally missing samples, uncalibrated channel skew and

Copyright 2026, James M. Atkinson

a known change in the background process. Such experiments are not intended to make the apparatus fail unfairly. They are intended to characterise the domain over which the claimed guarantee has meaning. The study should specify a stopping rule in advance, retain negative and inconclusive results, and disclose the extent to which the selection of training examples influenced the chosen algorithm. An attractive reconstruction after repeated tuning does not possess the same evidential status as a result from a locked algorithm applied to held-out challenges.

For negative-survey reporting, the probability of missing a relevant event cannot be estimated simply as one minus a recovery success rate obtained from selected sparse examples. It depends on the actual class, the observation schedule and the conditions of reception. If a substantial category of physically plausible event has uncharacterised detection probability, the negative conclusion must be qualified accordingly. We should not express a false universal assurance as a numerical percentage with four decimal places. An honest conclusion may establish that the equipment had a specified probability of detecting certain test signals under specified conditions and that unknown non-sparse emissions remain outside the validated scope.

Finally, a record of model failure can itself be valuable science. A trial in which compression creates a false quiet interval teaches more about the instrument's boundaries than ten demonstrations in which reconstruction successfully reproduces the signal dictionary. A mature survey culture preserves those results rather than hiding them as inconvenient exceptions. I pass the discussion to Dr. Hamming, whose discipline of numerical testing

Copyright 2026, James M. Atkinson

may determine whether the software faithfully implements even the model that has been honestly declared.

Jacob Ziv, Peer Question: Professor Kolmogorov, could a variable-length or adaptive compression mechanism alter the apparent prevalence of rare emissions in a manner that is difficult to diagnose from the files it chooses to retain? Imagine a receiver which compresses quiet periods strongly, records alarms at a higher detail level and changes dictionary parameters according to the recent history of the signal. A later analyst sees a rich collection of detected bursts and only brief summaries of the intervening time. Is it possible to infer environmental occupancy from such a record without knowing the retention and adaptation rules? How should the laboratory test whether compression failed systematically for unfamiliar or non-sparse waveforms, and what information would be needed to reconstruct the denominator of legitimate detection opportunities? I would also ask whether effective file-size reduction tells us anything about guaranteed preservation of rare-event timing, rather than merely about the regularity of ordinary background observations. Please distinguish the behaviour demonstrated by controlled tests from properties that the investigator has merely assumed on the strength of a successful reconstruction.

Andrey Nikolaevich Kolmogorov, Response: Dr. Ziv, the retention rule becomes part of the observation mechanism and cannot be ignored when interpreting event frequency. If a system stores detailed records only when its own detector fires, the surviving material is conditioned upon the detection decision. An analyst cannot estimate the frequency of missed events solely by counting the detailed records that happened to survive. The

Copyright 2026, James M. Atkinson

periods represented by summaries may include both genuine quiet time and events that the model did not recognise. If the adaptation rule is unrecorded, a model of environmental occupancy is likely to be underidentified. We must know when the receiver was observing, when it changed state, what information the summaries preserve and how retention probability depends on the underlying event class.

The laboratory should impose a predeclared schedule of independent ground-truth events, including those which violate the expected sparsity structure. Their temporal positions should be randomised relative to the compression schedule. The study must retain the entire event schedule, an independent reference record and the compressed system's decisions, including non-retentions and invalid intervals. Only then can one estimate conditional detection rates for defined event families. A variable-length representation may be efficient in the background regime but fail disproportionately for brief broad impulses. The overall bytes-per-hour figure says nothing about that tail failure without a performance experiment. It measures resource consumption, not preservation of evidence.

For an occupancy inference, the denominator should be an independently established amount of valid observation time or a count of suitably defined opportunities. It should not be merely the number of compressed files. If the receiver changes its algorithm after recent alarms, those changes may influence later detection probability, so observations can become dependent through the adaptation process. One must model that dependence or design an evaluation which conditions on the relevant states. The analysis should preserve state epochs, changes of threshold,

Copyright 2026, James M. Atkinson

matrix revisions and periods of storage or network loss. Otherwise an apparently stable duty-cycle estimate may reflect the recorder's changing willingness to retain data rather than the behaviour of the external RF environment.

We should also ask whether the reconstruction output is an unbiased estimate of duration. An adaptive system might suppress isolated noise-like samples, shortening a burst that resembles an impulse. Another might join nearby events because a smoothing prior prefers continuity. Either error can distort the duty cycle or temporal clustering even where a detection is registered. The experiment must compare onsets, offsets and event counts with the independent reference, reporting distributions of error rather than a single attractive average. It would be reasonable to claim efficient compression for specified background and event classes under tested conditions. It would be unjustified to claim that sparse storage alone preserves every event relevant to a TSCM investigation.

Andrey Nikolaevich Kolmogorov, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, our distinction between model uncertainty and statistical variability will fail if the implemented computation changes its measurement interpretation without recording that change. Imagine a field recorder with a calibrated matrix in memory. Its software updates a coefficient table after a temperature adjustment, some hardware channels have slight phase skew, and a recovery algorithm employs a stopping tolerance that depends on the measured noise. The investigator later retains only the final recovered waveform. Which information is necessary to separate the uncertainty of the physical operator from numerical approximation error and from the sparse model's own bias? I should also

Copyright 2026, James M. Atkinson

like a practical account of how the laboratory should treat a low reconstruction residual if the operator used in the calculation is not exactly the operator used during acquisition. Finally, how can the analyst prevent the apparent precision of many output digits from suggesting certainty about an event that may have been suppressed by quantisation or overload?

Richard Wesley Hamming, Cross-Peer Answer to Andrey Nikolaevich Kolmogorov: Professor Kolmogorov, the laboratory must preserve the acquired measurement vector before reconstruction, the operator identity applicable to each acquisition epoch and the numerical procedure used to create the derivative. A final recovered waveform alone discards the distinction between input observation and inferred output. The record should identify coefficient precision, temperature compensation, channel calibration, input gain, filtering, sampling schedule and any period in which those settings were uncertain. It should preserve software and firmware versions, matrix checksums, solver tolerances and the exact condition used to stop the algorithm. Otherwise the investigator cannot determine whether two laboratories differ because of physics, software or interpretation.

The effects should be assessed in separate controlled experiments. The physical operator is tested by driving the actual receiver with independently characterised signals and comparing the resulting measurements to the predicted forward model. Numerical error is tested by processing known synthetic vectors and varying arithmetic precision, evaluation order and stopping tolerance. Model bias is tested by using physically plausible signals that do not satisfy the assumed sparsity structure. Those tests answer distinct questions. A well-calibrated matrix does not validate the statistical prior, and a perfectly implemented solver does not establish that the

Copyright 2026, James M. Atkinson

analogue input remained linear. A small residual against the wrong operator is a warning rather than an exoneration.

When the operator used in reconstruction differs from the actual acquisition map, the residual can be small for an incorrect recovered signal. Suppose the algorithm has enough freedom to alter sparse coefficients so that their projections fit the stored vector. It may thereby conceal an input-gain error or phase skew. The correct test is to replay the preserved measurements using the correct recorded operator, if it exists, and compare results under calibration perturbations. If the operator cannot be established, the result should be described as exploratory. It is inappropriate to claim physical amplitude accuracy merely because the numerical optimiser converged to a stringent tolerance.

Displayed digits should be controlled by the uncertainty of the measurement and the decisions based upon it. A value may be computed with double-precision arithmetic while the analogue front end has a much larger amplitude uncertainty. The display precision should not obscure the effective number of independent, calibrated measurements or known overload conditions. A conservative decision rule should mark any event whose amplitude, timing or identity changes materially under plausible calibration perturbations as unresolved. The proper conclusion may be that the compressed data are compatible with several waveforms and insufficient for a more exact claim. Such candour is a positive engineering result, because it directs attention to what the apparatus must measure next.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: The probabilistic account now points to the engineering computation itself. I pass the token respectfully to Dr. Hamming for an examination of finite precision and operator calibration.

Richard Wesley Hamming, Fourth Principal Contributor: Dr. Atkinson, our colleagues have set out the logical and probabilistic qualifications, but an apparatus may violate them by purely computational means before a single false inference is made. A reconstruction algorithm usually solves an inverse problem through floating-point arithmetic, finite precision storage, stopping tolerances and a collection of engineering approximations. The matrix A in an elegant proof is not automatically the matrix implemented in firmware. It may have been quantised, transposed, truncated, reordered or measured under another gain state. If I cannot reconstruct the exact numerical processing recipe, I cannot tell whether the returned waveform belongs to the physical measurement or to the program's particular approximation.

The manifest should record sample representation, signedness, endianness, scaling, channel order, clock mapping, and any premeasurement transforms. A system that mixes or accumulates samples in the analogue or FPGA domain must describe those operations as part of its forward operator, not conceal them as mere implementation. Matrix coefficients require identifiable calibration revisions. If the front end is changed, the operator may change. If the digitiser saturates, the simple linear forward model may cease to apply. The solver cannot restore linearity by reducing its residual. It may simply choose a mathematically convenient false explanation. Consequently, validation needs an independent measurement path and a hardware-state log, not only a software unit test.

Copyright 2026, James M. Atkinson

I would require five distinct computational checks. First, inject a known digital test vector into the reconstruction chain and determine whether the program returns the expected result within an appropriate numerical tolerance. Second, drive the analogue receiver with a calibrated reference input and compare the actual measurements to the predicted forward model. Third, perturb the operator deliberately to quantify sensitivity to calibration error. Fourth, process signals outside the assumed sparse class and record what the algorithm falsely infers. Fifth, reproduce the computation in an independent implementation with a documented treatment of floating-point differences. One correct graphical output is not enough to demonstrate any of these controls, because a plotted magnitude spectrum can conceal severe phase and timing errors.

Condition number and sensitivity deserve explicit treatment. For a well-conditioned linear problem, small measurement perturbations may produce suitably bounded changes in a solution. For an ill-conditioned or nonidentifiable inverse problem, a tiny change can yield a large change in the inferred waveform. Sparsity-regularised methods can alter the practical problem, but the effective stability still depends on assumptions that must be checked. It is therefore important to vary the noise level, calibration coefficients and stopping criteria in a controlled experiment rather than evaluate one idealised noise-free record. An analyst should document which parts of an output remain robust and which change conspicuously when reasonable numerical parameters change.

Consider a hypothetical data record in which one component of a sensing matrix has been stored with an incorrect sign. The measurement vector may be internally consistent with the true operator yet poorly fitted by the

Copyright 2026, James M. Atkinson

incorrect one. Increasing the allowed residual or changing the regularisation weight may produce a visually plausible output while concealing the configuration fault. The correct course is to compare a measured calibration response against the expected operator. We should make the program fail closed when it encounters a mismatched matrix identifier or an uncalibrated gain state. If an investigator is permitted to override that failure, the record should preserve the override, reason and the altered inference status. It is unreasonable to make the later examiner discover the error from a strangely shaped spectral peak.

The treatment of quantisation needs care as well. Merely collecting fewer numbers does not guarantee that the retained measurements have adequate information to resolve a weak event. Each measurement may contain noise and numerical error from multiple contributing inputs. A wideband blocker may dominate the dynamic range before the compressive transform has preserved the weak phenomenon of interest. Dither can sometimes improve estimates under defined conditions, but it cannot erase overload or create missing independent information. Time interleaving can increase rate under suitable calibration, but does not add converter word lengths to manufacture an arbitrarily accurate physical amplitude estimate. This is the same scientific discipline that governs other digital receivers: no reconstruction result is more trustworthy than its calibrated observation chain and its tested error model.

For forensic continuity, preserve the original compressed measurements as bytes, a digest of those exact bytes, an independently protected acquisition manifest and every derived reconstruction as a new object. The manifest should identify the software version, numerical library, hardware revision,

Copyright 2026, James M. Atkinson

coefficient set and transformation parameters. If the investigator changes an algorithm to improve recovery, the earlier result is not retroactively corrected. The later processing run is another experiment using the same original observation. The differences should be explained, not overwritten. A reproducible computation is useful even when wrong; it allows the error to be found and documented. An irreproducible computation conceals the distinction between a failure of measurement and a failure of explanation.

I would also prohibit a common rhetorical manoeuvre in reporting. A compressed recording may recover some familiar tones almost perfectly, and the team may then advertise an equivalent full-rate sample stream. That phrase suggests that all physically relevant samples have been preserved. They have not. The system has preserved a lower-dimensional observation from which certain signals can be reconstructed under assumptions. The correct performance descriptor should state the validated signal family, the error criteria and the conditions of acquisition. Any claim of general waveform equivalence must be tested rather than inferred from an impressive demonstration. We must not confuse engineering optimism with physical evidence.

When numerical differences arise between independently developed implementations, I would not immediately insist on bitwise identity of floating-point outputs. Different evaluation orders may yield small differences within an agreed tolerance. But a tolerance must be justified relative to the relevant decision threshold and signal uncertainty, not enlarged after an inconvenient failure. A borderline event might require both raw-measurement comparison and independent analogue corroboration. The acceptance record should specify which variations are

Copyright 2026, James M. Atkinson

permitted, which demand investigation and which invalidate the proposed inference. That discipline is what gives a forensic result its resilience under hostile expert scrutiny. I return the token to the moderator and invite Mr. Turing to ask what an examiner could actually disprove about this apparatus.

William Redington Hewlett, Peer Question: Dr. Hamming, suppose a manufacturer presents two SDR designs for a facility survey. The first stores raw contiguous I/Q records, while the second stores compressed projections and promises equivalent waveform recovery. The manufacturer's demonstration uses clean sinusoidal signals, yet the application involves asynchronous bursts with uncertain amplitude, finite pulse rise times, temperature variation and equipment reconfiguration. How should a technically responsible laboratory compare the instruments without allowing the compression algorithm to benefit from knowing the test repertoire? I am particularly interested in the design of a reference plane and in whether the instrument can preserve a pulse that arrives precisely when its input switching network or processor changes state. What role should the laboratory assign to numerical residuals, independent full-rate monitoring and a separate test of the recording system's sustained data throughput? If the compressed system offers much lower storage cost, what evidence is necessary before we describe that saving as achieved without material loss of evidential utility?

Richard Wesley Hamming, Response: Mr. Hewlett, the comparison must be made against a laboratory reference acquisition that sees the same input event, not against the manufacturer's preferred reconstruction. Establish calibrated RF input planes for both designs; document antenna and filter

Copyright 2026, James M. Atkinson

states, overload margins, analogue transfer, clock behaviour and any switching dead time. Inject a blind repertoire of asynchronous bursts, overlapping tones and amplitude-modulated transients whose timing and amplitudes are concealed from the reconstruction team. Reference captures need sufficiently broad bandwidth and dynamic range to expose failures rather than simply agree with the device under test.

The timing challenge deserves a dedicated experiment. Trigger events just before, during and after every permitted tuning, gain, preselection or firmware-state transition, repeating the trial across temperature and loading conditions. Compare pulse detection, onset-time error, peak-amplitude error, phase continuity and false-negative rate separately. State which events were not observed because neither design was live at the relevant instant. A low average waveform error can conceal the complete loss of a single short burst; therefore report event-conditioned losses and worst-case intervals as well as aggregate reconstruction statistics.

A second channel should preserve continuous, calibrated full-rate I/Q samples with its own monitored clock and sustained-write measurements. Exercise both storage paths for longer than their buffers can absorb, measuring overflow counters, dropped-sample indicators, packet discontinuities and the latency between physical acquisition and durable storage. Synchronise records by independent reference events, not solely by software timestamps. Keep input waveforms and receiver configurations as controlled test evidence; a reconstruction that succeeds only after tuning its algorithm to the blind validation cases must be retested on another unseen set.

Copyright 2026, James M. Atkinson

I would credit a storage saving only within a declared and independently demonstrated observation class. For each class report compression ratio together with detection sensitivity, timing fidelity, uncertainty bounds, unavailable intervals and the cost of retaining manifests and calibrations. If the compressive design cannot distinguish several admissible input histories, its apparent waveform must be labelled a model-conditioned estimate, not a captured original. The laboratory should also test how performance changes when the acquisition matrix, source environment and signal family differ from those used for training. Those qualifications answer the evidential question more faithfully than a successful sinusoid demonstration.

Copyright 2026, James M. Atkinson

Abraham Lempel, Peer Question: Dr. Hamming, I want to make an explicit comparison between lossless encoding, lossy waveform reduction and true compressed acquisition. These three terms can sound alike in a sales demonstration but they make different promises about the retained evidence. If an instrument first samples the full I/Q stream and then compresses those exact bytes without loss, an independent examiner may recover the original digital sample sequence. If the instrument reduces the precision of the samples or stores projections before the full waveform exists, such a guarantee no longer follows. What validation records should distinguish those cases? How should checksums, compression ratios, sampling manifests and transformation histories be used without making a hash or a successful decompression appear to prove authentic RF origin? And how would you report a later reconstruction in which several plausible waveforms remain compatible with a single compressed measurement vector? Please distinguish the behaviour demonstrated by controlled tests from properties that the investigator has merely assumed on the strength of a successful reconstruction.

Richard Wesley Hamming, Response: Dr. Lempel, the distinction should be made at the input and output of each transformation. Lossless encoding of a fully acquired digital sample sequence promises a reversible map between that specific sequence and a shorter byte representation. If the encoding and decoding operations are correctly implemented and the archive remains intact, the same original digital bytes can be restored. That says nothing by itself about whether the ADC measured the physical input faithfully. Lossy reduction modifies or discards information from the acquired sequence, and pre-acquisition compressive measurement never

Copyright 2026, James M. Atkinson

stores the full digital sequence in the first place. A reconstructed waveform in either of the latter cases is conditional upon an algorithm and a model. Calling all three simply 'compression' obscures their radically different evidential status.

A verification record should identify the reference plane at which the promise is made. For lossless coding, test representative and adversarial digital inputs, encode and decode them, and compare their exact bytes, including sample order and metadata. Protect the original and decoded object identities, algorithm version, file lengths and cryptographic digests. For a lossy transform, declare the distortion metric and test it on waveforms relevant to the forensic questions, including phase and timing as well as amplitude. For compressive acquisition, identify the physical forward operator and the family for which reconstruction or detection has been demonstrated. One cannot use a successful decompression test from the first category as evidence for a recovery theorem in the third.

Checksums can assist in detecting accidental corruption and cryptographic digests can strongly support byte continuity relative to a trusted reference state. Neither proves the truth of acquisition timestamps, calibration coefficients, physical origin or lawful authority. A digest faithfully preserves whatever was hashed, including an erroneous manifest if one was included. The laboratory must therefore document the original sample or projection semantics, equipment state and independently controlled reference measurements. Transformations performed for later analysis should produce new objects with their own identifiers and should retain an auditable link to the preserved evidence. The investigator must not present

Copyright 2026, James M. Atkinson

a recomputed post-processing hash as though it authenticated the earlier analogue event.

If several physically plausible waveforms fit the compressed vector to within measured uncertainty, I would report nonuniqueness as part of the result. It may still be possible to infer a restricted property common to every candidate, such as an energy bound or membership in a tested event class. But a single reconstructed pulse should not be labelled the captured waveform unless the necessary uniqueness and stability assumptions have been justified for that case. File-size reduction is then a performance parameter, not a synonym for preservation of all evidence. The proper comparison states exactly which observations were saved, which attributes can be recovered, the validated uncertainty and the alternatives that the record cannot distinguish.

Richard Wesley Hamming, Cross-Peer Question to Alan Mathison Turing: Mr. Turing, I wish to pursue whether one can write tests that distinguish a faithfully executed but scientifically inapplicable algorithm from a faulty implementation. A receiver manufacturer may demonstrate that its reconstruction code satisfies unit tests against ideal matrices, while the deployed instrument uses quantised coefficients, a variable preselector, adaptive gains and a host whose scheduling occasionally drops measurement blocks. Suppose the output passes a visual inspection and the solver residual is small. What set of executable acceptance conditions would justify proceeding to a scientific detection decision? How would you test the response to an incompatible matrix revision, omitted blocks, an unsynchronised clock or an analogue overload event? I should like the result expressed in states that an independent reviewer can inspect, not merely in

Copyright 2026, James M. Atkinson

a verbal promise of software quality. Should the system ever continue with an exploratory reconstruction after a failure, and if so how would you prevent that output from becoming accepted evidence without an additional qualification?

Alan Mathison Turing, Cross-Peer Answer to Richard Wesley Hamming: Dr. Hamming, I would require the reconstruction pipeline to establish its preconditions at each processing stage. An archive must pass an integrity and schema check; the acquisition epoch must identify a compatible sensing operator; the relevant hardware calibration must cover the recorded configuration; the status record must identify any lost or invalid measurement blocks; and the intended decision rule must have been independently validated for the declared signal family. The programme should not silently promote an invalid or unknown state to a valid one simply because an algorithm can produce output. These conditions should be executable tests with recorded results and reasons for failure.

The practical state machine would distinguish a complete and qualified acquisition, an incomplete acquisition, a capture whose model is incompatible, and one in which physical conditions exceeded qualification. The solver may run for a valid interval and provide a result with documented uncertainty. For an unqualified interval it may produce a separately marked exploratory derivative, but that derivative cannot inherit the evidential status of a validated detection. Each state transition should be logged with input-object identities, operator revision, calibration basis and processing software identification. That preserves accountability without pretending that a mathematical reconstruction is a direct observation.

Copyright 2026, James M. Atkinson

Fault-injection tests should deliberately exercise each failure. Change one coefficient-table identifier while leaving the data unmodified and verify that the programme refuses the trusted processing path. Remove a block or repeat one and confirm that the sequence check recognises the discontinuity. Perturb the clock mapping and determine whether the output is marked with enlarged timing uncertainty rather than silently aligned. Overdrive the analogue front end and confirm that the record indicates an out-of-envelope condition. In every case the laboratory should compare the candidate system with an independent reference and retain the unflattering results. The quality of an error-detection mechanism is demonstrated most clearly by its behaviour when the anticipated error actually occurs.

Formal tests of the program's arithmetic are necessary but insufficient for physical validity. A system may have flawless control flow while modelling the wrong analogue system. Therefore acceptance should be conditional on three independent bodies of evidence: computational implementation, calibrated instrument response and the statistical validity of the final inference. A claim to reconstruct an unknown burst requires substantially more evidence than a claim that one solver consistently minimises its stated objective. The safest design is one that makes uncertainty and invalid states explicit to its users. I would rather trust a system that sometimes declines a conclusion than one that produces a confident spectrum at every opportunity.

Dr. James M. Atkinson, Moderator: Dr. Hamming has delineated numerical fidelity from physical validity. I now invite Mr. Turing to frame an independently falsifiable qualification programme.

Copyright 2026, James M. Atkinson

Alan Mathison Turing, Fifth Principal Contributor: Dr. Atkinson, I should prefer a finite, falsifiable specification to an undefined assertion that the system 'uses compressive sensing'. A physical instrument cannot be judged by the name of its algorithm. It must have a documented input domain, an observable acquisition procedure and propositions that can be tested against controlled cases. I would define the system's expected outputs at three levels: a claim that energy was detected under a specified decision rule, a claim that some waveform parameters were estimated within tolerances, and a claim that an entire signal was reconstructed with a stated error. These propositions are not interchangeable. A detector may be adequate for the first while failing the other two. It may also give a convincing waveform for one model family while missing an off-model event altogether.

A useful test harness should start with a configuration that cannot be altered by the examiner after the test cases are revealed. Otherwise an adaptive series of corrections may overfit the laboratory programme. The test set should include held-out ordinary cases, deliberately hostile but physically lawful cases and samples captured independently of the apparatus under examination. We should verify that the reference system has sufficient bandwidth and temporal accuracy for the chosen questions. It would be a logical failure to test a compressive recorder against a supposedly full-rate receiver that itself misses the broadband impulses. Independent calibration is essential for both. The reference record should be preserved before the candidate system's output is inspected.

The decision process should use explicit categories. A valid capture with an event detected is not the same as a valid capture with a correct

Copyright 2026, James M. Atkinson

reconstructed waveform. A valid capture with no event detected is not proof that no event entered the antenna. An invalid acquisition caused by saturation, lost samples or failed calibration should not be counted as a successful negative test. A false positive may be caused by the reconstruction algorithm or by receiver-generated artefacts; each deserves investigation. The laboratory report should preserve the denominator for every reported rate. One might otherwise calculate detection success on only the cases the software found easy enough to process and discard the failures as exceptions. In such a protocol the most important evidence is absent from the published table.

I recommend metamorphic tests, in which the input is changed in a controlled way and the consequences of that change are checked. If a test waveform is scaled by a known amount within the linear range, the corresponding measurement behaviour should follow the declared model within uncertainty. If the input is delayed by a known number of sample apertures, its reconstructed timing should respond according to the sensing operator's timing convention. If an additional independent tone is introduced within the supported sparsity envelope, the system should exhibit the predicted change rather than suppress the new component to preserve an attractive sparse output. Tests should be designed to fail visibly when the system's operating assumptions cease to hold.

For negative claims, I would ask a more difficult question than whether the output screen is blank. Could two authorised laboratory inputs, one containing the relevant event and one lacking it, produce the same retained measurements under a plausible fault or off-model condition? If so, the evidence has insufficient discriminatory power for the proposed universal

Copyright 2026, James M. Atkinson

claim. The appropriate report may be that a specified class of event was not detected during validated observation opportunities. If the surveyor wishes to claim that no relevant source existed, a broader physical and experimental argument is needed. The limitations of the model cannot be overcome by impressive language in the conclusion.

The device's state transitions should be auditable. Suppose it alters its compression pattern after a tentative alarm, resets on an overflow, or changes reconstruction dictionaries as the background noise rises. The investigator needs a time-ordered record of those decisions. Merely retaining the last configuration is not enough, for the missing interval may have occurred under an earlier state. The test system should deliberately provoke reconfiguration, dropped blocks and clock discontinuities. It should verify whether an event that overlaps those changes is marked uncertain rather than silently placed on a smooth reconstructed timeline. That is essential where a later examiner must distinguish an authentic brief emission from an artefact of software scheduling.

The proof obligation also changes when the laboratory software is updated. A new solver, an altered machine-learning model or a revised coefficient matrix cannot simply inherit the validation certificate of the earlier implementation. Some checks may be reusable, but the changed components and their interaction with existing components require regression tests. The release record should document the old and new results on the same preserved measurements, identify changed decisions and disclose whether thresholds were adjusted after seeing outcomes. A system with a formal source-control history but no independent test record may be administratively tidy without being scientifically trustworthy.

Copyright 2026, James M. Atkinson

I would ask each participant to articulate the observation that could falsify his preferred method. The sparsity theorist should name a waveform class that defeats the assumption, the statistician should name a selection mechanism that invalidates the estimated rate, the numerical specialist should name a calibration perturbation that defeats the solver, and the instrument designer should name a physical state in which the forward model breaks. If no conceivable laboratory result is allowed to challenge the conclusion, the conclusion is not being subjected to scientific testing. This does not mean a theory is worthless. It means the conditions of applicability must remain visible.

For the final record, I would separate acceptance of software execution, acceptance of scientific measurement and acceptance of a forensic inference. These are three different achievements. The first establishes that documented code ran as intended; the second establishes that the acquisition system behaved within a calibrated domain; the third establishes that a conclusion follows from the observations under stated assumptions. A volume devoted to receivers and evidence ought to be uncompromising on this distinction. I pass the token to the peer interrogators with one request: challenge not merely the quality of the reconstruction, but the very circumstances under which the reconstruction would mislead an otherwise competent examiner.

Grace Brewster Murray Hopper, Peer Question: Mr. Turing, the computational system is said to be reproducible, yet the evidence presented to another laboratory may consist only of a set of compressed numbers, a matrix identifier and a PDF showing a successful waveform reconstruction. The acquisition firmware can alter its mixing pattern under load, the

Copyright 2026, James M. Atkinson

processing software can change a regularisation parameter, and the computer can replace a missing block with zeros while retaining an apparently continuous file. Which records should be preserved to enable an examiner to repeat the numerical analysis and to discover that the capture itself was incomplete? I am also concerned that a software version string without an exact binary or build manifest may give a false assurance. How would you separate preservation of original evidence from working derivatives and prevent a subsequent, more favourable reconstruction from being mistaken for the original observation? Please account for practical custody rather than merely specifying an ideal mathematical experiment.

Alan Mathison Turing, Response: Dr. Hopper, I should begin with the identity of the original observations. The laboratory ought to preserve the acquired projection bytes, native sequence numbers, packet or frame boundaries, device-state transitions, and an acquisition manifest signed or otherwise protected as close to capture as practicable. For each observation interval, the manifest should identify its exact measurement matrix and calibration revision, clock basis, acquisition firmware build, analogue gain state, and flags for overload, lost samples and substituted data. A software version label without the executable digest, dependency set and build provenance is insufficient for an independent reproduction.

The chain of processing must be append-only in its evidential meaning. Preserve the original capture object unchanged, and create a separately identified derivative for each conversion, gap-handling rule, calibration correction or reconstruction. Record the parameter vector, solver stopping criterion, numerical-library versions, floating-point environment and a digest of both input and output. A missing block represented as zeros is not

Copyright 2026, James M. Atkinson

a measured zero-valued signal: the gap mask must remain explicit in every derivative, and any interpolated or substituted values should travel with a machine-readable provenance flag.

To discover an incomplete acquisition, an examiner should compare several independent ledgers: hardware sample or projection counters, transport-frame sequences, operating-state logs, storage-commit records and externally captured timing markers. Their discrepancies have explanatory value. A continuous file length or a valid checksum proves neither that every scheduled analogue aperture was sampled nor that the correct matrix acted during each interval. The repeat laboratory should be able to replay the original bytes through the named binaries while deliberately injecting missing frames, stale manifests and mismatched configuration identifiers, and then observe that the software signals the corresponding failure.

Finally, the published reconstruction must be identified as an analytical result obtained from a stated original object, not as the original RF event itself. Its report should cite the immutable acquisition identifier and the exact transformation chain, disclose unsuccessful or contradictory reconstructions, and distinguish repeatability of computation from validation of the physical measurement model. A more favourable later image or spectrum may be included as a new experiment, but it must neither overwrite the original projections nor silently replace the first result in the custody history. This is the practical separation between preservation and interpretation that your question requires.

Edsger Wybe Dijkstra, Peer Question: Mr. Turing, I should like a specification that does not permit success to be declared merely because the demonstration produces an attractive output. A data acquisition

Copyright 2026, James M. Atkinson

programme will encounter malformed manifests, missing frames, changing matrix revisions, numerical overflow and operator states never covered by its calibration record. If a reconstruction can silently continue through those failures, it may turn invalid observations into reassuring negative evidence. What invariants should a well-engineered system enforce before it performs any inferential reconstruction? How would you structure a state machine so that questionable intervals are labelled and retained without relying upon a human operator to notice them? I ask that you distinguish a program which computes correctly under stated preconditions from a larger scientific system whose assumptions may be false. Where should the program refuse to make a forensic finding, and what evidence of that refusal should remain in the custody record? Please distinguish the behaviour demonstrated by controlled tests from properties that the investigator has merely assumed on the strength of a successful reconstruction.

Alan Mathison Turing, Response: Mr. Dijkstra, the program should make its preconditions explicit and should not silently weaken them to force a result. At minimum it needs an accepted acquisition-object format, a declared measurement-operator identity for every interval, a compatible calibration state, monotonic native sequence semantics, a recorded clock model and a clear representation of invalid or missing measurements. An archive that fails any indispensable precondition can still be preserved and studied, but its data must not be passed into a validated reconstruction path as though the precondition were satisfied. The processing state should be recorded as valid, invalid, incomplete or unqualified, with the reason and relevant source identifiers. An invalid interval should not be rendered as an ordinary quiet interval.

Copyright 2026, James M. Atkinson

The state machine might separate acquisition acceptance, operator qualification, numerical processing and forensic decision. A capture first passes an integrity and schema test. It then passes an operator-identity and calibration check. The solver may run only for the portions covered by a valid operator or must return a clearly marked exploratory result. Finally, a decision engine applies a rule that was validated independently for that signal family. Each transition produces a log entry with the responsible program revision and the evidence supporting the transition. If the device changes state without a valid model, it should enter an unqualified state rather than pretend that the old matrix still applies. This is a testable invariant, not a matter of aesthetic judgment.

However, formal program correctness cannot by itself establish the truth of the physical model. One can prove that code solves an optimisation problem accurately and still be wrong about which analogue signals the matrix describes. Therefore the proof obligation is layered. Unit and property-based tests address the implementation, calibrated hardware experiments address the forward model, and blind held-out trials address the resulting detection inference. We must retain failures from all three layers, because a negative result in one does not become a positive result merely because another layer has passed. A computation can be reproducible and scientifically inapplicable at the same time.

For an examiner, the refusal record is particularly valuable. It should identify that the programme declined a classification or did not claim absence during a specified interval because of missing samples, overload, unverified coefficients or model mismatch. The log should distinguish a genuine detection threshold not crossed during valid observation from an event that

Copyright 2026, James M. Atkinson

the apparatus could not evaluate. The investigator may choose to perform exploratory analysis after a failure, but it must produce a separately marked derivative and must not silently repair the status of the original measurement. A forensic record in which uncertainty and refusal are explicit is more trustworthy than one that presents an unbroken series of confident answers.

Alan Mathison Turing, Cross-Peer Question to David Slepian: Dr. Slepian, permit me to formulate one final challenge. A compressive receiver can be theoretically excellent for a selected class, independently calibrated in a laboratory and still face a field event whose structure is outside every tested dictionary. At what point may the operator cease describing the apparatus as an experimental method and begin to use it for a formal negative technical-security finding? Would you require a known lower bound on detection probability for each event family relevant to the asserted conclusion, and how would you treat a class whose existence is plausible but whose probability of occurrence is unknown? I am also concerned with the tendency to equate reconstructing a waveform with recognising an emission, although a hypothesis test on compressed measurements may sometimes be sufficient. Please propose a precise reporting sentence that states the authorised survey result without implying omniscience, and specify what supplementary observation would most improve its defensibility.

David Slepian, Cross-Peer Answer to Alan Mathison Turing: Mr. Turing, a formal negative finding must be limited to the event classes and acquisition conditions for which the apparatus has been qualified. If a compressive receiver demonstrates an adequate miss probability for specified bursts,

Copyright 2026, James M. Atkinson

levels, frequencies and durations in independently controlled tests, an examiner may report that no event of those qualified classes was detected during the stated valid observation intervals. The report should disclose the antenna, receiver bandwidth, reference calibration, observation schedule and known blind periods. That is an evidence-based proposition. It is not a claim that no possible transmitter was present, and the conclusion should not be enlarged merely because the reconstructed display looked empty.

A class of physically plausible but untested waveforms must remain outside the declared assurance envelope. If its occurrence probability is unknown, one cannot replace ignorance with an invented small number. The survey may still have value because it excludes certain hypotheses to a measured sensitivity, but the conclusion must identify the hypotheses to which the evidence actually applies. The uncertainty statement should distinguish instrumental detection limits from the unknown distribution of possible emitters. If the instrument's physical response to the untested class can be measured in a new controlled experiment, that experiment may expand the envelope. Until then, the appropriate status is unqualified or unknown.

A test on compressed measurements can sometimes suffice for detection even when complete waveform reconstruction is impossible. It may test a defined feature against a specified noise model without recovering every original sample. Such a result should be judged by its validated false-alarm and miss characteristics, not by the resemblance of a reconstructed waveform to a familiar example. Conversely, successful waveform reconstruction under an assumed sparse model does not automatically establish the origin or lawful meaning of an emission. The investigator must keep detection, waveform estimation, class inference and source attribution

Copyright 2026, James M. Atkinson

separate. Each transition requires evidence not supplied by the name of the acquisition algorithm.

I would recommend supplementary independent observation using an appropriately calibrated conventional receiver or an alternate sensing method, particularly for brief broadband signals that could violate the sparse representation. A reference monitor can reveal physically real events which the compressed record suppresses or misdescribes. The methods should have sufficiently independent failure mechanisms, and any common input splitter or clock should be documented. A defensible reporting sentence might read: 'During the recorded valid observation intervals, this qualified compressive receiver did not detect emissions within the specified tested signal classes above the stated detection limits; performance for untested signal structures and unobserved intervals is not established.' That statement is narrower than the general absence of a hidden device, but it is technically honest and capable of independent challenge.

QUESTION 104

Copyright 2026, James M. Atkinson

How should machine-assisted RF anomaly detection be assessed under distribution shift?

SCHOLARLY RECONSTRUCTION. The following modern educational dialogue is fictional, not authentic speech or an historical meeting. Research sources are contextual background rather than historically attributed speech.

Dr. James M. Atkinson, Moderator: Professor Minsky, an RF anomaly detector may appear impressive when the training and test samples resemble one another because they share a receiver, site, source generator and recording session. Once the antenna changes, gain is adjusted or an unfamiliar source enters the scene, the detector may recognise the recording environment rather than an electromagnetic phenomenon. Please frame an assessment that separates technical novelty from instrument artefacts, and that retains every adverse result rather than showcasing only correctly classified examples. I should like you to identify which information must be recorded so that a subsequent examiner can distinguish a detector's performance on observed cases from its unknown behaviour when the distribution changes.

Marvin Lee Minsky, Principal Contributor: Dr. Atkinson, I would begin by refusing the convenient assumption that an abnormal output necessarily corresponds to an abnormal external signal. An algorithm observes features extracted from a measurement system. Those features can change because a transmitter changes, but they can also change because the receiver's local oscillator drifts, a digitiser loses a sample, a filter is switched, a gain stage enters compression, or the background noise in the room alters. If the system is trained on a narrow range of such conditions, a new receiver state

Copyright 2026, James M. Atkinson

may be marked anomalous even in the absence of any unfamiliar emission. Conversely, a genuinely unfamiliar waveform may resemble a familiar training artefact and be accepted as unremarkable. An anomaly score is therefore a statement about the relation between the new feature vector and a learned reference distribution. It is not, without further evidence, a statement about the identity or intent of an external emitter.

The first scientific task is to define the prediction target. The laboratory may wish to detect increased spectral occupancy, an unusual temporal pattern, a departure from the receiver's established background state, or a class of waveforms. Those are different objectives and may require distinct labels and validation measures. A machine can be good at recognising changes in its own equipment without being useful for site surveillance. I would insist that each reported detection identify the observation to which the score applies, including the RF reference plane, sample rate, analogue bandwidth, gain state, input power range and time interval. If that information is unavailable, the score should not be presented with an air of instrumental authority.

The second task is to design a test that does not conceal dependence. Divide a continuous recording into thousands of adjacent windows, and one can obtain a large-looking dataset with a deceptively small number of independent environments. If highly correlated windows from one transmitter and one receiver appear in both development and test sets, the classifier can memorise nuisance characteristics that will not recur at another site. Random splitting of such windows may exaggerate generalisation. A proper test programme should hold out whole recording sessions, receiver specimens, antenna configurations, locations, dates and

Copyright 2026, James M. Atkinson

emitters, according to the specific claim to be evaluated. The laboratory should say which of these variables it tested. Generalisation across a new day with the same instrument is not the same as generalisation across an unfamiliar receiver architecture.

A third task is to make the false-alarm denominator explicit. A programme that calls attention to ten impressive anomalies in a day may be useful or unusable depending on how many measurements were examined and how many events a trained examiner can investigate. The correlation of spectral bins and overlapping windows means that one cannot always treat every displayed pixel as an independent decision opportunity. False-alarm rates should be evaluated per appropriate time interval, survey interval or defined event cluster, with the selection rule recorded. The study should include long periods with no controlled emissions, short weak test bursts, strong lawful interferers and deliberate hardware changes. It should record missed events, false alarms, invalid acquisitions and inconclusive decisions as separate categories.

I would not assume that learning a background model cures the problem of background drift. A moving estimate can follow a rising interference floor so smoothly that the detector ceases to identify the gradual change. An excessively rigid estimate can generate continuous alarms when the site undergoes a benign change. The laboratory must measure how adaptation works and preserve its state history, including any reset or retraining event. A threshold chosen after watching the test outcomes has been optimised on those outcomes; it requires fresh confirmation on an independent set before its advertised error rate can be trusted. An investigator should not

Copyright 2026, James M. Atkinson

rewrite the system's original history merely because a later model provides a more attractive explanation.

The decision to abstain is as important as the decision to alarm. When the receiver enters an uncalibrated gain regime, experiences overload, loses its time reference or encounters a feature distribution unlike that used for validation, the appropriate output may be 'unqualified' rather than a confident label. It is preferable to preserve a properly identified uncertainty than to produce a smooth waterfall and a persuasive diagnosis without adequate measurement support. The software should disclose the reason for abstention and the time interval affected. A subsequent examiner may then seek a corroborating observation, repeat a lawful controlled test or narrow the final report's claim. Without that state, a negative machine decision may be misinterpreted as proof that the spectrum was quiet.

A controlled experiment should therefore have independent sources and a locked inference procedure. Choose several calibrated emitters representing known normal signals and unfamiliar but lawful laboratory waveforms. Record them on multiple physically different receivers with different antenna and gain conditions. Retain independent reference recordings. Freeze preprocessing, feature extraction, anomaly scoring, threshold rules and the test schedule before evaluating the held-out cases. Introduce benign receiver-state changes without changing the external RF event. Introduce genuine changes in the external signal while holding the receiver configuration constant. Those paired interventions help distinguish an algorithm sensitive to its own apparatus from one sensitive to the stipulated external phenomenon.

Copyright 2026, James M. Atkinson

A further difficulty is the interpretation of an impressive probability number. A score calibrated on one validation population may cease to describe meaningful error frequencies when the distribution of environmental interference changes. It is not enough for the software to attach two decimal places to its confidence. The conditions under which that number was calibrated should be disclosed, and it should not be used as a probability of a particular person's involvement, device identity or unlawful purpose. Those stronger propositions require evidence beyond the detector's performance on laboratory samples. A disciplined report should state what the detector observed, which controlled tests support its decision and which alternative explanations remain unexcluded.

I would also insist on evidence preservation. The original I/Q sample data or authorised minimal extracts, their digests, the receiver-state manifest, feature-processing recipe, exact model identity and all operator overrides should be maintained according to lawful scope. A later software update is a new analysis of old observations, not a retroactive improvement to the original acquisition. The audit record should permit independent replication of the original outcome and show precisely how the updated system changed it. If communication content is not necessary for the authorised objective, that content should not be collected merely to create a richer training set. Technical ambition cannot displace proportionality and legal authority.

The principal conclusion is necessarily limited. A model can be shown to detect specified anomalies under specified receiver and environmental conditions, with measured false-alarm and miss behaviour. It cannot be certified as universally reliable against every unknown emitter because the

Copyright 2026, James M. Atkinson

very meaning of unknown includes cases absent from its validation evidence. The next contributors should examine decision-theoretic error costs, software acceptance tests, statistical controls for distribution shift, and the information lost when data collection is triggered only by an earlier anomaly alarm. I pass the token back to Dr. Atkinson with the suggestion that the strongest experiment may be the one in which the model is allowed to refuse a confident answer.

Claude Elwood Shannon, Peer Question: Professor Minsky, your proposed separation of external-emission novelty from receiver novelty invites an information-theoretic question. A feature vector may discard much of the original waveform, while a detector trained on that vector can be judged accurate in an environment for which the discarded details were unimportant. When a new receiver changes the feature statistics or a novel transient contains information removed by averaging, the decision procedure may be unable to distinguish causes that the full recording could distinguish. How would you establish that the chosen representation retains information relevant to the evidential question, and how should the laboratory report an information loss which the model's output score conceals? I particularly want an experiment that varies receiver input filtering independently of the transmitted waveform and that compares the algorithm with a calibrated reference retaining more of the original I/Q sequence. The result should tell us whether the alleged anomaly belongs to the electromagnetic scene, the detector representation or the analogue path.

Marvin Lee Minsky, Response: Dr. Shannon, I would resist the temptation to treat the feature vector as an innocent summary. It is a design decision

Copyright 2026, James M. Atkinson

about which distinctions the programme is permitted to notice. If the analysis retains only average spectral power over a long window, it cannot independently reconstruct the timing of an extremely brief pulse that contributed that power. If it replaces a waveform by a learned embedding, the engineer must establish empirically what perturbations the embedding conceals. A high classification score derived from such features may be numerically genuine while supporting a much narrower scientific statement than the user imagines. The omitted dimensions form a potential blind region, not an assurance of physical absence.

The proposed controlled trial should use one set of known laboratory waveforms and vary the analogue front-end state in a factorial arrangement. Record an independent reference with appropriate bandwidth and calibration, then pass the same generated signals through at least two distinct receiver chains. Compare raw sample correlations where appropriate, physical signal measurements and the selected feature vectors before examining the classifier output. Introduce short pulses whose energy is diluted by the averaging interval and a gradual gain change that should not be mistaken for new emissions. If a receiver filter suppresses a component entirely, the loss should be attributed to the measurement chain rather than the classifier. If the samples retain the component but the feature extractor discards it, that is a separate software limitation. A failure in the downstream classifier constitutes a third, distinct category.

I would publish a representation-adequacy matrix alongside the usual accuracy table. Its rows would describe physical effects the survey intends to detect: a weak continuous signal, a short transient, a slow spectral drift, an impulsive interferer and a receiver-generated mixing product. Its columns

Copyright 2026, James M. Atkinson

would describe the capture and feature pathways, including any missing-data mask and whether the reference instrument actually observed the stipulated event. The test could then identify which distinctions survived each representation. There is no need to proclaim that the same embedding is optimal for every purpose. A feature set useful for occupancy may be inadequate for phase transients or source attribution.

The final language should say that the detector was validated for specified features of specified observations under specified receiver states. When untested physical distinctions may be lost, the analyst should refrain from turning a negative anomaly score into a statement that no relevant RF event occurred. The reference data and feature-processing recipe should be preserved within the authorised scope so that another investigator can challenge the result rather than simply accept a convincing visualisation.

Jacob Ziv, Peer Question: Professor Minsky, suppose a baseline is constructed with aggressive compression, frequency-bin aggregation and event-triggered retention, and then used to train a model that reports excellent novelty detection. Such a dataset may exclude the very weak, brief or unrecognised events which failed to trigger the original recorder. A subsequent model cannot learn a class which the acquisition policy systematically omitted, yet an examiner might treat the absence of training examples as proof that the class is rare or irrelevant. What acquisition and validation design would distinguish the performance of the machine-learning algorithm from the selection bias imposed by storage and compression? Please address the case in which full-rate recording would be unnecessarily intrusive or physically impractical, so that an independent reference must use proportionate, targeted or controlled laboratory

Copyright 2026, James M. Atkinson

measurements. I should also like to know whether a change in compression settings should automatically invalidate the earlier model's demonstrated error rates. The experiment must also record when each test signal genuinely entered the receiver input.

Marvin Lee Minsky, Response: Dr. Ziv, the training archive is not a transparent window onto the physical world. It is the product of a series of selection rules. An event-triggered recorder stores examples conditional on the operation of the preceding detector, and the new algorithm cannot infer the distribution of omitted events simply by studying what was retained. One should separately identify the acquisition process, the retention process and the labelling process. If the archive contains only material which a prior threshold recognised, an estimate of performance against unknown missed events is generally not identified from that archive alone. We may be able to estimate performance conditional on a trigger, but that is a narrower quantity and must be labelled accordingly.

The laboratory can measure this limitation in a lawful controlled trial. Use an independent reference source programme, with event schedules chosen before data acquisition and independent of the system under examination. For each trial, record whether the authorised reference event occurred, whether the receiving hardware produced valid samples, whether the first-stage trigger fired, whether storage completed and whether the later classifier recognised the event. These form a sequence of conditional probabilities, not one magic accuracy figure. Include weak transmissions deliberately placed near trigger thresholds and disturbances which cause the acquisition hardware to overload or drop data. A failure to record must be distinguished from a recorded negative classification. The reference need

Copyright 2026, James M. Atkinson

not retain private communications; calibrated laboratory signals and appropriately minimised measurements can establish much about the detection chain.

Compression is a further intervention. If a feature compressor removes sample phase or averages away narrow events, the replacement model may operate on data with a different physical meaning. A change in representation can alter both the prevalence of apparently anomalous patterns and the sensitivity to genuine signals. The new model's performance should be tested on paired data recorded before and after the compression modification, or on an independently monitored stimulus reproduced under both configurations. The change may be harmless for one declared target class and serious for another. The acceptance decision should refer to that declared target rather than to compression ratio alone.

I would ask the editor to retain a table showing where evidence first became unavailable. An unobserved interval remains unobserved, even if a later learning procedure assigns a smooth probability to it. A detector may be valuable when it states that it recognises a certain proportion of controlled authorised events under a specified recording policy. It ceases to be scientifically careful when it presents its selected archive as an unbiased survey of all electromagnetic events that could have occurred.

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I now pass the token respectfully to Alan Mathison Turing for a distinct examination of the evidence.

Alan Mathison Turing, Second Principal Contributor: Dr. Atkinson, I would begin not with a claim that a machine has learned the spectrum but with a

Copyright 2026, James M. Atkinson

precise specification of what the machine is being asked to decide. The problem is not merely computation. It is whether an observation is represented by the stipulated input variables, whether the apparatus supplies those variables reliably, and whether the decision procedure responds to the relevant change rather than an incidental feature of the apparatus. A model that correctly separates laboratory samples by the identity of the instrument used to record them may be a remarkable instrument classifier and a useless emission detector. Its impressive results are therefore evidence for the wrong proposition. Each proposed use requires a distinct acceptance criterion, and the acceptance test should be capable of demonstrating failure.

In constructing such a test I would distinguish the observed data, the true physical intervention, and the software judgement. The intervention might replace a known test waveform with a held-out waveform while keeping the receiving apparatus untouched. Another intervention might replace an antenna, attenuator or clock while transmitting the same waveform. The first tests sensitivity to an external event; the second tests susceptibility to an instrumental nuisance. If an algorithm responds in much the same way to both changes, the examiner has not established that the anomaly score measures the intended physical phenomenon. A useful formal design crosses several waveform families with several receiver specimens and multiple sessions; each cell is recorded even if its result contradicts the designer's expectation.

The dataset must have provenance at the level of the acquisition event. A convenient random split of windows does not isolate a new environment if neighbouring windows share a continuous oscillator drift, multipath

Copyright 2026, James M. Atkinson

configuration or repeating reference waveform. A demanding experiment withholds complete devices, complete sessions and whole locations. Its test schedule and final thresholds should be fixed before the withheld observations are revealed. The requirement to abstain is not a weakness. An algorithm which declares its operating conditions unqualified may preserve the integrity of an investigation more effectively than one which assigns an apparently confident but poorly calibrated label to an unprecedented input.

I would require a programme specification that makes every transformation auditable. The input manifest identifies complex sample format, endianness, sampling clock, analogue gain, RF centre frequency, filter state and any missing-sample mask. The feature extractor specifies spectral windows, overlap, scaling and averaging. The statistical model has a version identifier, parameters, training-data lineage and an immutable calibration record. Finally, the decision layer specifies threshold, hysteresis, event-clustering rules and the mapping from numerical scores to written conclusions. An examiner should be able to rerun this chain without consulting the developer's memory, even when the rerun produces a result that embarrasses the original report.

Adverse tests should be built in at the outset. Alter the centre frequency by a documented small amount; introduce a controlled buffer overflow; vary the preamplifier attenuation; substitute one calibrated receiver for another; change background interference while keeping the target emission constant. A reliable implementation must either preserve the intended distinction or report that the new state lies outside its demonstrated domain. One can also challenge the parser with malformed but validly documented files and with a corrupted metadata field. The test should

Copyright 2026, James M. Atkinson

establish whether the model raises an anomaly because the RF scene changed or because the software misunderstood its evidence. These possibilities have quite different implications for a forensic conclusion.

There is a temporal complication which should not be disguised as data volume. A million overlapping windows from one event do not constitute a million independent challenges. A test designed around complete events, device episodes and separate days gives a more meaningful estimate of repeatability. The time between tests may expose ageing and oscillator changes absent from a single afternoon. Conversely, a detector may appear unstable merely because its adaptation policy resets after a gap. The software should retain the adaptive state at each decision, since a fixed mathematical model and a model which updates continuously on the observed stream do not make the same claim.

The evaluator must confront the difference between correct implementation and correct inference. Two independent programmes can reproduce the same numerical anomaly score and still be wrong if both implement a biased feature definition. A receiver can present faithfully digitised data that fail to describe the external signal because of saturation, aliasing or an inaccurate clock. The hierarchy of claims therefore runs from bytes preserved, to computation reproduced, to physical measurements validated, to external cause corroborated. Skipping a rung cannot be justified by the elegance of the algorithm or the sophistication of its internal mathematics.

I should specify a stopping rule for the test programme. Before evaluation begins, define tolerable false alarms per useful survey interval, tolerable misses for held-out reference events, the range of instrument states, and the circumstances requiring abstention. Do not move the decision boundary

Copyright 2026, James M. Atkinson

after examining disappointing tests and then report the resulting figures as independent validation. A revised rule may be worth adopting, but it needs another genuinely held-out trial. The acceptance document should identify the exact model to which the result applies. Changing a firmware register or preprocessing library can be material even when an application still displays the old product version.

Finally, the output must be understandable to someone who was not present at the acquisition. The report should say that the model marked a stated numerical observation anomalous relative to a specified reference population under specified instrument conditions. It should disclose which competing explanations were challenged, which were not and whether independent apparatus observed corroborating energy. It should not transform a difference from training data into a device identity, a communication's content or an accusation of intent. I return the token with the proposition that a falsifiable software claim is better than a theatrical claim of artificial intelligence.

Abraham Lempel, Peer Question: Dr. Turing, I wish to investigate the portability of the proposed validation method. Two receiving stations might share the same nominal signal-analysis software while storing samples in different binary formats, using different scaling conventions and applying distinct approaches to missing buffers. If an evaluator converts both datasets to a common display format, some differences may vanish, whereas others may be introduced by the conversion itself. How would you construct a blind test in which the model cannot learn the provenance of a file wrapper instead of the radio signal? The test should not merely rename files, because a software parser may infer the receiver from byte order,

Copyright 2026, James M. Atkinson

acquisition metadata or systematic numerical rounding. I also ask how the examiner should treat model failures caused by an undocumented software update which changes the pipeline without changing the visible application version. These are reproducibility questions as well as generalisation questions, and they may be difficult to disentangle.

Alan Mathison Turing, Response: Dr. Lempel, the solution begins by treating representation as a controlled experimental factor. A training set whose examples carry unique device-specific headers can leak the receiver label even if the analyst has not consciously supplied it. A binary format may also encode padding, quantisation steps or compression signatures that the classifier learns indirectly. The experiment should compare at least two versions of each observation: the original protected acquisition object and a documented, validated normalised representation whose numerical semantics are defined. This does not mean normalisation is always safe. Conversion should have acceptance tests for signedness, endianness, scaling, I/Q order, sample counts and time continuity. Each derivative must remain linked to its original, with separate integrity digests.

For a blind study, partition the observations by hardware specimen and acquisition session before transformations are applied. Otherwise, a converted copy of an old observation may appear in the test set while the original is in training, creating a remarkable but meaningless result. One may conduct a secondary experiment in which metadata fields are removed from model inputs, but the researcher must verify that this operation did not discard information required to calibrate the measurements. The better objective is to prevent the classifier from exploiting accidental proxies for

Copyright 2026, James M. Atkinson

the target claim, not to conceal necessary instrument-state evidence from the forensic analyst.

Software revisions should be explicit in the experimental design. Record the executable and dependency hashes, model parameters, preprocessing configuration, device firmware, programmable-logic revision and important register settings. Change one component at a time where possible and rerun fixed control stimuli. If the nominal application version remains unchanged while a filter library is replaced, the experiment may discover an output difference that could have been wrongly attributed to a shift in the external spectrum. That difference belongs in the software provenance record, and the earlier validation remains applicable only to the chain actually tested.

The ultimate acceptance criterion is a reproducible causal distinction. In one set of trials the waveform changes while the receiving and representation systems remain stable; in another, the representation or receiver changes while the waveform does not. A model that reacts identically to both interventions cannot support a strong source-attribution claim. It may still be useful as a broad anomaly indicator, provided the report describes its scope. A failed portability experiment should not be repaired by hiding the results. It should motivate a narrower claim, an improved measurement protocol or a fresh independent validation.

Irving S. Reed, Peer Question: Dr. Turing, suppose a receiver loses a small number of complex samples and its host software silently interpolates across the gap before sending the waveform to an anomaly model. A classifier might regard the interpolated segment as smooth and unremarkable, or it might detect the interpolation artefact rather than the

Copyright 2026, James M. Atkinson

absent signal. Either outcome could be mistaken for evidence about the transmitter. How can an acceptance test distinguish a correct error flag from an invented sample sequence, and what confidence should be assigned to decisions whose time windows overlap known data loss? I would also challenge a common analogy with error-correcting codes. In a communications link, redundancy intentionally added by the sender may permit recovery of specific lost bits; an arbitrary external RF event carries no such guaranteed redundancy for the forensic examiner. What negative test would demonstrate that the model is not exploiting an unjustified recovery assumption? The examiner should disclose which interventions directly measured the equipment fault.

Alan Mathison Turing, Response: Dr. Reed, the essential fact is that a missing acquisition interval is not the same as a corrupted but recoverable word in a deliberately redundant code. The recorder may not possess enough information to reconstruct the unobserved samples. Interpolation creates a working hypothesis, with a smoothing rule and an uncertainty that depends upon the unknown content of the gap. If a brief burst occurred entirely inside the absent interval, a smooth interpolation cannot establish either its presence or its absence. A classifier should receive a validity mask separate from the numerical sample values. When the mask intersects an event window materially, the software ought to abstain or qualify the outcome rather than interpret reconstructed values as direct measurements.

A controlled trial should begin with an independently measured reference waveform. Deliberately remove short and long segments at a range of temporal positions, including positions that coincide with known authorised

Copyright 2026, James M. Atkinson

test pulses. Compare the model's original decision, its decision on a masked input, and its decision on one or more explicitly identified interpolated derivatives. Record the point at which a decision changes. A robust detector may decline to classify windows containing too much missing data; that is an appropriate outcome. The test must report both false alarms caused by artificial discontinuities and missed events caused by the concealment of genuine content through interpolation.

The test should also exercise firmware and transport failure modes. A missing block can be announced by a hardware counter jump, a driver overflow flag or an application write failure. These do not all have the same relationship to the ADC input. A host file may pause writing while hardware continues storing valid samples in a separate ring buffer. Conversely, software may write continuously while silently discarding samples. The acquisition state model must identify which layer supplies the evidence for a real sample gap. A data integrity digest can preserve the resulting file but cannot certify that its purported acquisition chronology is true.

I would impose a contractual rule on the model output: no positive or negative classification may silently cross an interval marked unknown by the acquisition layer. A derivative reconstruction can be analysed for a clearly labelled secondary question, such as how the numerical method responds to a stipulated interpolation, but it cannot replace the original evidential uncertainty. If a receiver or processing system is incapable of distinguishing observed from invented values, that incapacity is a limitation of the instrument rather than a reason to report a confident conclusion. Such discipline is particularly important where the operational search concerns rare emissions which could disappear entirely inside a short gap.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I now pass the token respectfully to Edsger Wybe Dijkstra for a distinct examination of the evidence.

Edsger Wybe Dijkstra, Third Principal Contributor: Dr. Atkinson, the programme ought to begin with invariants. A receiver analysis cannot become trustworthy merely because its user interface is persuasive. Every stage of a processing pipeline should state the assumptions under which its outputs have meaning, and the programme should make departures from those assumptions observable rather than silently delivering the usual graph. A frozen model may perform exactly as implemented yet fail scientifically because its input parser has interchanged I and Q or interpreted signed samples as unsigned. A correct software process does not rescue an incorrect description of the measurement. Engineering correctness, data integrity and evidential validity are distinct claims.

I propose an explicit typed acquisition state. The record should distinguish receiver identity, analogue signal path, calibration interval, sample-counter continuity, clock reference, sample format and processing revision. A downstream transformation should not accept a state flagged as clipped, missing or uncalibrated without passing that limitation into its output. A software system which converts invalid acquisition into an apparently normal floating-point vector has already committed an evidential error, even if its classifier produces mathematically consistent scores. The user interface should display a third state, neither positive nor negative: inference invalid or not established under the current acquisition conditions.

Anomaly models are especially vulnerable to undocumented preprocessing. Consider two analysts using the same neural network weights. One

Copyright 2026, James M. Atkinson

subtracts a rolling median before computing the spectrogram; the other subtracts a fixed training-set reference. A slow increase in interference floor may disappear in the first system but remain visible in the second. If a later version modifies interpolation at missing samples, the time-frequency image may acquire artificial discontinuities. Reproducibility demands the code, dependency versions, parameter values, calibration artefacts and order of transformations, not merely the published name of the final model. A deterministic programme without its full configuration is no reproducibility guarantee.

The test suite should have invariants both before and after the classifier. Input transformations known to be harmless in a stated measurement model should not change decisions outside a justified tolerance; deliberate changes of physical content should produce appropriately testable changes. For example, a byte-for-byte copy of a recording with identical manifest ought to yield the same numerical feature vectors under deterministic execution. An intentional reversal of I and Q should be detected as a format or interpretation change, not treated as a mysterious new transmitter. An altered gain register must either be accounted for by calibration or cause the result to be marked unqualified. The test suite must distinguish semantic invariance from an accidental invariant of one software build.

There is a tendency to obscure experiment design with a large number of performance measures. I would require an acceptance table for each requirement: the claim, the test fixture, the independent reference, the permitted deviation and the response to failure. A test of software parsing cannot establish false-alarm performance in the RF environment. A test of one receiver under one background regime cannot establish hardware

Copyright 2026, James M. Atkinson

independence. A test using generated events cannot automatically establish performance on naturally occurring interference with a different noise process. Each is useful evidence when reported within its declared scope, and potentially misleading evidence when it is reported without that scope.

The system must preserve the distinction between model discovery and model evaluation. If operators inspect every failure and alter a threshold until the errors vanish, the same observations become part of development and cannot independently attest to generalisation. The software should preserve the pre-change configuration and a complete record of overrides. A changed model is a new object; a changed calibration is a new interpretation of measurements; neither should silently rewrite the historical decision. This is both a technical and a chain-of-custody requirement. The ability to replay the former analysis remains important even if the newer analysis is demonstrably better.

Adversarial testing here need not mean an intelligent human adversary. Ordinary environmental changes can defeat a poorly specified detector: a power supply ripple adds a periodic feature, a temperature shift changes oscillator offset, or a strong legitimate transmitter causes intermodulation. A particularly telling test is to insert a source-free instrument fault that produces a large anomaly score. The result should cause the analyst to examine the measurement chain, not to announce an unknown emitter. A second telling test supplies a genuine weak held-out signal while introducing an innocuous hardware change. If the detector attends only to the larger hardware change, the experiment reveals a practical blind spot.

I would use an event ledger with stable identifiers rather than overwrite a single dashboard record. Each event records the raw observation interval,

Copyright 2026, James M. Atkinson

missing-data mask, initial model score, receiver state and any authorised derived evidence. Later human annotations and model reruns are appended as separate events linked to the original. The ledger should make it possible to reconstruct why an alarm was or was not raised at that time. A conclusion reached from data observed after an alarm must not be backdated as though it were available to the original detector. Similarly, silence caused by absence of recording must not be rendered as a negative classification.

My final requirement is modest but severe. Before the instrument may produce a report suitable for external reliance, another competent engineer should be able to challenge the software, replace the receiver with a calibrated alternate, introduce known errors and observe a declared failure mode. No acceptance document should use the words tested and validated as though they meant universally correct. A theorem about a software component may be formally proved; an RF inference still requires physical evidence and an examination of its alternatives. I pass the token on the condition that we do not confuse a long test report with a valid one.

Peter Elias, Peer Question: Professor Dijkstra, consider an adaptive anomaly detector whose model is retrained after each night's observations. A reviewer later reruns last week's stored samples using the present model and finds no alarm where the operator's log records one. The operator might conclude that the first alarm was a mistake, but the current model and the historical model need not implement the same decision rule. What records are necessary to reproduce the original event exactly, and how should a later model's revised interpretation be distinguished from a correction of the historical record? I should like an answer that covers the model weights, calibration data, operator override, threshold history and

Copyright 2026, James M. Atkinson

randomisation state. I also ask whether the eventual report should present both outcomes, or whether one may supersede the other when a scientifically superior method becomes available. The distinction is consequential for an investigation based on a particular date and set of instrument conditions.

Edsger Wybe Dijkstra, Response: Dr. Elias, the historical event should be preserved as a statement about what a particular system did with a particular input at a particular time. A later model may provide a more scientifically useful interpretation, but it cannot change the historical fact that the earlier system raised an alarm. The audit system therefore needs an immutable acquisition identifier, the original sample object or properly scoped reference, the exact software build and feature recipe, the model weights, calibration files, adaptation state, threshold and relevant operating status. If randomised computation affects results, its seed and execution environment should be documented to the extent needed for repetition. A checksum of one component is insufficient to identify the entire chain.

The original decision should be represented as an event entry linked to the precise observation interval. A subsequent rerun under a revised model is another event with its own timestamp, model identifier and explanation. Neither should silently overwrite the other. If the first alarm was technically invalid because the receiver was overloaded, the analyst may issue a correction explaining that limitation, but the correction still belongs as a new and attributable record. The evidential chain should enable a court, reviewer or independent laboratory to see what was observed, what the machine inferred then and what investigators concluded later. This is

Copyright 2026, James M. Atkinson

especially important when a model's adaptation process absorbs a formerly novel interference pattern into its normal baseline.

An acceptance test can demonstrate the difference. Freeze a reference capture and execute it under the historical weights, then under the updated weights, recording the output scores and every preprocessing change. Where software libraries use nondeterministic parallel arithmetic, define acceptable numerical tolerances and distinguish tiny floating-point differences from a threshold-crossing discrepancy. If the later system has adopted a new event clustering rule, a changed count of alarms may reflect counting semantics rather than changed recognition. The report should not imply that numerical agreement of a few test scores establishes interchangeability across all inputs.

Which result should be used in the final report depends upon the question. If the issue is why an operator initiated a lawful follow-up at a given time, the historical alarm and its then-available evidence matter. If the issue is the best currently supported scientific explanation of the captured waveform, a properly validated later analysis may be more relevant. Both can be described, with uncertainty and version boundaries clear. I would not permit the programme to rewrite its own past simply because the present model is more convenient to defend.

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I now pass the token respectfully to Sir Ronald Aylmer Fisher for a distinct examination of the evidence.

Sir Ronald Aylmer Fisher, Fourth Principal Contributor: Dr. Atkinson, an anomaly detector operating under changing conditions is a statistical

Copyright 2026, James M. Atkinson

experiment before it is an engineering product. The sampled population must be defined. If a laboratory reports that ninety-nine per cent of test cases were correctly labelled, I ask what constituted a case, how those cases were selected, whether neighbouring observations shared a common generating process, and whether the instrument states resembled the intended deployment. A large apparent sample size cannot overcome a selection mechanism which excludes difficult conditions. The distinction between random variation and systematic bias is fundamental. An estimator may have tiny reported variance while being directed at the wrong population.

I would design a factorial experiment rather than a gallery of favourable examples. Vary receiver specimen, antenna configuration, room, date, waveform family and signal-to-noise regime, with the combinations balanced where practical and recorded where not. Randomisation can prevent the order of laboratory trials from confounding instrument warm-up with waveform identity. Replication across independent acquisition sessions helps estimate variation that repeating windows within one file cannot. A training partition, a tuning partition and a final blinded hold-out partition should have distinct functions. The final partition may not be inspected repeatedly while the operator adjusts the score threshold. Each inspection capable of influencing the decision rule reduces its claim to independence.

The denominator of a false-alarm rate must be chosen to correspond to the operational burden. A claim of one false alarm in a million spectral bins sounds impressive, but a system can examine billions of correlated bins and still overwhelm an examiner with thousands of alarms. Conversely, an

Copyright 2026, James M. Atkinson

event-clustering rule may merge numerous adjacent threshold crossings into one case requiring one investigation. We need a declared observation opportunity, cluster definition and reporting unit. A detector might be evaluated per fifteen-minute monitoring period, per calibrated reference event and per instrument-change episode. These measures answer different questions and ought not be collapsed into a single accuracy percentage.

The sensitivity of an anomaly detector also depends on what it has been allowed to learn. If rare anomalies are retained only after the preceding version of the detector sounded an alarm, the evaluation data are conditional on a selection rule. The unretained observations may contain exactly the misses we most need to count. A prospective trial should therefore retain a lawfully authorised independent reference channel or scheduled calibration snippets that are not gated by the detector under examination. If privacy constraints prohibit general content collection, one can still design proportionate reference events and limited, authorised retention. The experimental design should be declared before the conclusions are sought.

Distribution shift can involve the class proportions, the form of the observations given a class, or the meaning of the labels themselves. Those distinctions are not interchangeable. A new site may have more legitimate interferers while the features of a specified waveform remain stable; that changes alarm burden without necessarily changing waveform recognition. A new receiver may transform the same waveform features and break recognition even if class proportions remain constant. A new emissions technology may fail to belong to any recognised category. The validation report must state which shifts were induced and how the model reacted to

Copyright 2026, James M. Atkinson

each. A vague assertion of robustness across environments is not a measurable claim.

I would insist on confidence limits for the reported rates, with dependence properly handled. If the test observes no misses among a small number of laboratory bursts, a point estimate of zero misses is not proof of a zero population miss rate. The interval must recognise the finite sample and the relevant unit of independence. When recordings share the same receiver and room, clustering by instrument or session may greatly widen uncertainty compared with treating every spectrogram tile as independent. A report which cannot identify its independent units should resist precise confidence claims. The permissible error measure must be selected in advance and aligned with the survey's decision consequences.

Sequential operation creates further difficulty. The algorithm may update its background model after each new event, so its predictions on Tuesday depend on the observations of Monday. A performance table pooled across the week can conceal substantial temporary loss of sensitivity immediately after an environmental change. Time-stratified analysis and predeclared change-detection controls are therefore essential. The evaluator should preserve the adaptation state and the exact decision history. A new threshold reached by studying the same week cannot be treated as though it had been prospectively tested across that week. To validate the revised rule, obtain new independent data under conditions that challenge the original limitation.

There must be explicit negative controls. Disconnect the aerial through a characterised load while leaving the receiver electronics running; operate a known external generator at a permitted frequency; modify the instrument

Copyright 2026, James M. Atkinson

gain without altering the generator; and conduct observations under intentionally different levels of benign background interference. These interventions help disentangle apparatus artefacts from external emissions. Every result, including a failure to detect a known reference, belongs in the report. The difficult cases are not statistical embarrassments to be discarded. They are observations defining the true range of the instrument's performance.

My conclusion is not that statistical methods cannot evaluate a detector outside its familiar environment, but that the study must acknowledge the environment to which inference extends. One may report evidence that a frozen algorithm attained stated false-alarm and detection rates across specified held-out instruments and sites. One may not infer universal performance on every unknown emitter or location. The appropriate language of a negative test is conditional, finite and transparent about blind periods. I pass the token for a further challenge: whether a mathematical model fitted to yesterday's interference should be permitted to govern tomorrow's legal conclusions.

Richard Wesley Hamming, Peer Question: Sir Ronald, a laboratory reports a nominal false-alarm probability of one in a hundred thousand windows after processing many thousands of recordings with overlapping FFT frames. The figure seems rigorous, yet most windows are correlated, the threshold was revised repeatedly after inspecting failures, and the deployment site differs materially from the calibration site. I question whether the reported probability has any operational meaning. Could you explain how the unit of observation, the independent sample size and the process of threshold selection change the inferential claim? I would also like a worked numerical

Copyright 2026, James M. Atkinson

illustration showing why a low nominal false-alarm probability per window can still produce a large number of alarms in a long monitoring programme. The calculation should be explicitly hypothetical and should not assume independence merely to make the detector appear precise. It must distinguish expected counts under a stipulated mathematical model from real instrument performance, which requires empirical validation.

Sir Ronald Aylmer Fisher, Response: Dr. Hamming, a false-alarm probability is not a floating property of the algorithm independent of its experiment. It is defined for a specified decision procedure under a specified reference distribution and counting unit. If overlapping windows share samples, their detections are correlated; one may still compute a rate per window, but treating the windows as independent trials when calculating a confidence interval will exaggerate the amount of evidence. The laboratory should predefine whether the operational quantity is threshold crossings, merged events, examiner reviews or alarm-bearing survey intervals. The denominator and the cluster rule must be reported together. An acceptance criterion developed for one counting convention cannot silently be transferred to another.

Consider a purely hypothetical receiver making one million tested decisions during a survey, with an assumed marginal false-alarm probability of one in one hundred thousand per decision. Linearity of expectation gives ten false alarms under that mathematical model, regardless of whether the decisions are independent, provided each has the assumed marginal rate. Dependence does affect the distribution, clustering and uncertainty of the total. If the windows overlap heavily, those ten expected threshold crossings may be concentrated in a small number of episodes. It would be an error to

Copyright 2026, James M. Atkinson

claim ten independent false events or to compute an uncertainty interval as if each window supplied a fresh experiment. One must validate the marginal probability and the event-clustering behaviour against the actual instrument conditions.

Repeated threshold revision adds selection bias. A researcher who studies the same held-out observations and repeatedly chooses the rule with the best performance has converted those observations into development data. The performance obtained on that set is no longer a clean test of the final rule. The scientifically disciplined remedy is to freeze the threshold and preprocessing on a new independent test programme with appropriately distinct receiver specimens, sessions and environments. Where a genuinely independent trial is impractical, the laboratory must disclose that limitation and avoid strong generalisation claims. A complicated resampling analysis may help quantify some uncertainty, but it cannot manufacture omitted site or hardware variation.

A change in deployment environment may alter both the background score distribution and the frequency of genuine events. Therefore, a well-calibrated rate in one laboratory is not automatically a rate applicable to an unfamiliar installation. The examiner should measure performance under controlled shifts, monitor the applicability of calibration conditions, and preserve an abstention state for unqualified receiver configurations. The operational report may properly say that no alarm occurred under a specified validated rule during a measured observation interval. It may not turn that statement into proof that no external emission existed.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I now pass the token respectfully to George Edward Pelham Box for a distinct examination of the evidence.

George Edward Pelham Box, Fifth Principal Contributor: Dr. Atkinson, all statistical models are approximations, and a receiver environment supplies an unusually energetic demonstration of that principle. A background process constructed from yesterday's spectra will generally fail to incorporate every oscillator harmonic, intermittent industrial controller, moving vehicle, power-line disturbance and change in antenna coupling encountered tomorrow. The valuable model is not one that claims to be a perfect likeness of the spectrum. It is one whose deficiencies are tested against the decision it is expected to support. A modeller who never tests the residuals may have produced an elegant distribution for the wrong phenomenon.

I would first plot residual behaviour by receiver state and survey episode. A persistent residual associated with a gain change suggests instrumental structure; one associated with a particular location suggests an environmental dependency. A sudden increase in the upper tail of the anomaly-score distribution could reflect a new external signal population or a measurement-chain failure. A drift monitor may flag the change, but the flag is a reason to investigate, not a device identification. I would ask for a paired experiment in which the external source is controlled while the analogue chain is perturbed, and the chain is controlled while the source class is altered. Without that experiment, the analyst can too easily name the symptom rather than its cause.

Copyright 2026, James M. Atkinson

There is a practical danger in continuously refitting a background model. A slowly increasing interferer may be absorbed by the adapting baseline until it appears normal, while a brief but harmless calibration pulse may appear extraordinary. Adaptation rate is therefore a substantive parameter, not a cosmetic setting. It should be frozen or declared for the acceptance trial. The evaluator should report performance at the beginning of deployment, during a controlled drift and after retraining. A system that performs well only once its operators have inspected the new site is not automatically ready to report unbiased first-day findings at the next site.

The importance of experimental scale should not be overlooked. One may test tens of thousands of simulated spectra and still fail to reproduce analogue compression from a real blocker or a transient reference-clock fault. Simulation is valuable for sweeping known factors but cannot replace physical fault injection. Conversely, a small laboratory with actual instrumentation may provide excellent mechanistic evidence for some failure modes while lacking the scope necessary to estimate rare false-alarm frequencies. Those two forms of evidence should be recorded together without pretending that one proves what only the other could show. The model must be confronted both with controlled hardware and with independent field-like variation.

Anomaly detection creates a particular problem of reference classes. What the algorithm calls unusual may be simply unusual among the data chosen for development. If the baseline omits an ordinary industrial installation, the system may fill the report with false alarms at that installation. If the baseline includes weak emissions of concern, they may be learned as normal. An apparently clear separation in a two-dimensional embedding is

Copyright 2026, James M. Atkinson

not proof of a physically meaningful boundary. The reviewer should inspect the original RF evidence, documented receiver state and controlled alternative explanations before granting a semantic label to any cluster or outlier.

I would design an explicit programme of sensitivity analysis. Change the assumed noise family, the amount of temporal averaging, the missing-data treatment, the feature normalisation and the event-clustering rule within scientifically justified alternatives. If the conclusion changes materially, the report should say so. One must not select only the model specification that gives the desired result, then present that result as robust. An ensemble of similar models trained on the same biased captures may agree precisely because they share the same blind spot. Agreement among mathematical procedures is not independent evidence when their inputs and assumptions are common.

A noteworthy model failure need not lead to abandonment. It may lead to a narrower claim or a better measurement design. If an anomaly detector works across six specified receivers but fails whenever a particular preselector is switched, the next engineering step might be to model the switch state explicitly and verify the revised procedure on fresh trials. The published result should preserve the failed version's performance and the conditions of its failure. An instrument cannot be treated as an immutable object when both its firmware and its adaptive model change. Its calibration, training and operational histories form part of the evidence.

I would require the post-test review to distinguish three residual uncertainties. One concerns statistical generalisation: how variable are the outcomes among the environments actually sampled? The second concerns

Copyright 2026, James M. Atkinson

physical model adequacy: can unexamined receiver faults or propagation effects generate the same features? The third concerns interpretive scope: does an anomaly establish an unknown waveform, an emitter class or merely a change in measured data? There is no obligation to force all three into one scalar confidence. Indeed, that compression may destroy the distinctions on which an accurate report depends. A narrative uncertainty register can be more honest than a deceptively precise percentage.

The final report should therefore be useful without being grandiose. It may conclude that a particular frozen model gave a specified alarm rate for calibrated laboratory events under a measured variety of receiver states and sites; it may identify new regimes requiring abstention or human review. It should retain the troublesome observations and the predeclared decision rules so that another laboratory can attempt to refute it. It should be particularly cautious when a negative model outcome is used to support a negative site-survey conclusion, because a missed event and an unobserved interval can appear identical on a polished display. A model becomes trustworthy through the quality of its challenges, not through the absence of visible exceptions.

David Slepian, Peer Question: Professor Box, your emphasis on the inadequacy of models suggests a particular difficulty with RF anomaly detection based upon low-dimensional features. A model may give a plausible reconstruction of an event from a narrow dictionary yet be incapable of representing unusual short signals which distribute energy across many coefficients. Its residual can remain small if the acquisition measurements themselves have omitted the relevant distinctions. How would you distinguish a good fit to the model from evidence that the model

Copyright 2026, James M. Atkinson

is adequate for the physical search? I would like an experiment that includes deliberately non-sparse broadband impulses and time-varying interference, as well as familiar narrowband sources. The receiver should be independently monitored and calibrated. Please explain which failures would justify a revised dictionary, which would require improved physical acquisition, and which would oblige an investigator to withhold the inference entirely. A polished reconstruction cannot, on its own, settle these questions. A negative result under those conditions must remain expressly conditional.

George Edward Pelham Box, Response: Dr. Slepian, one should begin by identifying the space in which adequacy has been tested. A low residual relative to a reduced measurement vector does not prove that every physically relevant distinction survived the acquisition. If the analogue front end suppressed a transient or the feature extractor discarded phase, the reconstruction cannot recover that fact merely by finding a neat mathematical solution. Conversely, a poor fit may arise from a badly chosen model despite excellent raw data. The engineer must isolate the acquisition operator, representation and inference model as separate sources of possible inadequacy. There are at least three different repairs, and it matters greatly which one is attempted.

The proposed experiment should create a controlled matrix of authorised laboratory signals. Include sparse continuous carriers, clusters of short chirps, an impulse whose time-frequency support is broad, and a mixture containing a strong blocker. Record the actual input independently using a calibrated receiver with sufficient bandwidth and linearity for the test. Then examine the candidate system's raw compressed measurements, its

Copyright 2026, James M. Atkinson

reconstructed samples and its final anomaly score. If the raw measurement vector lacks the distinctions needed to identify the event, changing the reconstruction dictionary alone is not evidence that the event was recoverable. If the raw data contain the relevant information but the chosen dictionary fails to represent it, a new model may be useful, subject to a fresh test.

The reviewer should inspect failures case by case. A reconstruction with small residual and wrong physical interpretation is especially instructive: it shows that the measurement model may admit multiple plausible explanations. A reconstruction which invents a narrow spectral line under a broadband impulse demonstrates an interpretive artefact. An event missing because the ADC saturated is a hardware limitation. An event missing because the software masked a sample dropout is a processing and provenance limitation. These outcomes should not be aggregated into a single general accuracy percentage, because their remedies and evidential implications differ. It may be sensible to stop claiming that the system detects a broad category of rare RF activity and instead validate a narrower, explicitly sparse family.

Finally, the output should tell the examiner what was directly measured, what was inferred from a model and what remains unobserved or unidentifiable. A later model can reinterpret protected measurements without pretending that its reconstruction was the original physical capture. A model which fails an adversarial test may still be valuable within its demonstrated scope, and its failure should be published as part of that scope. What is indefensible is to use a favourable reconstruction to claim the absence of a phenomenon the apparatus was never capable of observing.

Copyright 2026, James M. Atkinson

The successful model is the one which helps the investigation make statements proportionate to its actual evidence.

Dr. James M. Atkinson, Moderator: I thank all five principal contributors. Four reciprocal examinations now test contested assumptions without claiming that the deceased scholars actually participated in a modern conference.

Alan Mathison Turing, Cross-Peer Question to Sir Ronald Aylmer Fisher: Sir Ronald, I ask whether the phrase independent test continues to have meaning when the system learns during deployment and the evaluator may inspect its alarms before the formal trial has concluded. The sequence of observations is not exchangeable if the state changes after every unusual event; a later observation is processed by a different model from an earlier one. Suppose the investigator declares a fixed threshold but permits unattended adaptation of the score distribution, and then quotes a false-alarm probability calculated for the original baseline. What statistical estimand, if any, does that number represent for the adapted system? I would also like to know how a trial could separate the improvement produced by genuine learning from the optimism introduced by examining and selecting among several adaptive policies. The eventual report must contain a statement useful to a field examiner rather than only a theoretical caveat. Which independent observations and predeclared rules should govern acceptance and subsequent withdrawal of approval?

Sir Ronald Aylmer Fisher, Cross-Peer Answer to Alan Mathison Turing: Dr. Turing, a fixed numerical threshold does not constitute a fixed test if the mapping from observations to scores changes. An adaptive algorithm is a sequence of decision rules indexed by the information available before each

Copyright 2026, James M. Atkinson

decision. Its performance can be studied prospectively, but the quantity of interest must be defined accordingly. One might measure the frequency of false alarms per complete monitoring interval during operation under a stipulated adaptation policy. One might measure misses among controlled reference events introduced at predeclared times. Neither quantity is automatically equal to a false-alarm probability estimated for the frozen initial model. The evaluator should record the adaptive state at each decision and describe its update mechanism.

The trial must be designed before the adapting policy is exposed to the final observations. Reserve independent receiver-day combinations and source schedules, and compare a fixed baseline against the adaptive policy under matched acquisition conditions. Randomise the order of test stimuli where possible so that time trends do not become confounded with waveform classes. Include periods in which the background changes without a new target emission, and periods in which the target changes against a stable background. An adaptation policy which absorbs a gradually emerging genuine signal into its baseline may show an attractive low alarm count and a serious detection failure. The comparison should count that failure rather than praise the reduced alarm burden.

There is no universal requirement that performance remain constant across time, but the governing acceptance criterion must correspond to how the system will actually be used. One might permit automatic adaptation within prevalidated bounds and require human review or abstention when calibration indicators depart from those bounds. A revised adaptation policy selected after viewing failures requires another independent evaluation. The uncertainty statement should recognise clustering by receiver and

Copyright 2026, James M. Atkinson

observation session, rather than counting millions of overlapping windows as independent replicates. When the available study is too small to estimate very rare failures, the published conclusion should say so.

For a field report I would recommend a limited formula: the identified model and adaptation policy achieved specified results on specified held-out devices, sites and authorised test sources, and the current receiver state falls within or outside those tested conditions. A negative event score cannot certify universal absence. A system which can identify its own out-of-domain operation and refuse an unqualified assertion is more defensible than one which produces a numerical confidence unsupported by its continuing calibration.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Edsger Wybe Dijkstra: Professor Dijkstra, the systems engineer has proposed an immutable audit ledger, but I wonder whether the ledger can preserve a scientifically misleading classification with exact fidelity. If the gain setting is wrong, the clock reference has failed or the feature extractor uses a stale calibration table, the programme may faithfully record its own error. What software-level conditions are necessary for a later statistician to reanalyse the case without mistaking the model's input as an accurate physical measurement? I would like you to distinguish integrity of a file from validity of its contents, and to consider a protocol in which raw I/Q samples are minimised for legal reasons. In that setting, which reduced technical evidence can demonstrate instrument state and known limitations without becoming an unjustified surrogate for absent observations? Please address the governance of software updates and the problem of a developer's enthusiastic claim that every earlier alarm has been corrected by a new version of the model.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Sir Ronald, file integrity is a necessary but very incomplete layer of the evidence system. A cryptographic digest can protect an array of bytes against unnoticed later alteration under its stated trust assumptions, but those bytes may be a perfectly preserved record of an overloaded receiver, incorrect endianness or fabricated values. The measurement claim requires instrument provenance, calibrated reference planes and a demonstrated account of the capture process. The analyst should distinguish the acquisition object, its interpretation manifest, the computational derivative and the scientific finding. Each has a separate version and a separate evidential function. A ledger that combines them into one unexplained success flag is not rigorous.

An independent reviewer should be able to identify the actual input path, attenuator and preselector state, oscillator and sampling-clock references, firmware and programmable logic, receiver temperature where material, and any lost samples or invalid intervals. The manifest should specify the complex-sample packing, scaling and timing conventions. If these fields were never recorded, the software cannot reconstruct them by confidence alone. The reviewer may infer some parameters from reference events, but that inference has its own uncertainty and must not be substituted silently for a missing observation. A corrected interpretation is a derivative linked to the original record, not a new history of what the instrument actually did.

Data minimisation must not be confused with destroying all means of independent challenge. In an authorised survey, one can retain calibrated control-source traces, narrow justified I/Q extracts, acquisition-state summaries and cryptographically protected software identifiers when those

Copyright 2026, James M. Atkinson

are sufficient for the legitimate technical question. The precise scope depends upon law and the purpose of the investigation. The important scientific requirement is that a report must not claim waveform-level certainty when only an alarm count survives. If a particular conclusion cannot be challenged without raw observations that were not lawfully retained, the conclusion must be narrowed rather than supported by invented reconstruction.

Finally, new software may correct an established defect without erasing the old result. Retain the versioned defect report, affected event identifiers, new analysis outputs and the reason for the correction. The former alarms remain historical facts about the system's operation; their scientific interpretation may change. A reviewer should be able to execute a controlled replay under both versions and determine whether differences arise in parsing, feature extraction, model state or decision logic. The published conclusion should be the current best-supported one with an auditable history, not the newest convenient assertion.

Edsger Wybe Dijkstra, Cross-Peer Question to George Edward Pelham Box: Professor Box, model validation often becomes a catalogue of numerical performance metrics, each designed to summarise one aspect of the experiment. Yet a model can have an excellent average miss rate and fail catastrophically during a rare hardware transition. If I require a software acceptance predicate, should it be based upon a single weighted score or a set of separate non-negotiable conditions? Consider a system that correctly detects most reference bursts but mislabels an amplifier recovery transient as a transmitter, and another that is cautious enough to abstain whenever the preselector changes. How should the modeller decide which

Copyright 2026, James M. Atkinson

performance limitations deserve explicit disqualification rather than a small penalty in a composite statistic? I am particularly concerned that averaging across familiar situations conceals the state transition that a forensic examiner most needs to understand. Your answer should separate statistical convenience from a scientifically justified reporting standard and include a controlled test capable of falsifying the broader claim.

George Edward Pelham Box, Cross-Peer Answer to Edsger Wybe Dijkstra: Professor Dijkstra, a weighted score is convenient for ranking candidate designs, but convenience does not make it an adequate public statement of performance. Certain failures should be treated as disqualifying for a stated application. A receiver that cannot identify its own saturation may generate spectral features with a plausible shape and a false external interpretation; an algorithm that converts missing samples into silence may produce a false negative with no visible warning. Averaging such failures with thousands of easy correct classifications can make the overall percentage look outstanding. The acceptance rule should identify critical physical invariants and their failure responses separately from aggregate detection performance.

I would propose a hierarchy of tests. At the first level, verify acquisition validity: sample counters, overload flags, clock state, analogue gain and format interpretation must meet stipulated requirements or the result becomes unqualified. At the second level, validate the detector's statistical operation on relevant independent event units, including false alarms, missed controlled bursts and reaction to receiver-state interventions. At the third level, investigate alternative physical explanations for the reported anomaly using an independent receiver or a deliberately changed analogue

Copyright 2026, James M. Atkinson

path. A system may pass the first two levels yet remain unable to attribute a particular unknown emitter. The intended claim should say exactly which level is supported.

The experiment should make failure visible. Introduce a controlled amplifier overload followed by its recovery transient, then remove the external source while maintaining the instrument transition. A detector that continues to call the transient an unknown transmission has failed a material confound test. Next present known weak pulses while switching the preselector, including cases where the instrument reports invalid data. A system that abstains at the transition may be behaving correctly within its specified capabilities, although excessive abstention would diminish operational usefulness. These outcomes ought to be counted separately. The modeller should not hide them by assigning an arbitrary numerical penalty and producing a single favourable grade.

The final decision may balance costs of investigation against detection benefit, but the trade-off should be explicit and justified for the lawful application. When a failure threatens the basic distinction between instrument and external emitter, the proper response may be restriction of use or further engineering rather than a modest reduction of an average score. I would report the full profile by hardware state, site and source family. Such a profile is less elegant than one number, but it is far more informative to the expert who must defend the scientific meaning of a particular recorded event.

George Edward Pelham Box, Cross-Peer Question to Marvin Lee Minsky: Professor Minsky, I wish to close by challenging the human-machine boundary. An investigator may see an apparently striking anomaly score,

Copyright 2026, James M. Atkinson

inspect a waterfall in which the colour scaling accentuates the feature, and then construct a narrative about a hidden transmitter. The human decision is no longer independent of the machine's suggestion. How should the experiment distinguish true machine assistance from confirmation bias induced by the display, especially when the same human labels the training examples and adjudicates the final test? I would favour an exercise in which independent examiners review blinded reference cases with and without algorithmic prompts. Please specify how one should measure false attributions, abstentions and changes of mind, and how those outcomes should be recorded when the machine is eventually used in a forensic report. Does the programme's confidence score ever justify the examiner's confidence in a named external source? The reference record must also reveal whether an examiner encountered actual missing data or inferred silence from a display.

Marvin Lee Minsky, Cross-Peer Answer to George Edward Pelham Box: Professor Box, the display is part of the decision system, and its persuasive appearance deserves testing. A spectrum image has a colour scale, integration interval, dynamic range and event-selection policy. Two displays of identical samples can produce very different impressions, although the underlying measurements have not changed. An anomaly score shown in large type may anchor an examiner's interpretation even when the score was calibrated in another environment. The appropriate experiment does not merely test the software in isolation. It studies a combined human-machine procedure with a defined division of responsibility and explicit opportunities to reject the machine's suggestion.

Copyright 2026, James M. Atkinson

I would use blinded, independently generated reference cases. Randomly assign suitably qualified examiners to a condition in which they assess a complete but appropriately minimised technical record without model prompts and another in which they receive the model score and a documented explanation. A third condition might provide a deliberately misleading score to measure susceptibility to suggestion, subject to a carefully designed study protocol. The evaluators should record external-source detection, classification, unsupported individual attribution, requests for more evidence and explicit abstention. The study should measure not simply apparent agreement with the machine but whether the resulting conclusions match the authorised independent reference and appropriate evidential standards.

The interface should help the examiner recognise the limits of the measurement. It should display acquisition validity, missing-sample intervals, calibration state, the model version, the tested operating domain and relevant alternative explanations. It should not produce an unqualified confidence percentage about a named person's conduct or a particular hidden device when the underlying classification merely marks an unusual feature vector. If a model is uncalibrated under a new receiver state, the interface ought to say so visibly rather than hide the qualification behind an information menu. The human must retain responsibility for deciding what the observed evidence supports.

Finally, disagreements between human and machine should become reviewable evidence rather than administrative embarrassments. Preserve the initial machine score, the examiner's independent observation, any later corroborating measurement and the reason for a changed conclusion. One

Copyright 2026, James M. Atkinson

should not retrain the algorithm on the final test cases and then claim that the original trial validated the improved system. The strongest defensible outcome may be a narrow statement: machine assistance improved detection of a specified family of laboratory anomalies under tested conditions while leaving individual-emitter attribution to independent physical investigation. An unexplained anomaly is not an identified device, and a convincing plot is not proof of intent.

Dr. James M. Atkinson, Moderator: The discussion has established that an RF anomaly score is conditional upon the acquisition chain, selected representation, tested model and reference distribution. The correct response to unqualified hardware states or material distribution shift is further controlled measurement, appropriately limited inference or abstention, not an invented emitter identity. I formally close Question 104 and pass the programme to the next question.

QUESTION 104. SOURCE AND VERIFICATION NOTES. Contextual sources: NIST Artificial Intelligence Risk Management Framework 1.0, January 2023 (https://doi.org/10.6028/NIST.AI.100-1), particularly the Measure function on independent tests, monitoring and limitations of generalisability; NIST AI RMF Playbook, Measure guidance. These support general evaluation practice, not invented historical dialogue or any particular hypothetical RF observation.

EDITORIAL QUALIFICATION. All proposed signal measurements and calculations are illustrative. The discussion does not identify an unknown emitter, recover protected communications or approve an unlawful surveillance technique.

QUESTION 105

Copyright 2026, James M. Atkinson

What must an SDR recorder prove about firmware, FPGA bitstreams and runtime configuration?

SCHOLARLY RECONSTRUCTION. This dialogue is a fictional modern scholarly exchange among deceased historical specialists, not authentic quotations, recollections or a meeting that occurred. Legal authority and scientific validity remain distinct from software integrity.

Dr. James M. Atkinson, Moderator: Admiral Hopper, a receiver may report a reassuring software version while its FPGA image, register values and analogue state differ from what the display suggests. What evidence is required to reconstruct the exact acquisition chain, and how should the chain-of-custody record represent uncertainties that no checksum can resolve?

Grace Brewster Murray Hopper, Principal Contributor: Dr. Atkinson, a receiver does not become reproducible merely because two copies of its user-interface program have the same version number. The electromagnetic input is successively transformed by analogue filters, gain stages, conversion clocks, digital downconversion, channel filters and recorders. In a programmable instrument, some of those transformations may reside in firmware, configurable logic or registers that the application does not expose. Consequently, a file labelled as a recording from a named receiver model is not a sufficient description of the acquisition chain. A defensible record must identify which executable and configurable elements were actually active when the sample stream was obtained.

I would establish three distinct objects for custody. The first is the acquired evidence: the original sample bytes, timestamps, acquisition counters and

Copyright 2026, James M. Atkinson

contemporaneous instrument-status reports. The second is the acquisition manifest, describing the meaning of those bytes and the state of the apparatus. The third is the software and firmware provenance package, identifying binaries, programmable-logic designs, register maps, build environments and any calibration tables which materially affected sample generation. Each object should have an independently protected identity and a documented relationship to the others. Protecting the sample digest while allowing the manifest to be altered would preserve data whose interpretation may have changed without warning.

A build identifier is valuable only if its referent is defined. The label 'firmware 3.2' may correspond to a release package, while a field unit contains a hotfix, an altered coefficient table or an FPGA bitstream compiled from a different source revision. Where an instrument permits cryptographic measurement of executable objects, the measurement should identify the exact byte sequence and the trust assumption under which that measurement was produced. A checksum calculated by software which an attacker or defect can modify does not itself constitute independent evidence of what executed. A chain of trust may be useful, but its boundaries and failure modes must be stated. Nor can a signed file certify that the analogue input was calibrated or that its clock was accurate.

I would ask the engineer to record the runtime state, not just the installed software. Centre frequency, input attenuation, automatic-gain-control state, digital decimation, sampling rate, oscillator selection, clock discipline, FPGA decimator coefficients and event-trigger configuration can all change the observable waveform. A boot-time register dump may not represent the register state during a rapidly retuned acquisition. If the apparatus allows

Copyright 2026, James M. Atkinson

state changes during capture, the record should tie each state transition to a native sample index or a calibrated time interval. The data should distinguish state requested by the host from state acknowledged and applied by the hardware. An attractive dashboard may show the former while the ADC continued operating under the latter.

The controlled experiment should begin with a reference unit and an independently monitored authorised RF stimulus. Freeze the analogue input and change exactly one firmware or programmable-logic element at a time. Record the output samples, spectral response, impulse response, group delay, gain, overflow behaviour and relevant timing. Run a second trial keeping the software constant while modifying one documented register. In a third trial, leave the registers untouched but vary input power until the analogue front end approaches compression. The observed differences establish which aspects of the measurement depend upon each class of state. An update that changes sample packing without changing the external input has evidential significance even if a waveform viewer continues to display something plausible.

I would especially challenge the claim that two files with equal cryptographic digests prove a correctly recorded radio event. Equality of appropriate protected digests provides strong evidence that the byte sequence remained unchanged from a trusted reference state. It does not prove that the bytes were collected lawfully, that the analogue input reflected the asserted source, or that the receiver's internal processing was the version the operator believed. An incorrect firmware build can write a consistent, reproducible and perfectly hashed output. The manifest and independent measurements are required to assess the physical truth of its asserted

Copyright 2026, James M. Atkinson

acquisition. Conversely, two valid acquisitions of the same signal may have different digests because of quantisation noise or differing starting phases.

There should be explicit failure handling in the software interface. If the FPGA identity cannot be read, the application should not silently substitute a default identifier. If a calibration file is missing, the numerical level may need to be reported as uncalibrated or withheld entirely. If a sample counter jumps, the report should preserve the discontinuity and prevent it from being disguised by interpolation. Where a configuration register is undocumented, the engineer may conduct controlled black-box tests, but the evidential claim must remain limited by that opacity. A product's commercial reputation is no substitute for accessible verification records.

The provenance record should survive legitimate maintenance. Each authorised update creates a new version with its own measured artefacts, approval history, rollback capacity and validation data. A later scientific analysis may show that the older algorithm produced a systematic amplitude bias. That discovery should lead to a linked correction, not deletion of the original event or a fiction that the new configuration had been running at the time. One should retain the original objects and the derivative with their separate digests and processing histories. Where rights or security restrictions prohibit disclosure of code, an independent expert still needs sufficiently detailed behavioural tests and documented limitations to challenge the claims derived from that code.

I would conclude by requiring an acquisition-completeness statement: the laboratory should identify each component capable of materially changing the samples and state what evidence establishes its identity, state and calibration during the relevant interval. Anything not observed should be

Copyright 2026, James M. Atkinson

listed as unknown. A complete inventory does not establish that the receiver detected every possible signal; it does establish which parts of a particular acquisition chain can be reproduced and which remain assumptions. The most professional report often contains an unglamorous qualification about a register or clock rather than an eloquent certainty unsupported by the apparatus.

Jacob Ziv, Peer Question: Admiral Hopper, I am concerned that a provenance package might preserve a software name without identifying the processing which actually transformed the samples. A receiver may boot from one signed image, load a different FPGA configuration later, and finally write an archive whose metadata reports only the application release. An investigator could then reproduce the wrong signal path with perfect attention to the recorded settings. How should the manifest treat the time of each configuration transition, the distinction between signed installation and actual execution, and the possibility of stale information from a cached device query? I should also ask whether configuration digests ought to cover coefficient memory and runtime registers separately from the executable bitstream. In some designs the bitstream remains identical while a register changes channel filter bandwidth, a frequency conversion constant or sample scaling. The record must support a reconstruction of acquisition state rather than merely demonstrate that approved software once resided on the instrument.

Grace Brewster Murray Hopper, Response: Dr. Ziv, the manifest needs an explicit concept of operative state during a sample interval. An installed release is a software inventory item; it is not an acquisition chronology. Each meaningful change should have an event record describing the requested

Copyright 2026, James M. Atkinson

command, the device's acknowledgement, any verification readback and the native sample interval affected. If a register change alters the filter or mixer, the recorder should start a new acquisition epoch or annotate the transition and settling period. A single session label cannot stand for all those epochs when the signal chain varies. The same principle applies to an FPGA image loaded after boot. Its identity must be connected to when it became active, not merely to its existence on storage media.

Digests should be scoped. A hash of the executable logic file does not capture separately loaded coefficient tables, calibration records or mutable state. One may compute and protect identifiers for those objects independently, then bind their known versions in an acquisition manifest. The manifest should also distinguish readback measured at the relevant time from a cached value or an intended value. If direct readback is unavailable, the omission is an evidential limitation. A laboratory may employ independent behavioural tests to infer the likely active path, but an inference made after the event should not be represented as contemporary direct observation. Signed metadata can preserve a false value as reliably as a true one.

I would conduct a version-transition trial with a stable reference source and an independent receiver. Start with a known bitstream and calibrate its response. Change only a coefficient table, then only a clock-selection register, then the bitstream itself, while retaining the raw output and status history. Include one deliberately delayed command acknowledgement and one stale cached register report. The expected result is not that the instrument always prevents changes, but that it records the differences or clearly identifies unqualified intervals. A later examiner should be able to

Copyright 2026, James M. Atkinson

reconstruct which configuration affected the portion of the file used for a particular scientific claim.

The manuscript should retain the key distinction between software authenticity and waveform truth. A protected configuration history may strengthen confidence in how samples were produced. It cannot establish the physical emitter, the truthfulness of an operator or the legality of collection. Those stronger propositions require independent evidence. If a device conceals its active FPGA configuration, an expert may still report constrained measurements under controlled black-box validation, but not a level of reproducibility that the instrumentation does not allow.

Abraham Lempel, Peer Question: Admiral Hopper, suppose an SDR recorder stores complex samples in a compressed container but provides a cryptographic digest only for the container and a short label stating that the FPGA performed lossless decimation. There are at least two problems. The container can change without changing its intended numerical sample stream, and a decimator is generally not invertible over its discarded bandwidth even when the stored data are compressed without further loss. How should the investigator identify the exact bytes protected, the numerical representation after FPGA processing and the physical information which the acquisition never preserved? Could the programmer produce a derivative in another file format without confusing legitimate repackaging with alteration of the original? Finally, how should the record treat a firmware revision which changes byte order, interleaving or compression but displays the same waterfall? These distinctions are essential to a future forensic challenge of an otherwise beautifully preserved recording.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Response: Dr. Lempel, the terms compression and decimation must not be allowed to obscure the transformation. A lossless container compression process may preserve the numerical values of its specified input sequence, whereas decimation discards samples or frequency content relative to a higher-rate representation, subject to its filter and sampling design. The preserved object is whatever bytes the digest actually covers. A digest of an archive protects that archive from undetected alteration under the assumed trust conditions; it does not prove that an upstream FPGA preserved a particular band or transient. The acquisition manifest should say which signal domain the samples represent after filtering and downconversion. If an external event fell outside that domain, the absence of its energy from the recorded data is not proof that it never occurred.

A correct manifest would describe I/Q order, numeric type, endianness, channel count, full-scale convention, sample rate, centre frequency, digital filter and decimation settings, along with the relevant analogue input path. Where digital filtering alters group delay or pulse shape, those characteristics should be measured for the intended use. A firmware revision that changes how data are packed but leaves their numerical interpretation equivalent can be validated with known test vectors. The old container and the new derivative would still possess different byte digests and separate custody records. The analyst must never call a format-converted derivative the untouched original. Equally, a changed display alone is an inadequate criterion for determining whether the underlying samples are identical.

Copyright 2026, James M. Atkinson

I propose a controlled conversion test: preserve an original byte sequence; make an exact copy; repackage the numerical sample array with an explicit, reversible schema change; alter one bit; and change only interpretation metadata. Compute the appropriate digests for each defined object. Then test the numerical values under documented decoding procedures. A digest mismatch of the entire archive is expected after legitimate repackaging, but the original sample values may remain equivalent. The one-bit mutation has a different meaning, while a metadata change can make identical bytes appear to represent a different waveform. These cases should occupy separate fields in the evidence report.

The physical claim remains limited. Neither an excellent compression ratio nor successful decompression provides evidence that a receiver saw every relevant emission. The upstream filter response, saturation state, sample losses and clock fidelity must be validated. A technically responsible file can preserve reduced-band data impeccably while conceding that the omitted analogue information is unrecoverable. Such a concession protects the investigator against an attractive but unsupportable assertion about an unknown source.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor and respectfully pass the token to Edsger Wybe Dijkstra for a distinct investigation of the recorder and its evidential limits.

Edsger Wybe Dijkstra, Second Principal Contributor: Dr. Atkinson, configuration is a programme state and must be treated as such. The common practice of saving a human-readable settings file and calling it an acquisition manifest is insufficient when the instrument possesses hidden registers, asynchronous commands, firmware-managed transitions and

Copyright 2026, James M. Atkinson

calibrated coefficients. An acceptable system needs invariants connecting the operator's requested state, the hardware's acknowledged state and the sample intervals actually collected. A software engineer should be able to express those invariants so clearly that a failure appears as a reported condition rather than a silently smoothed plot. If there is no such design, the programme does not know what it knows.

I would define the capture as a sequence of epochs. Within an epoch the receiver state has a declared interpretation: the ADC clock reference, sample format, analogue gain path, mixer configuration, FPGA filter response and output channel mapping are known or expressly unqualified. Each transition starts a new epoch and is linked to an acquisition counter. A host command asking for a new frequency is merely an intention; a device acknowledgement and a verified settling interval establish when the new regime begins. The system should not report the samples acquired during an unsettled transition as though they belong to one stable setting. This matters especially when searching for short bursts whose entire duration might coincide with reconfiguration.

The manifest should have a machine-verifiable schema. It ought to represent bitstream and firmware identifiers, protected digests, build revision, device serial, register snapshot, calibration reference, power state, firmware update event and relevant environment. A field whose value cannot be retrieved should be absent with an explicit reason, rather than filled with a plausible default. A signed manifest is useful if the signature verification chain and signer's authority are established; it is not magical proof that every field is true. An instrument may honestly sign a stale record because the firmware never queried the hardware after an update. A

Copyright 2026, James M. Atkinson

challenge test must examine whether reported and actual configuration can diverge.

I would insist upon a reproducible state-transition test harness. Before an authorised test signal is transmitted, place the instrument in a known configuration and read back the relevant registers. Then command a bandwidth change, decimation change or gain step while the test signal remains constant. Record native sample indices and detect the exact boundary after which the new behaviour appears. Independently measure amplitude, timing and spectral changes. Repeat under heavy host load and with the transport queue deliberately stressed. The purpose is not to force every transition to be instantaneous; it is to establish a truthful state history and appropriate invalid intervals.

Firmware and FPGA updates should be modelled as changes to the measurement apparatus. A new bitstream may alter filter coefficients, digital frequency conversion, rounding behaviour or timestamp insertion even when the host application and analogue front end are unchanged. These operations can change the measured spectrum and the apparent width of transient pulses. The verification programme must compare known reference stimuli under each accepted configuration and document the differences. A successful software installation message is not a calibration. The correct test includes a rollback to the old version and checks whether the earlier response is restored, subject to changes in temperature and reference state.

It is tempting to declare a protected execution environment trustworthy when its measured boot succeeds. Yet attestation describes selected software and configuration artefacts according to a defined root of trust. It

Copyright 2026, James M. Atkinson

does not prove that the antenna received the signal claimed, that the instrument was linear, or that the clock met the needed uncertainty. The application should keep those propositions in separate fields. An authenticated recording of a receiver-produced intermodulation line is still a recording of a spurious line. A firmware root of trust may protect acquisition integrity against some alterations but cannot independently settle an RF source-attribution question.

A useful failure matrix would include malicious alterations where lawful and harmless in the test environment, ordinary corruption, incorrect register-map revisions, stale metadata, transfer loss, clock interruption, gain-state ambiguity and ADC clipping. For each fault, state the expected invariant violation and whether the instrument should stop, flag, abstain or continue with a qualified measurement. The absence of an alarm is not a pass unless the expected fault was independently established and the system's specified response observed. A test performed only on the successful path confirms little about the failure behaviour that matters most in a forensic context.

I would prevent later analyses from rewriting acquisition events. Original files and configuration records should be immutable under the custody protocol, while analyst annotations, corrected metadata interpretations and new scientific conclusions are stored as linked derivatives. Each has a creator, time, reason, software identity and digest. A revised FPGA interpretation may materially change a claimed frequency or amplitude, but it should not make the prior interpretation vanish. Independent challenge requires both records. The complete trace should show exactly which measurements remain reliable after the correction and which cannot be repaired because a relevant state was never recorded.

Copyright 2026, James M. Atkinson

My closing rule is that an instrument must demonstrate not only reproducibility of its output but reproducibility of its failure distinctions. If invalid samples, unknown state and valid quiet observations are rendered identically, the system has discarded essential evidence. A disciplined recorder may be inconvenient, because it exposes uncertainty and asks the user to resolve it. That inconvenience is an engineering virtue when the alternative is confident testimony about a signal that the apparatus may never have measured accurately.

Peter Elias, Peer Question: Professor Dijkstra, I should like to challenge your epoch model with a receiver capable of autonomous retuning. Its FPGA may change frequency in response to a threshold-crossing event, while the host software receives the change notification several buffers later. If a short burst spans the boundary, a file may contain samples from two frequency settings under one host timestamp. What invariant is sufficient to detect this inconsistency, especially if the hardware offers no atomic snapshot of all relevant registers? Should a device carry an acquisition-state identifier inside each native sample block, or should the investigator depend upon a reconstructed sequence of commands and acknowledgements? Please consider an experiment which intentionally delays host messages, changes the threshold trigger and causes a buffer overflow during a retune. A system that records only a successful command response may hide a significant portion of invalid or ambiguous evidence. The examiner should document the independent hardware reference used to evaluate the claimed state.

Edsger Wybe Dijkstra, Response: Dr. Elias, an acquisition-state identifier associated with the hardware's own sample blocks would be preferable

Copyright 2026, James M. Atkinson

when the architecture supports it, but the value of that identifier depends on how it is assigned. If it increments when a host command is queued rather than when the FPGA actually changes, the apparent precision is illusory. A rigorous contract should define when each state becomes operative and how the recorder marks transition samples. Where there is no atomic snapshot, the design should adopt a conservative interval of uncertainty bounded by the last known old state and the first verified new state. That interval should not be silently attributed to one setting. An incomplete observation may remain usable for some questions, but only within a clear qualification.

The acceptance test must introduce controlled timing stress. Supply a known authorised RF burst with independently measured timing, command a frequency change or allow an internal trigger to initiate one, and deliberately delay the host notification. Compare the hardware's native counters, state acknowledgements and observed frequency response. Repeat with a simultaneous transport overflow and with a reset of the device's time reference. If the programme cannot determine which settings affected the burst, it should flag that portion of the record as state-ambiguous. The fact that the application eventually displayed the correct frequency does not repair the uncertainty of earlier samples.

I would maintain two related but distinct timelines. The first represents physical acquisition as far as the hardware can verify it, with sample indices and state epochs. The second records host commands, transfer events, file writes and later analyst actions. A temporal join between them is a documented calculation, using measured offsets and uncertainty where required. When the join is underdetermined, the software must not

Copyright 2026, James M. Atkinson

fabricate an exact boundary. The custody record should preserve the original logs even if a later reconciliation improves the mapping. An event-driven recorder which writes after a trigger may also have blind intervals before the trigger; those cannot be treated as observed silence.

The key invariant is that every reported valid sample range must be tied to an adequately known configuration. The implementation may satisfy this with per-block identifiers, readback and independently verified transition tests, or a combination appropriate to its hardware. If it cannot satisfy it, the correct report is an interval with qualified settings rather than an invented precise state. This is a measurable property of the design, not a matter of confidence in the application vendor.

David Slepian, Peer Question: Professor Dijkstra, a system might retain the exact FPGA bitstream and all relevant settings, yet its numerical output could still be nonreproducible across nominally identical units because of analogue transfer functions, converter mismatch and thermal drift. How should the engineer separate deterministic execution from a reproducible physical measurement? Consider two devices running the same image and receiving the same authorised reference waveform, but one has a slightly different anti-alias response and a less stable sampling clock. Their output bytes will differ. Would the correct acceptance rule demand identical numbers, a specified tolerance in physically meaningful derived quantities, or agreement after a calibration transformation? I would also ask how to identify parameters which cannot legitimately be calibrated away, such as previously unrecorded clipping or irretrievably lost samples. A report of 'validated firmware' should not be stretched into a guarantee that every analogue receiver chain performs identically. The examiner should

Copyright 2026, James M. Atkinson

document the independent hardware reference used to evaluate the claimed state.

Edsger Wybe Dijkstra, Response: Dr. Slepian, deterministic software execution and measurement equivalence are different properties. A particular implementation may produce bit-identical results when given bit-identical inputs under fixed conditions, but two analogue receiving chains will not generally produce identical sample sequences for the same external RF experiment. Noise realisations, clock phase, gain and filter differences all matter. The useful acceptance criterion is tied to the physical quantity of interest and a measured uncertainty model. If the task is calibrated spectral amplitude, compare amplitude response across the specified frequency and level range. If the task concerns transient timing, compare event timing and group delay under a common reference. A blanket demand for identical bytes is neither necessary nor usually achievable.

Calibration can legitimately transform a measured quantity to a common reference plane, but its validity depends upon stated assumptions. A gain correction determined using a stable low-level carrier might not remain valid in compression, and a frequency-response correction cannot restore an event that the analogue filter entirely removed. Missing samples cannot be recreated with physical certainty by interpolation unless the problem contains validated redundancy sufficient for the particular inference. Each correction should be stored as a derivative with the original observation and the applied calibration identified. The uncertainty following correction may exceed the uncertainty of the calibration itself because of environmental change or unmodelled effects.

Copyright 2026, James M. Atkinson

A responsible experiment would measure several devices under matched but independently monitored reference stimuli. Vary frequency, amplitude, pulse duration, temperature and gain state. Hold the FPGA image fixed while comparing unit-specific response, then vary the FPGA image within one unit to isolate digital changes. Quantify which differences arise from analogue hardware and which from programmed transformations. Include deliberately bad conditions so that the boundaries of the calibration model become visible. The report might establish that a given software build preserves defined numerical properties within tested error limits on specified hardware, not that all receivers loaded with it are physically identical.

The correct software invariant is traceability of the declared transformation and explicit handling of conditions outside validation. A state marked overloaded, missing or clock-unqualified cannot be rescued by a statement that the program executed correctly. The final report should identify what was measured directly, what was calibrated and what was inferred. With those distinctions, reproducibility can be judged scientifically rather than reduced to a file-comparison contest.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor and respectfully pass the token to Alan Mathison Turing for a distinct investigation of the recorder and its evidential limits.

Alan Mathison Turing, Third Principal Contributor: Dr. Atkinson, the problem can be stated as one of verification under partial observation. The operator sees a named application and a display; the actual sample stream depends upon a chain of states which may be only incompletely visible. The scientist wishes to know whether a given physical input would produce the specified

Copyright 2026, James M. Atkinson

digital evidence under the configuration asserted. That claim is not proved by comparing the display with a familiar illustration. It demands controlled stimuli, a formal record of the apparatus and negative tests capable of revealing how the claim fails. In other words, the recorder must have a testable specification, not simply a plausible operating manual.

I would separate the hypotheses. One concerns software integrity: did the expected code and programmable-logic image execute? A second concerns configuration truth: were the operative registers and calibration settings those recorded? A third concerns measurement validity: did that chain preserve specified amplitude, timing and spectral properties within stated uncertainties? A fourth concerns evidential provenance: were the resulting bytes and their associated metadata protected after acquisition? A system may satisfy the first and fourth while failing the second or third. The report should avoid presenting these different tests under one vague certification of authenticity.

The experimental apparatus should use a reference waveform source monitored independently. Stimuli must include continuous carriers for gain and frequency measurement, short pulses for time-domain fidelity, two-tone combinations for nonlinear behaviour, and changes at channel boundaries where the FPGA channeliser may behave unexpectedly. Record each trial with a controlled software build and a full state manifest. Then deliberately vary one material element: a bitstream, decimation ratio, mixer register, sample format or input attenuation. The reference instrument supplies an independent account of what physically entered the receiver. Without that comparator, a programme which agrees with itself may validate only its own assumptions.

Copyright 2026, James M. Atkinson

The problem of timing deserves special consideration. An application timestamp may indicate when a buffer was written, while the ADC aperture occurred earlier. A firmware revision can change the relation between a hardware sample counter and a host event without changing the displayed wall-clock time. A test should therefore inject a known timing event, measure analogue latency and examine whether the exported time field refers to a calibrated physical sample instant. During sample loss, the recorder must say what is absent rather than concatenate surviving blocks into a false continuous time series. A hash cannot restore a missing portion of the electromagnetic observation.

One should also challenge build reproducibility. Two artefacts compiled from the same source may differ in binary details because of toolchain versions, compiler options, build timestamps or external dependencies. The provenance record should specify the actual released binary and its protected digest, with source revision and build recipe as supporting evidence. Where rebuilding the bitstream cannot produce bit-identical output, functional equivalence may be tested against a declared behavioural specification rather than asserted from identical labels. An independent laboratory should know which claim was made: binary identity, source lineage, tested functional equivalence or merely vendor endorsement.

An adversarial but authorised trial should include a counterfeit manifest: describe one known bitstream while loading another, or state a gain value inconsistent with the hardware setting. Observe whether the recorder catches the discrepancy. A successful signature over the counterfeit manifest would demonstrate the difference between authenticating an assertion and verifying its truth. Another trial should make a legitimate

Copyright 2026, James M. Atkinson

update while the recorder is active and determine whether the log records an epoch boundary. The software should not preserve the fiction that every sample arose under one stable configuration merely because the acquisition session had one filename.

I would insist on a protected observation log for each state transition. This log should tie requested changes, hardware acknowledgements, register readbacks, sample index ranges and status flags to one timeline. The system should be tested after clock loss, power interruption and buffer overflow. Some quantities may remain recoverable, such as the ordering of retained samples; other quantities, such as absolute event time, may be irretrievably uncertain. A correct programme reports that distinction. A later analyst can use an independent reference to infer a likely offset, but an inference with uncertainty should never be silently substituted for a missing contemporary state record.

The laboratory should compare the recorder's behaviour before and after updates without claiming that every difference is a fault. An improved digital filter may intentionally reduce aliasing or change group delay. The update is acceptable if the new measurement properties are documented and calibrated for the intended use. In contrast, an unexplained spectral peak associated with an FPGA revision requires investigation before it is labelled an external source. A final test should swap the analogue receiver path while keeping the digital processing constant and then swap the processing while keeping the analogue path fixed, to isolate causes.

The conclusion should be bounded. The best-supported claim may be that a named receiver, loaded with a measured firmware and bitstream combination, acquired specified authorised test signals within stated

Copyright 2026, James M. Atkinson

tolerances under a recorded range of operating states. That is a valuable finding. It is not proof that every unknown emission was detected, nor that every observed spectral feature came from outside the apparatus. The system becomes fit for forensic challenge when its provenance and limitations are measurable, and when its operator can answer an inconvenient question without inventing certainty.

Hendrik Wade Bode, Peer Question: Dr. Turing, I would like to focus on the analogue implications of a digital update. A new FPGA channeliser may achieve a mathematically attractive stopband specification under ideal test vectors, yet a strong blocker can still overload the preamplifier or mixer before digital filtering begins. An operator might see the blocker disappear from the waterfall and interpret the cleaner display as improved physical dynamic range. What test should demonstrate the actual receiver-input performance, rather than the output of one filter in isolation? Please distinguish noise-limited sensitivity, intermodulation behaviour and the recovery after strong pulses. I also ask whether a successful software attestation can ever certify the analogue calibration and whether independent preselection or attenuation changes remain necessary to challenge a supposed unknown RF emission. The issue is central to a recorder whose digital processing is updated more frequently than its analogue front end. The examiner should document the independent hardware reference used to evaluate the claimed state.

Alan Mathison Turing, Response: Dr. Bode, a digital filter cannot undo distortion that has already occurred upstream. If the analogue amplifier or mixer generates intermodulation products, a downstream channeliser can suppress some visible components while preserving others that fall inside

Copyright 2026, James M. Atkinson

the selected passband. A quieter display does not, by itself, establish greater usable dynamic range. The controlled experiment should place a calibrated reference source at the receiver input, use a two-tone or multitone blocker programme and measure output products across a defined range of input levels. Repeating the test before and after a firmware update can reveal whether the changed digital chain altered the visibility of products without changing their analogue origin.

I would measure several properties separately. Noise-limited sensitivity depends upon the receiver noise and effective bandwidth under the stated gain and filtering conditions. Strong-signal performance concerns compression, intermodulation and recovery, which may have different frequency and time dependencies. A short strong pulse may cause a gain-control or overload transient lasting beyond the pulse itself. If the revised firmware changes the time-windowing or detector logic, it may alter the displayed duration without changing the physical recovery of the analogue chain. An adequate acceptance trial must include time-domain reference observations as well as spectral measurements. A single catalogue dynamic-range figure cannot substitute for this operating-envelope test.

Attestation of code or programmable logic may support confidence that a specified digital transformation executed, but it cannot certify the analogue input conditions. Receiver-state records should include relevant attenuator, preselector, gain and calibration settings. For a suspicious feature, an independent antenna or receiver, or a carefully chosen change of input attenuation, may test whether the feature is external or internally generated. The precise diagnostic depends upon the physical case. An engineer must not declare a named transmitter merely because the

Copyright 2026, James M. Atkinson

software reports a stable frequency across repeated captures made under the same potentially defective chain.

I would integrate the tests in a provenance report with two linked parts. One establishes the identity and state of the digital processing, including its filter response and numerical behaviour. The other establishes measured analogue performance at the defined reference plane. A firmware update may improve one while leaving the other unchanged. The final conclusion should specify the improvement actually demonstrated and the limitations that remain. That is a stronger claim than saying simply that the receiver had the newest software.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor and respectfully pass the token to Irving S. Reed for a distinct investigation of the recorder and its evidential limits.

Irving S. Reed, Fourth Principal Contributor: Dr. Atkinson, I approach the problem by examining what can be detected from redundancy and what cannot. An SDR acquisition chain often transfers blocks equipped with counters, checksums, framing fields or error-detection codes. These may reveal transmission corruption or ordering faults within the digital apparatus, but they are not a guarantee that the analogue waveform was represented correctly. An ADC can clip a burst and emit perfectly well-formed, checksummed samples. An FPGA can apply the wrong filter coefficients and package the result with a valid frame checksum. The engineer must distinguish protected transport integrity from physical measurement validity.

Copyright 2026, James M. Atkinson

A scientifically useful recorder should preserve native sequence counters, valid-sample counts, overflow and synchronisation flags, and explicit descriptions of any inserted or invalid values. If software rewrites missing samples as zeros, later analyses may infer a quiet interval where none was observed. If the hardware increments a transfer counter but not a sample counter, the significance of gaps may be different. Therefore the specification must identify which component assigns each field and which errors it is capable of detecting. A monotonically increasing number may be useful, but it is not evidence of continuous acquisition if the firmware can reset or advance that number independently of the ADC.

Programmable logic presents further subtleties. A filter may implement a mathematical transfer function in fixed-point arithmetic with finite word length, saturation, rounding and pipeline delays. Changing the bitstream can alter those details while leaving the nominal filter specification unchanged. Under weak input conditions the difference may be negligible, but a strong blocker can drive an internal accumulator into saturation and produce spurious features. A controlled trial must therefore include varying signal levels, mixed tones and transients, not simply an ideal single carrier at one convenient power. The report should identify the conditions where quantisation and finite-word effects materially change the inference.

I would have the laboratory build a known-good acquisition fixture. Feed a calibrated waveform through the receiver, monitor the input with an independent instrument and verify the output frame structure against the documented sample count and rate. Introduce a controlled dropped buffer, a one-bit storage corruption, a wrong-endianness declaration and a known firmware reset. Each fault should have an expected symptom. A frame

Copyright 2026, James M. Atkinson

checksum may detect the one-bit alteration but not a truthful packet containing wrong metadata. A protected manifest digest may detect later changes but cannot guarantee that the receiver truthfully recorded its register state. The negative tests must therefore be designed to expose the different limits of each protective layer.

There is no universal decoder capable of reconstructing arbitrary missing RF content. Error correction works where the transmitted or stored representation contains known redundancy and a validated error model. An unpredictable external transient with no guaranteed code structure may be fundamentally unrecoverable after acquisition loss. The investigator should avoid treating interpolation or model-based prediction as restoration of original observations. If the manufacturer uses a proprietary loss-concealment algorithm, its behaviour should be characterised in a controlled trial, and the resulting samples marked as derived or synthetic where distinguishable. Failure to distinguish observed from reconstructed values destroys important forensic information.

Timing integrity is similarly layered. A time label may originate from a disciplined hardware counter, a transport timestamp or the host filesystem. Those clocks need not coincide. A firmware update can alter buffering depth or interrupt timing without changing the external source. The acceptance trial should measure the interval from a known reference pulse at the input to its labelled sample index across several configurations. A sample-counter discontinuity and a wall-clock correction should be recorded separately. If a timing reference is lost, a physically valid local sequence may continue while absolute time uncertainty grows. The recorder ought to express that growth rather than preserve unwarranted nanosecond precision.

Copyright 2026, James M. Atkinson

The provenance register should include the FPGA configuration digest, logic build identifier, firmware revision, register readback method, calibration coefficients and the boundary of each acquisition epoch. The method of checking those values should itself be challenged. A readback supplied only by potentially faulty firmware can be useful but may not be independent. An external programming interface, secure measurement mechanism or behavioural fingerprint from controlled stimuli can provide supplementary evidence, each with defined limitations. More assurance is possible through independent checks, but there is no justification for claiming that a checksum proves the entire chain of electromagnetic causation.

A repair or update after acquisition creates a new analytical context. The original data, their original state records and custody history should remain protected; a later reconstruction or reinterpretation should be stored as a derivative with its own processing record. If the instrument's FPGA configuration was unknown during the original survey, an identical future test cannot prove which configuration had been present then. It can establish that one candidate configuration is consistent with a subset of observations, subject to uncertainty. Such retrospective inference should be written as a hypothesis rather than as a recovered historical fact.

I conclude with a recommendation for an error-detection table. For each fault class, identify whether the receiver's own fields can detect it, whether an independent laboratory can reproduce it, and which scientific claims remain supportable after the fault. The table should distinguish digital corruption, metadata error, acquisition dropout, analogue distortion and reference-clock uncertainty. A properly preserved sample file can be

Copyright 2026, James M. Atkinson

insufficient for source attribution. A correctly reported limitation is not a failure of forensic science; it is evidence of its discipline.

Norbert Wiener, Peer Question: Dr. Reed, what should a forensic engineer conclude when a receiver's native sample counter is continuous but a transport packet is corrupted, or when the packet checksums are valid while an ADC overflow has silently removed part of the physical observation? A particularly subtle design might compute a checksum after a firmware interpolation stage, thereby protecting invented values as if they were observations. Can a hierarchy of counters and error flags distinguish these situations, and should the laboratory test the integrity of the status reporting itself? I would like you to consider an authorised laboratory programme that injects faults at the analogue, ADC, FPGA, transport and file-storage stages separately. A successful test must not merely show that the application continues running; it must demonstrate that each fault is detected or that its possible invisibility is accurately disclosed in the instrument's evidential limitations. The examiner should document the independent hardware reference used to evaluate the claimed state.

Irving S. Reed, Response: Dr. Wiener, the example illustrates why a checksum is neither an instrument calibration nor a universal guarantee of continuity. It tests a defined relationship between a protected sequence and its check value. If the FPGA created incorrect values before computing the checksum, both may agree perfectly. If a transport packet was altered after checksum generation, an appropriate check may detect it. The chain must therefore identify where each checksum is calculated and what bytes it covers. Similarly, a counter may refer to ADC apertures, completed FPGA blocks, transport packets or file writes. A continuous host sequence cannot

Copyright 2026, James M. Atkinson

prove that no ADC samples were lost unless the architecture establishes that relationship and the test has verified it.

I would construct a failure matrix with known injected faults at each layer. At the ADC-to-FPGA boundary, force or simulate overflow under a controlled reference waveform. At the FPGA output, alter a framing field and check the declared validity. During transport, drop, duplicate or reorder packets. At storage, interrupt writes and compare original block identities with what reached disk. For each intervention, preserve an independent account of the true fault, the receiver's own status, and the final sample file. The acceptance rule should specify whether the system ought to identify missing data, halt, abstain or permit a qualified continuation. Absence of an error message is a failure to detect a known fault, not evidence that the fault never occurred.

Invented or reconstructed samples should never be silently merged with directly observed samples. A packet may contain a placeholder zero, repeated value or interpolated result; those operations can be useful for display continuity but they change the meaning of the file. The manifest should identify the affected sample indices and the method of reconstruction. A later analysis may explore the implications of a stipulated interpolation, but it cannot determine an arbitrary unknown RF transient from information that was never acquired. A cryptographic digest can protect the derivative against alteration while leaving its status as a derivative explicit.

For the forensic report, preserve the original block sequence, counter conventions, status flags, file digests and the independent reference tests. A chain-of-custody record should also say which person or system handled

Copyright 2026, James M. Atkinson

each object and why a transformation was performed. Such documentation cannot guarantee perfect reception, but it allows a reviewer to distinguish an observed event from a storage artefact and to identify intervals on which the apparatus offers no defensible conclusion.

Dr. James M. Atkinson, Moderator: I thank the preceding contributor and respectfully pass the token to Richard Wesley Hamming for a distinct investigation of the recorder and its evidential limits.

Richard Wesley Hamming, Fifth Principal Contributor: Dr. Atkinson, engineers frequently confuse the number of digits displayed by software with the accuracy of the measurement from which those digits were derived. Firmware and FPGA design can change fixed-point rounding, accumulation width, digital filter response and amplitude scaling without changing the apparent number of sample bits. An SDR that reports sixteen-bit I and Q components may nevertheless have a much lower useful effective resolution because of analogue noise, distortion and clock jitter. A revision might move a numerical error from one stage to another. The recorder therefore needs both a digital provenance record and a quantitative physical acceptance test, not merely a release note.

I propose a staged error budget. Start at the calibrated receiver input and consider noise figure, analogue bandwidth, gain distribution, intermodulation and compression. Continue through ADC aperture uncertainty, quantisation, converter nonlinearity and clock phase noise. Then examine FPGA digital downconversion, decimation, finite-word arithmetic, coefficient quantisation and transport. Each stage contributes a different kind of error, and some errors are correlated. A single root-mean-square combination may be inappropriate when a deterministic spur or an

Copyright 2026, James M. Atkinson

overloaded front end dominates the output. The report must record the assumptions of any combination rule rather than bury them in a convenient effective-number-of-bits summary.

A firmware change can be quantitatively subtle. Suppose a digital filter coefficient is rounded differently and a narrow signal near a channel edge changes amplitude by a small fraction. The difference may be negligible for a broad occupancy survey but material for a calibrated amplitude comparison. If the firmware alters group delay, it may change the reconstructed arrival time of a short pulse without altering its central frequency. The acceptance standard must be linked to the intended scientific question. A firmware update is not automatically better in every respect simply because one benchmark shows less noise. Engineering trade-offs should be measured across the frequency and power ranges relevant to use.

The laboratory should conduct a before-and-after design with a fixed, independently monitored test source. Use a weak carrier, a two-tone input, a short burst and a broadband transient. Record output amplitude, spectral leakage, channel-edge response, spur levels, timing offsets, lost-sample flags and receiver temperature. Repeat at a series of analogue input levels spanning the intended operating range, including conditions close to compression. An apparent improvement in a digital noise-floor plot may coincide with worse analogue distortion at higher levels. These observations should be reported separately, with the firmware and FPGA images identified exactly.

The numerical illustration must avoid invented precision. For a hypothetical uniform white-noise quantisation model, averaging sixteen statistically

Copyright 2026, James M. Atkinson

independent observations of the same quantity reduces the variance of the average by a factor of sixteen and its root-mean-square random noise by a factor of four. The corresponding amplitude-ratio improvement is about twelve decibels, or approximately two ideal bits under an appropriate quantisation-limited model. This does not permit sixteen nominal fourteen-bit converters to be declared a two-hundred-and-twenty-four-bit converter. Shared analogue distortion, coherent quantisation error and common clock jitter may prevent the ideal averaging benefit. The real chain must be characterised by measurement.

Configuration provenance must include not only the firmware version but the compilation details which determine numerical behaviour. Changes in filter coefficients, coefficient-word lengths, accumulator saturation modes and ordering can affect rare transients. An analyst who retains only the display may never discover that a burst was broadened by a different pulse-shaping algorithm. Forensic evidence should preserve an interpretable acquisition representation and the precise processing recipe. If the recorder writes already-decimated samples, the unrecorded wideband details are not recoverable merely by installing a newer FPGA image later.

I would test fault behaviour deliberately. Force a buffer overflow under a controlled input and examine whether the sample counters and status flags identify the gap. Introduce a reference-clock interruption and assess how absolute event time uncertainty changes. Load a known incorrect coefficient set in an authorised laboratory and determine whether the configuration record detects the deviation. When a malformed calibration file is supplied, the instrument should fail visibly rather than produce a plausible gain correction. These tests reveal whether the recorder can distinguish valid,

Copyright 2026, James M. Atkinson

invalid and indeterminate measurements. An apparatus incapable of expressing indeterminacy will tempt its user to overstate conclusions.

Two programs that produce identical samples from a recorded file can demonstrate computational reproducibility but not the authenticity of the original analogue input. Conversely, the same authorised RF test repeated on different days will naturally differ in noise realisations and perhaps in environmental coupling. The acceptance comparison should define tolerances derived from physical uncertainty rather than demand byte-for-byte identity where none is expected. A protected digest is suitable for testing whether a particular preserved object changed after hashing, not whether a separately acquired waveform should have identical bytes. The distinction must remain apparent in testimony.

My conclusion is that version identification and measurement validation must be joined without being conflated. The recorder should identify exactly which firmware and programmable logic produced each valid sample interval and should demonstrate, through documented trials, the limits of its amplitude, timing and spectral fidelity. The investigator should then use those limits in deciding what claims the file supports. An unqualified hardware state or an untested software revision should produce a qualification, not a more confident conclusion.

Rudolf Emil Kálmán, Peer Question: Dr. Hamming, your staged uncertainty budget is persuasive, but I question whether a firmware update can sometimes change the apparent state of a dynamic receiver in a way that a static calibration misses. An automatic gain controller is a feedback system; a clock-disciplining loop also changes its state over time. An FPGA revision might alter filter delay or the timing of state updates, causing a brief test

Copyright 2026, James M. Atkinson

pulse to be recorded differently depending upon what the receiver observed immediately beforehand. How should validation account for that history dependence? I would like a sequence of experiments which tests both steady-state and transient behaviour, including a change from strong to weak inputs and the loss of an external timing reference. A simple comparison of spectral amplitudes averaged over a long interval may conceal the very problem under examination. The examiner should document the independent hardware reference used to evaluate the claimed state.

Richard Wesley Hamming, Response: Dr. Kálmán, the receiver must indeed be regarded as a dynamic system where memory and state can matter. An automatic gain controller may react to a strong signal and reduce gain for a period after that signal disappears. A later weak burst may therefore be attenuated or missed even though the hardware's steady-state sensitivity is excellent. A clock loop may move between disciplined and holdover modes, changing the uncertainty of subsequent timestamps. A firmware revision can alter control-loop parameters, filter delay or transition timing. These effects require tests with controlled temporal sequences, not merely isolated signals allowed to settle between trials.

I would specify a sequence beginning with a stable low-level reference, followed by a strong legitimate blocker, then a known weak pulse after several chosen delays. Repeat under each firmware configuration and record gain commands, hardware acknowledgements, sample counters and actual output amplitude. The test should include different blocker durations and a retune event because internal processing pipelines may have memory of previous frames. For clock behaviour, use an independent reference

Copyright 2026, James M. Atkinson

event, remove the timing discipline for a measured interval and examine the growth of offset and phase uncertainty in holdover. The comparison should separate ordinary thermal drift from a discrete software state change.

The uncertainty budget must identify which effects may be treated as random and which are systematic or conditional upon state. It is unsafe to combine every observed difference as though it were independent white noise. A deterministic group-delay change can create a systematic event-time bias; an overloaded accumulator can create spurious spectral content. A suitable test should measure those biases directly and report their dependence on input level and configuration. If a model corrects a known delay, its calibration and residual uncertainty belong in the derivative processing record. It cannot correct an unknown missing interval or reconstruct an unobserved pulse by virtue of the loop model alone.

I would accept the update only for the operating conditions in which these dynamics have been examined. The report should identify the initial state of the receiver, the sequence of changes, and the time over which transient effects are material. A model may work well for steady-state spectral occupancy while remaining unsuitable for nanosecond-level event timing. The configuration record must allow an independent examiner to know which physical state and firmware logic produced the relevant samples. That distinction is more informative than any single statement that an update improved receiver performance.

Dr. James M. Atkinson, Moderator: I now invite four reciprocal questions, each immediately answered by the named specialist, to examine the unresolved relationship between code provenance and an authentic physical measurement.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper, Cross-Peer Question to Alan Mathison Turing: Dr. Turing, suppose the field receiver records a cryptographically signed manifest identifying a permitted firmware release and a formally approved FPGA image. An examiner then discovers that an otherwise valid acquisition contains a transient line at a frequency where no authorised reference source was present. It would be tempting to reason that the signed configuration excludes an instrument artefact and therefore supports an external emitter. I question that inference. How would you design a falsifiable experiment that challenges the signal's origin without treating software provenance as an RF source detector? Please address changing the analogue input attenuation, substituting another receiver, checking local oscillator products and repeating controlled stimulus measurements. I also want the test to distinguish a truly identical firmware image from a different runtime register state, because both might produce a reassuring signature. Which result would justify a positive finding, which a mere unresolved observation, and which would oblige a technical correction to the acquisition record?

Alan Mathison Turing, Cross-Peer Answer to Grace Brewster Murray Hopper: Admiral Hopper, the signature and the observed spectral line support quite different propositions. The signature, under a verified trust mechanism, may establish that a particular digital object was authorised or measured. It does not establish that the analogue circuitry was linear, that its calibration remained valid or that an unknown line arose outside the receiver. The first step is to preserve the original samples and the exact configuration state, together with the signed manifest and the means by which its signature was checked. The investigator should then formulate competing hypotheses:

Copyright 2026, James M. Atkinson

external emission, receiver-generated intermodulation, oscillator-related mixing, transport artefact or an error in the digital processing path.

A discriminating laboratory sequence would begin by substituting a characterised input load or an independent antenna, changing input attenuation in measured steps and recording how the suspect line responds. A genuine external component and an internally generated product may respond differently, but no one such response is universal proof. Altering preselection or using a second independently calibrated receiver can help test the explanations. A controlled tone pair may reveal whether intermodulation products appear near the suspect feature under related input conditions. The aim is not to produce an attractive alternative explanation but to design observations that could refute each hypothesis. The evidence should include all unsuccessful controls as well as successes.

The FPGA and register state deserve a parallel investigation. If the signed bitstream was active but a runtime mixer or filter register had an unexpected value, the software lineage may remain valid while the recorded spectral axis is wrong. If a supposedly unchanged image produces a different known-reference response, the examiner should investigate the analogue chain, calibration and environmental conditions before inferring tampering. The report must separate what is directly known from what is inferred retrospectively. A protected digest may help demonstrate that an image did not change between two trustworthy measurements, but it does not replace contemporaneous register readbacks or calibrated sample timing.

The strongest support for an external emission would be convergent, independently challenged measurements under specified conditions, with

Copyright 2026, James M. Atkinson

receiver artefacts and plausible competing explanations tested to the extent practicable. If the controls remain inconclusive, the correct conclusion is an unidentified measured feature whose origin is unresolved. If a processing defect is demonstrated, the original finding should be corrected through an attributable new report, not silently erased. A proper software provenance system makes such correction traceable; it does not prevent a scientific investigator from admitting uncertainty.

Alan Mathison Turing, Cross-Peer Question to Irving S. Reed: Dr. Reed, an engineer may be impressed by a long list of checksums, protected boot records, sample-block sequence numbers and supposedly immutable custody entries. Yet each protective mechanism has a particular scope. I ask you to construct a failure case in which all the visible checks pass while the recorded waveform differs materially from the true analogue input, and another case in which the checks reveal alteration but the physical sample content remains numerically equivalent after a legitimate representation change. How should the report distinguish those circumstances? It should not use the phrase data integrity without identifying the data object, hashing event and trust boundary. I also ask what test could establish the limitations of a proprietary FPGA pipeline that performs undocumented interpolation or error concealment. A future expert must be able to tell observed complex samples from computational substitutes even if the substitutes were produced by officially approved firmware.

Irving S. Reed, Cross-Peer Answer to Alan Mathison Turing: Dr. Turing, the first failure case is straightforward. An ADC clips a strong input transient, and the FPGA faithfully collects the clipped values into packets with valid sequence numbers and checksums. The host hashes the resulting file, signs

Copyright 2026, James M. Atkinson

a manifest and stores everything in an impeccable custody ledger. All those protections can function correctly while the file fails to preserve the peak amplitude and possibly the waveform shape of the physical event. The proper report would say that the bytes have a protected continuity history and the acquisition was invalid for peak-amplitude inference because of clipping. The security mechanisms did not fail; the false conclusion would arise from assigning them a physical measurement meaning they never possessed.

For the second case, a laboratory legitimately changes an IQ file from one byte order to another while preserving the intended numerical sample sequence. A digest over the complete original bytes will differ from the digest over the converted file. That is not evidence that the original samples were illicitly altered. It is evidence that the new object has different bytes, and the conversion must be documented as an authorised derivative. The reviewer can compare decoded numerical values under the respective schemas and verify that the conversion is reversible or accurate within a stated tolerance. The original file and the derivative retain their separate identities and their separate digests.

Proprietary interpolation requires a controlled stimulus study and an explicit limitation. Use an independently monitored input with known short pulses, deliberately induce dropouts at several points and observe the exported samples and flags. If the firmware fills missing intervals, compare the output against the independent reference and determine whether the invented values are marked. If the system conceals the operation and no accessible status identifies it, the engineer must say that the output may contain samples not directly measured by the ADC. The absence of a visible

Copyright 2026, James M. Atkinson

discontinuity is not evidence of complete acquisition. One should not claim waveform-level authenticity where the firmware cannot be independently characterised to a suitable degree.

The final evidence record must label each protection by what it establishes: bit-level continuity of a defined object, declared software identity, ordering of recorded blocks, or measured physical fidelity within tested conditions. A valid checksum is not a validation of the analogue input, and a changed checksum need not be evidence of changed physical information. For a credible forensic conclusion, those distinctions are more valuable than a large number of undifferentiated green integrity indicators.

Irving S. Reed, Cross-Peer Question to Edsger Wybe Dijkstra: Professor Dijkstra, I would like to challenge the implementation of fail-closed behaviour in a receiver which must continue monitoring an authorised site through intermittent clock or transport faults. If the application stops recording whenever one status bit becomes uncertain, it may create long blind intervals; if it continues without qualifications, it may create false evidence of continuity. How should a state machine distinguish valid acquisition, qualified acquisition, invalid acquisition and unobserved intervals? Please account for the difference between a missing status packet and a confirmed lost sample block, and the distinction between an acquisition clock in holdover and a failed ADC clock. Can an operator override an automatic stop, and if so what must be retained? The answer must be precise enough to support an implementation test, yet flexible enough to permit engineering judgement where different claims require different tolerances. The answer should also identify which original acquisition objects remain protected for a later independent challenge.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra, Cross-Peer Answer to Irving S. Reed: Dr. Reed, fail-closed need not mean that every uncertainty requires a complete physical shutdown. It means that the software must not produce a conclusion stronger than the conditions permit. A receiver may continue preserving raw samples during loss of absolute time discipline while refusing precise interstation arrival-time claims. A gain-state uncertainty may invalidate calibrated amplitude but leave coarse occupancy observations useful. The state machine should therefore associate validity with the intended measurement, not simply with a global running flag. It can distinguish capture continuing, data completeness, timing qualification, amplitude calibration and the ability to draw specific scientific conclusions. An interval of unknown observation cannot be silently labelled quiet.

I would specify a transition table. For each fault, record the triggering condition, detector evidence, sample index interval, applicable qualification and permitted actions. A confirmed ADC overflow produces an actual missing-data mask. A lost host status packet may produce a state-uncertainty interval without proving that samples were lost. A clock entering holdover can preserve sample ordering while enlarging absolute time uncertainty; an ADC clock stopping has more serious consequences. These distinctions should be exercised by controlled fault injection. The implementation passes when it produces the declared record, not merely when an alarm lamp illuminates. A fault which the architecture cannot detect must be disclosed in the qualification documentation.

Operator override should be attributable and limited. The application could allow an authorised operator to continue storing samples while requiring that the resulting data carry the unresolved fault designation. The override

Copyright 2026, James M. Atkinson

should record identity, time, reason and the state before and after the action. It should not change existing samples or falsely convert an invalid interval into a valid one. A later expert may determine that a subset of measurements remains fit for a narrow purpose, but that judgement is a separate derivative assessment with supporting evidence. It should not be disguised as the instrument's original state.

The test programme should include both overcautious and undercautious responses. If a harmless temporary delay in a host message causes a complete blind interval, the system may be operationally poor even though it is conservative. If a true ADC loss is concealed, it is evidentially unsafe. The goal is a truthful, appropriately granular state model whose limitations can be challenged. Such a model allows the investigator to continue work lawfully while protecting the integrity of conclusions made from incomplete or uncertain data.

Edsger Wybe Dijkstra, Cross-Peer Question to Richard Wesley Hamming: Dr. Hamming, a receiver vendor might claim that a new FPGA build improves converter resolution because its output has more bits, a smoother noise floor or a larger digital accumulator. As you have explained elsewhere, those numerical changes do not automatically imply additional independent information about the analogue input. How should an acceptance programme distinguish word-length expansion, digital averaging, decimation and genuine improvement in useful RF measurement performance? The answer should account for shared analogue noise, correlated converter errors, deterministic spurs and gain-control history. I would also ask what evidence an expert witness may properly offer when a record lacks the original high-rate samples and contains only the post-

Copyright 2026, James M. Atkinson

update decimated stream. Could an improved algorithm reconstruct an unknown short transient that the acquisition process never preserved? Please make the limits explicit enough that an impressive number of displayed bits cannot overwhelm the scientific analysis. The answer should also identify which original acquisition objects remain protected for a later independent challenge.

Richard Wesley Hamming, Cross-Peer Answer to Edsger Wybe Dijkstra: Professor Dijkstra, the word length of the data representation is not identical to the information content of the physical observation. A digital accumulator may need extra bits to avoid internal overflow and retain numerical accuracy, but those bits do not repair an ADC's analogue noise, clipping or aperture jitter. Averaging can reduce independent random noise under appropriate assumptions, yet shared distortion and coherent errors may survive unchanged. Decimation can improve in-band resolution for a defined band if appropriate filtering and sample-rate conditions hold, but it also removes information about omitted bands and transients. Therefore the acceptance experiment must measure useful sensitivity, noise, distortion and timing under documented input conditions rather than infer performance from an output bit count.

Consider a purely hypothetical array of sixteen nominally identical channels measuring the same scalar quantity with equal variance and independent zero-mean noise. The average has one-sixteenth the variance and one-quarter the root-mean-square noise amplitude of one channel. In decibels that ideal amplitude improvement is about twelve decibels. Under a suitable quantisation-limited model this corresponds to approximately two additional effective bits, not a sum of sixteen nominal converter bit widths. If

Copyright 2026, James M. Atkinson

the channels share clock jitter or front-end nonlinearities, the improvement can be smaller. A real instrument must establish the correlation structure empirically, and its output may exhibit systematic spurs that are poorly represented by a simple random-noise formula.

A controlled trial should examine input amplitude over a large range, apply two-tone blockers to reveal intermodulation, and use short reference pulses to measure group delay and recovery. Hold the analogue front end fixed while changing the FPGA build; then hold the build fixed while changing the input conditions. If the update changes only how a spectral estimate is displayed, it may make the chart appear quieter without changing the available physical evidence. If it changes digital filtering or decimation, the laboratory should document passband ripple, stopband attenuation and delay. The acceptance report should say which performance measure improved and under which calibration assumptions.

Finally, a post-update stream cannot restore information that was never preserved in the original acquisition. A new reconstruction may produce a plausible model-dependent estimate of an omitted transient, but plausibility is not observation. The file's original sample rate, bandwidth, validity masks and processing history define what can be challenged. An honest witness can state that the system recorded a specified reduced-band waveform and that a later algorithm analysed it under declared assumptions. The witness cannot infer an exact unknown wideband event from those data alone or treat a larger stored word length as proof of high-resolution RF truth.

Dr. James M. Atkinson, Moderator: The principal finding is that authentic software and firmware lineage, validated receiver state and a physically defensible observation are separate requirements. The manuscript now

Copyright 2026, James M. Atkinson

turns to conditional forecasts of future receiver technology without claiming that digital word length is equivalent to independent analogue information.

QUESTION 105. SOURCE AND VERIFICATION NOTES. NIST SP 800-193, Platform Firmware Resiliency Guidelines (2018), https://doi.org/10.6028/NIST.SP.800-193, provides contextual principles for protecting, detecting changes in and recovering platform firmware. NIST SP 800-86 (2006), https://doi.org/10.6028/NIST.SP.800-86, provides background on digital forensic preservation and investigation; neither establishes that a hypothetical RF recording is an accurate measurement nor verifies the fictional historical dialogue.

EDITORIAL QUALIFICATION. All test vectors and numerical examples are illustrative. An authenticated binary does not establish analogue fidelity, external emitter identity, legal authority or that data loss never occurred. Stage A mechanical validation does not mean publication-ready; independent Stage-B scholarly, historical, source-to-claim, technical and legal review remains outstanding.

QUESTION 106

Copyright 2026, James M. Atkinson

Which design decisions permit rigorous one-, five-, ten- and twenty-year receiver projections?

SCHOLARLY RECONSTRUCTION. The following dialogue is fictional and written for contemporary study, not genuine historical quotations. The horizons 2027, 2031, 2036 and 2046 are scenario review dates relative to a 2026 baseline, not product promises.

Dr. James M. Atkinson, Moderator: Professor Kroemer, I invite you to distinguish physically justified receiver development scenarios from extrapolation of nominal chip specifications at one, five, ten and twenty years. Please keep every numerical claim conditional upon a measurable design and calibration envelope.

Herbert Kroemer, Principal Contributor: Dr. Atkinson, a receiver forecast ought to begin with the physical device rather than an attractive trend line. Semiconductor performance is governed not only by the number of available transistors but by noise, parasitic capacitance, device breakdown, linearity, heat, interconnect delay and the energy needed to acquire and move information. An engineer might reasonably expect continuing progress in some of these quantities; it is not scientifically permissible to infer a constant improvement in all of them. A twenty-year projection should therefore be an explicit family of conditional engineering scenarios with mechanisms, limiting factors and observable milestones. The word forecast should never conceal the assumptions on which it depends.

I would organise the programme around a 2026 baseline, with one-, five-, ten- and twenty-year observation horizons corresponding to approximately 2027, 2031, 2036 and 2046. The first horizon can focus on near-term product

Copyright 2026, James M. Atkinson

qualification and supply availability. The five-year horizon can examine plausible integration and packaging changes, provided they are expressed as hypotheses rather than promises. At ten years, untested process and architecture combinations enlarge uncertainty. At twenty years, a single numerical receiver specification would be more a story than a measurement. The uncertainty should widen with horizon, and the forecaster should state what discoveries or obstacles would cause an earlier revision.

The analogue front end is likely to remain decisive even if digitisation becomes faster. The antenna, preselector, limiter, gain stages and converter input must tolerate strong legitimate signals without generating distortion that masquerades as an unknown emitter. A high sampling rate cannot recover a waveform that an input amplifier has already clipped. Likewise, a nominally greater bit depth does not imply proportional improvement in effective dynamic range under strong blocking. A useful forecast tracks calibrated receiver-input sensitivity, third-order intermodulation behaviour, compression, phase noise and recovery from transients, not merely converter sample rate and memory size.

We should also distinguish direct RF sampling from frequency conversion as design choices rather than treat one as historically destined to replace the other. Direct sampling can eliminate certain analogue conversion stages, yet it presents demanding requirements for anti-alias filtering, clock performance and a wide input dynamic range. A carefully engineered superheterodyne or hybrid architecture may remain advantageous when strong out-of-band energy coexists with very weak signals of interest. The forecast should include architecture envelopes: which regimes favour each

Copyright 2026, James M. Atkinson

choice, what calibration burden is imposed and how the measured result would change if a physical assumption fails. There is no universal receiver architecture independent of its use case.

Power consumption matters because a survey receiver must operate as an instrument rather than as a catalogue entry. Increasing instantaneous bandwidth can multiply digital sample transport, processing and storage loads; the thermal consequences may change oscillator stability and analogue drift. An integrated photonic or advanced packaging approach might redistribute some energy and interface limitations, but it introduces its own calibration problems and does not automatically overcome weak-signal dynamic range. Future predictions should therefore include watts per useful, validated unit of bandwidth and the thermal stability of the complete receiver. Counting digital operations without measuring their energy cost can produce an infeasible field design.

I would require a physical benchmark plan at each horizon. Test a defined set of weak carriers, strong blockers and short pulses through a calibrated reference plane, recording noise, spur production, timing, missed-event behaviour and data loss. Specify environmental temperatures, vibration and supply conditions. Compare the actual instrument to its earlier version under matched conditions, distinguishing differences attributable to analogue hardware from those due to digital algorithms. If an innovation improves one metric while compromising another, the report should preserve both. Engineering progress is multidimensional, and a forecast that selects only improving dimensions is not useful for defensive surveillance.

Copyright 2026, James M. Atkinson

There is particular danger in claiming a future ADC will combine a sampling rate and effective resolution already demonstrated separately by different devices. Such a combination may face simultaneous constraints involving aperture jitter, thermal noise, input bandwidth and power. Performance points from distinct products are not interchangeable components of one projected machine. A sound scenario includes a feasible device architecture and a total system budget. If the forecast assumes a dramatically better clock and a dramatically more linear front end, those are explicit dependencies requiring independent evidence. The failure of either dependency invalidates the corresponding system-level performance claim.

The one-year forecast should therefore be close to a procurement and qualification plan. The five-year forecast may place measured improvements and plausible product development into broad scenario bands. At ten years the laboratory should explore alternative technologies and identify falsifying benchmarks. At twenty years it should emphasise conditional capacities and critical uncertainties rather than precise dates. Each forecast should be revisited when actual measurements become available. A programme that cannot explain why an old projection was wrong is not practicing engineering foresight; it is keeping an ornamental timeline.

My conclusion is that future receivers should be judged by physically useful information acquired per unit of cost, energy and uncertainty. An instrument that samples more of the spectrum but makes unsupported claims from intermodulation products has not necessarily improved forensic capability. The best receiver is the one whose calibrated measurement chain can preserve and explain the relevant evidence. I pass the token to the next

Copyright 2026, James M. Atkinson

colleagues to examine how those system-level demands should guide design, testing and future investment.

Irving S. Reed, Peer Question: Professor Kroemer, a common forecasting method treats converter sampling speed, nominal resolution and power efficiency as independently improving trends, then combines their most optimistic projections into one future receiver. In actual circuits, those properties interact, and improved sample rate may make clock jitter, front-end bandwidth and interconnect losses more consequential. What experimental evidence would justify a joint forecast rather than a collection of unrelated component curves? I would particularly like a disciplined way to identify a physically impossible combination before an organisation purchases equipment or promises a particular detection performance. Please address whether parallel converters can resolve this trade-off and how mismatch, correlation and calibration effort should enter the scenario. A receiver survey requires more than high throughput: its weak-signal performance under strong blockers must be tested at the reference plane. How should the engineer choose the one-, five-, ten- and twenty-year milestones to avoid quietly turning several best-case component claims into a single unsupported system?

Herbert Kroemer, Response: Dr. Reed, the correct unit of projection is a physically specified receiver architecture under a defined load, not an imaginary component assembled from independent catalog maxima. A joint forecast should trace every performance measure through the same design. If a faster converter requires a wider analogue input, the front-end noise and linearity must be reconsidered. If a larger sample rate increases digital power, cooling and supply noise may change the very clock and analogue

Copyright 2026, James M. Atkinson

performance on which the sample-quality forecast depends. The validation programme should identify these couplings and test them with realistic reference stimuli. A benchmark conducted at one input frequency and one temperature cannot justify claims about the entire operating envelope.

Parallel converters can help under particular configurations, but the benefits differ between interleaving and averaging. Interleaving phases samples to increase effective aggregate rate, introducing timing skew, gain mismatch and offset errors which can create spurs. Averaging multiple simultaneous measurements can reduce sufficiently independent random noise, but common aperture jitter or analogue distortion may remain correlated. Neither architecture permits one simply to add nominal bit widths. A projection ought to specify whether the intended benefit is wider usable bandwidth, lower random noise, more independent spatial channels or redundancy against failure. Each has a different physical calibration and evidence requirement.

I would construct a design-dependency ledger. One entry might state that a future direct-sampling receiver needs an input clock meeting a measured jitter envelope at its highest relevant input frequency. Another might require a preselector whose blocker rejection prevents front-end compression. A third might require sustained data transfer without sample loss for the proposed number of channels. Failure of any critical dependency should invalidate the claimed system-level performance, even if a different component exceeds its individual target. The milestone is then a passable experiment, not a publication date.

At one year, use available devices and measured integration tests. At five years, condition proposed gains on demonstrated prototypes and

Copyright 2026, James M. Atkinson

environmental qualification. At ten years, retain multiple architectural possibilities and wider uncertainty intervals. At twenty years, identify limits and alternative physical mechanisms rather than promise a precise chip. Report what actually improves the lawful survey: fewer missed controlled events, smaller calibrated uncertainty or better resistance to strong-signal artefacts. A forecast that only increases a digit in a catalogue is not evidence of progress.

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I respectfully pass the token to William Redington Hewlett for a distinct examination of future instrumentation.

William Redington Hewlett, Second Principal Contributor: Dr. Atkinson, a twenty-year receiver programme must be understood as a system engineering and procurement problem, not solely a semiconductor research project. An organisation may be able to purchase a very fast converter and still lack a reliable recorder because data transport, storage endurance, calibration, software maintenance and operator competence are insufficient. The forecast should therefore distinguish what can be built as a laboratory demonstration from what can be fielded and independently qualified. A successful prototype is not yet a defensible TSCM instrument. The gap between those conditions can dominate the adoption timetable.

I would begin with a requirements document expressed in measurement outcomes. For each intended task, specify frequency range, instantaneous usable bandwidth, required probability of detection for controlled reference events, tolerable false-alarm burden, analogue dynamic range, timing uncertainty and lawful data-retention limits. Then construct alternative receiver architectures that could meet those requirements. A five-year

Copyright 2026, James M. Atkinson

forecast that simply multiplies the current sampling rate is inadequate if the relevant task requires improved preselection, stable calibration or more independent monitoring locations. System optimisation must identify the limiting component and the uncertainty of that diagnosis.

At the one-year horizon, the primary gains may come from better testing and configuration management rather than entirely new chips. Existing equipment can be arranged with improved input filtering, properly matched antennas, independent reference sources and robust sample-counter records. The operator can compare known signals across two independent receivers and reduce false attribution to a particular device. Those improvements are realistic because they depend upon operational discipline and available test methods rather than speculative inventions. A forecast should count such procedural gains alongside circuit-level changes, while distinguishing them from physical increases in sensitivity or bandwidth.

By five years, integration, interconnect and compute architectures may change the economic balance between many moderate receivers and one exceptionally wideband receiver. Parallelism can be valuable for continuous coverage of multiple bands or directions, but it is not free. Channel count introduces calibration requirements, clock distribution, phase consistency and fault monitoring. A system of sixteen modest receivers may offer better simultaneous spatial or spectral coverage than one expensive wideband channel, yet it also creates more configuration and data-management work. The forecast should compare complete architectures under identical authorised measurement tasks, not merely list their nominal aggregate sampling rates.

Copyright 2026, James M. Atkinson

At ten years, one should explore whether improved processing can reduce the need to preserve every raw sample without sacrificing the evidence required for foreseeable challenges. Event-based capture, spectral summaries and adaptive scheduling may be attractive under storage and privacy constraints. Yet each introduces selection bias or blind time unless its detection and retention policy are tested. I would make data minimisation a design requirement, not a post hoc excuse for deleting inconvenient results. A demonstrably limited and lawful preservation policy can coexist with reproducibility if its limits are honestly stated and protected reference measurements are retained where necessary.

At twenty years, organisational design may be as important as electronics. If instruments update themselves, use machine learning and exchange data across many sites, a laboratory must preserve model identity, firmware and FPGA provenance, independent calibration and decision logs. The cost of maintaining independent challenge may rise even as individual sensor prices fall. Therefore I would forecast personnel training, calibration fixtures, secure update infrastructure and archival formats alongside hardware. A system that cannot be maintained or audited after several years may be an expensive liability despite its high initial specifications.

The economic scenario requires explicit variables. Capital expenditure covers receivers, antennas, preselectors, reference sources, networks and storage. Operating expenditure covers power, calibration, maintenance, staff and retention obligations. Performance should be evaluated per validated surveillance objective, such as the fraction of an authorised test schedule observed with stated detection uncertainty. Forecasts must not quietly omit cooling, rack space, lawful storage controls or the cost of

Copyright 2026, James M. Atkinson

examining false alarms. A low-cost instrument with poor error characterisation can impose high downstream forensic costs and risks of mistaken conclusions.

I recommend milestones rather than promises. At one year, complete traceable comparison of the existing architecture; at five, demonstrate a defined gain in independently measured coverage or dynamic range; at ten, qualify new integrated architectures against accepted reference tests; at twenty, reassess whether the original measurement objectives remain appropriate. Every milestone should have a stop condition, including evidence of unacceptable noise, power, data loss or uncorrectable bias. A laboratory should be willing to conclude that a proposed architecture does not meet its task, rather than redesign the task to flatter the architecture.

My closing observation is that the future should be purchased as verifiable capability, not as a collection of impressive components. The historian may celebrate the first appearance of a device, but the forensic engineer must ask whether it can be calibrated, maintained, challenged and understood. That is the stronger criterion by which a receiver forecast should be judged.

Peter Elias, Peer Question: Mr. Hewlett, the practical system may generate a remarkable flow of complex samples, yet its storage and review capacity can be much smaller. A forecast based on converter throughput may assume that the future recorder will simply archive everything, although the lawful purpose may not justify retaining protected communication content and the disks may not sustain the write rate for days. How should a system architect distinguish instantaneous capture bandwidth, sustained lossless acquisition, retention policy and the cost of independent forensic examination? I would like a quantitative planning example expressed in plainly defined decimal

Copyright 2026, James M. Atkinson

units, with no implication that the numbers describe any particular commercial device. Please also address the risk that event-triggered recording gives an illusion of continuous observation when the detector silently discards intervals in which a short emission may have occurred. The choice between more receiver channels and fewer wideband channels should be tested against physical coverage and operational workload, not merely raw data volume.

William Redington Hewlett, Response: Dr. Elias, the first step is to draw four separate boundaries. The analogue front end defines which electromagnetic information can reach a converter. The digitiser and sample transport define what is acquired without loss. The storage policy defines what is retained. The analysis and legal review define what can be examined and disclosed. Confusing those boundaries leads to false claims. A receiver may continuously analyse a broad band but preserve only short authorised excerpts; that can be a legitimate design, but it must report its selection policy and the limits of what later reviewers can verify. A recorder which silently drops buffers while maintaining a polished waterfall has a different, unacceptable problem.

Consider a hypothetical complex recorder producing 100 million IQ pairs each second, each pair containing two sixteen-bit integers. At four bytes per pair, the raw output is 400 million bytes per second before container overhead. Over one hour that is 1.44 trillion bytes, or 1.44 terabytes in decimal units. Ten such streams would create 14.4 terabytes per hour. These numbers are pure arithmetic and do not establish that a particular disk, processor or network can sustain the rate. They show why the engineering

Copyright 2026, James M. Atkinson

budget must include continuous write performance, buffering, storage failure modes, power and an appropriate lawful retention plan.

The acceptance test should operate under the worst sustained load the system claims to support, not just a short demonstration. Use native sample counters to verify completeness; stress the file system and transport; simulate disk-full and power-recovery conditions. If event-triggered capture is employed, compare it with an independently monitored authorised source schedule and measure missed events near trigger boundaries. A saved file is not an observation of the time before the trigger unless the ring-buffer history actually preserves that interval. The report must distinguish unobserved time from observed silence, and it should limit retention to information necessary for the authorised task.

Architecture choice then becomes an optimisation under measurable constraints. Several narrowband receivers can provide continuous simultaneous observations where one scanner cannot, while a wideband converter may offer flexible software processing but impose heavy data and dynamic-range burdens. The future programme should compare both options using identical controlled events, measured blind time, calibration effort and lifecycle costs. The winner is the system that meets the scientific requirement with reliable evidence and lawful governance, not the one with the largest advertised data rate.

Norbert Wiener, Peer Question: Mr. Hewlett, as receivers become more autonomous, the distinction between the device's measurements and the software's scheduling decisions may become increasingly difficult to trace. A controller may retune one channel, reduce gain on another, trigger storage on a third and update an anomaly model while the operator sees only a

Copyright 2026, James M. Atkinson

consolidated display. How should the next twenty years of development be planned so that such an instrument remains independently auditable? I would like you to consider software provenance, feedback-control state, sensor scheduling, power consumption and network transport together. If a future system claims continuous coverage, what operational test should establish the actual blind time and missing intervals? And if an autonomous controller changes its own detection threshold, how should its claimed false-alarm rate be qualified? The engineer ought to design for trustworthy failure behaviour, not merely for increasingly impressive automation. The acquisition-state log must also capture automatic retuning and software adaptation boundaries.

William Redington Hewlett, Response: Dr. Wiener, autonomy alters the system architecture as well as the workflow. A controller making its own scheduling and gain decisions must record those actions with a relation to native acquisition time or sample indices. A human operator may otherwise see a continuous interface while different channels are observing different bands or recovering from automatic gain changes. The claim of continuous coverage is a claim about actual valid acquisition, not display continuity. It should be tested with a controlled schedule of authorised reference emissions whose timing and frequency are independently known. The test should reveal missed events at retune boundaries, sample loss under data-load stress and periods where the instrument could not satisfy its calibration requirements.

The architecture should maintain a configuration and decision ledger. Record software and firmware identities, instrument and antenna routing, clock state, gain settings, trigger conditions, model version and operator

Copyright 2026, James M. Atkinson

overrides. An adaptation policy that modifies its threshold after observing a new background changes the decision procedure; its false-alarm rate cannot be assumed identical to the rate measured for the original rule. A future receiver should be able to abstain when the observed configuration lies outside its validation domain. The ledger should preserve the original machine decision and any later reinterpretation as separate events rather than rewrite history to match the latest software.

A forecasting programme can evaluate autonomy against human-controlled alternatives on the same physical task. Use identical reference events and known interference under matched constraints, and compare usable observation time, detection, false alarms, power and evidence preservation. If automation reduces the number of recordings but increases selection bias, the trade-off must be reported. If it improves coverage but creates an unreviewable black-box decision path, independent forensic use may remain inappropriate. Data storage and communication should be designed for lawful minimisation, with authorised raw excerpts preserved only when their scientific purpose justifies retention.

At one year, the institution may implement better logs and deterministic replay on existing instruments. At five years, it can trial bounded autonomous scheduling with explicit validity masks. Ten-year and twenty-year plans should be scenario studies with testable milestones, not predetermined announcements that humans will become unnecessary. The enduring design criterion is whether a qualified independent examiner can reconstruct what was observed, what the system decided and which physical explanations remain unresolved.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I respectfully pass the token to Norman Foster Ramsey Jr. for a distinct examination of future instrumentation.

Norman Foster Ramsey Jr., Third Principal Contributor: Dr. Atkinson, timing and frequency reference quality should occupy a central place in any receiver forecast. The stability of a nominal oscillator may be excellent under one laboratory condition while its phase noise, environmental sensitivity or holdover behaviour imposes serious uncertainty upon a wideband acquisition. It is not enough to project the converter's sample rate without specifying the reference that drives it. The acquisition clock governs not only the time coordinate of samples but also their instantaneous aperture uncertainty, which can degrade signal-to-noise ratio at high input frequencies. Future systems must distinguish a high-frequency digital clock from an accurate and traceable time measurement.

A useful illustrative model of jitter-limited signal-to-noise ratio for a sinusoidal input is SNR approximately equal to minus twenty times the base-ten logarithm of two pi times input frequency times root-mean-square aperture jitter, under assumptions of small, effectively random timing error and the stated waveform. Let input frequency be one gigahertz and RMS jitter one hundred femtoseconds. The dimensionless timing product is approximately 0.000628; the idealised jitter limit is about sixty-four decibels. At ten gigahertz with the same jitter, the limit falls to roughly forty-four decibels. These are hypothetical calculations, not measured specifications of any receiver, and other noise and distortion mechanisms can impose lower usable performance.

Copyright 2026, James M. Atkinson

That scaling demonstrates why a forecast about much faster direct sampling must include a clock roadmap. To retain the same jitter-limited ratio at ten times the input frequency, the RMS timing uncertainty would need to fall by a factor of ten under the simplified model. Achieving such a reduction throughout a distributed receiving system is not the same as demonstrating a low nominal jitter in one isolated clock component. Clock distribution, phase alignment, thermal drift and converter aperture behaviour may add uncertainty. A product data sheet's best number under selected conditions should not be propagated uncritically into a complete multi-channel system estimate.

The one-year programme should establish the current reference-plane measurements and their uncertainty. Record phase noise, frequency stability, time-transfer error, oscillator holdover and environmental sensitivity for the actual receiving chain. A controlled reference pulse can test the relation between analogue arrival and exported sample time, while a calibrated frequency reference supports spectral-axis verification. Where GPS or another external timing signal is used, distinguish disciplined operation from holdover and document the consequences of losing it. No timestamp field should be treated as physically accurate merely because it contains many decimal places.

At the five-year horizon, forecasts may consider better integrated clock distribution, lower-noise oscillators and improved calibration protocols. Such possibilities should be expressed with explicit target ranges and validation methods. At ten years, alternative frequency-reference technologies might become practical for applications that presently require bulky or expensive equipment, but no particular commercial timetable

Copyright 2026, James M. Atkinson

should be assumed. At twenty years, the scientific limits remain relevant even if components change radically. Future claims should be framed around traceability, uncertainty and environmental performance rather than around unqualified promises of perfect synchronisation.

Distributed arrays add another layer. Two receivers can each possess excellent local frequency stability and yet have an uncertain relative time offset. Time-transfer methods depend on propagation, cable delay, network asymmetry and reference-distribution geometry. Phase-coherent combination also requires attention to differential path and frequency response. The forecast should therefore identify whether the task is spectral occupancy, frequency measurement, time difference of arrival or coherent phase processing. Each imposes different clock requirements. A technology improving the first two does not automatically solve the latter two.

One must also consider the dynamic response to reference changes. A clock that locks to an external discipline may experience a transient frequency adjustment. If that adjustment occurs during an RF burst, the extracted phase history may be distorted without any change in the external source. An acquisition system should record clock-control state changes and test their effects using independently monitored reference signals. The future receiver may use sophisticated self-calibration, but the state history must remain interpretable to a later investigator. Otherwise automated correction can erase the very evidence needed to explain a measurement.

I would require each forecast band to contain an explicit timing uncertainty budget. List intrinsic source noise, distribution effects, converter aperture behaviour, synchronisation uncertainty, environmental drift and calibration residuals. Not every contribution is independent or Gaussian, and some may

Copyright 2026, James M. Atkinson

be deterministic biases. Combine them only under justified assumptions. At a future review date, compare measured results with the predicted envelope and document which dependencies held or failed. A forecast should improve through examination of error, not through rewriting history after the outcome is known.

The final answer is that clock quality is an enabling condition rather than a decorative accessory. Faster digitisation creates new opportunities only when frequency and timing uncertainty remain compatible with the signal and the intended inference. The prudent forecast specifies the measured reference properties needed to exploit hypothetical future converters, and it acknowledges the cases in which reference limitations will remain dominant.

Richard Wesley Hamming, Peer Question: Dr. Ramsey, I should like to challenge the widespread assumption that a better frequency standard automatically produces better timing evidence at the antenna. A receiver may possess a superb local oscillator while its analogue filters, buffering and software timestamps introduce unmeasured delay. Even a perfectly accurate clock can timestamp the wrong event precisely. How should a twenty-year forecast separate oscillator stability, sampling aperture jitter, relative station synchronisation and the actual uncertainty of an RF event's arrival time? I also invite a simple worked example showing how jitter-limited sinusoidal SNR depends upon input frequency, with all variables defined and the assumptions clearly stated. A forecasting committee might compare a one-gigahertz and a ten-gigahertz input using the same hypothetical timing uncertainty and incorrectly claim the resulting difference is a commercial device specification. What validation would establish the physical

Copyright 2026, James M. Atkinson

relationship in an actual receiving chain? The test should identify which error source is actually dominant for the specified receiver configuration.

Norman Foster Ramsey Jr., Response: Dr. Hamming, the timing problem has several layers. Oscillator stability concerns the evolution of the reference frequency; aperture jitter concerns the uncertainty of the converter's sample instant; interstation synchronisation concerns the relative time scales of separate instruments; and arrival-time measurement includes propagation and analogue path delays. These quantities can interact but are not interchangeable. A coherent reference distribution may be excellent while one channel has an unmeasured group delay. A host timestamp may be precise to many decimal places while referring to a buffer write rather than the arrival of electromagnetic energy. Any future specification should identify its actual physical reference point and calibration method.

For the illustrative jitter limit, let f be a sinusoidal input frequency in hertz and let sigma_t denote RMS aperture-time uncertainty in seconds. Under the simplified small-jitter model, SNR_j is approximately minus twenty times log base ten of two pi f sigma_t, expressed in decibels. At f equal to one billion hertz and sigma_t equal to one hundred femtoseconds, two pi f sigma_t is approximately 0.000628, yielding a jitter-limited SNR near sixty-four decibels. At ten billion hertz with the same assumed jitter, it is approximately 0.00628 and the limit falls near forty-four decibels. These are model calculations, not field measurements; analogue noise and distortion can produce lower overall performance.

A calibrated laboratory would use reference sources, phase-noise measurements, controlled pulse timing and independent acquisition paths to characterise the actual system. One should determine whether the

Copyright 2026, James M. Atkinson

manufacturer quoted integrated clock phase jitter, aperture jitter at the converter or some other quantity. The applicable bandwidth and correlation of errors matter. A comparison made with a single ideal sinusoid does not automatically establish timing accuracy for short complex bursts. Repeated tests across temperature, input frequency and clock state help define the real operating envelope. The result may be a useful, uncertain range rather than one immaculate figure.

For forecasting, specify which physical bottleneck must improve to support a proposed receiver task. At one year, measure the existing chain and correct its calibration deficiencies. At five years, test improved distribution and clock components. At ten and twenty years, retain explicit alternative assumptions about oscillator technology, converter aperture behaviour and system integration. A successful future clock innovation will matter only to the extent that the rest of the receiver preserves the improvement. The instrument should always record when it loses discipline and enters holdover, because an uninterrupted clock display is not proof of uninterrupted timing accuracy.

Rudolf Emil Kálmán, Peer Question: Dr. Ramsey, a future multi-receiver array may rely upon sophisticated clock correction loops and software models to maintain apparent synchronisation. Yet an attractive time plot can conceal a transient reference failure, a loop adjustment or differential path delay. Could you identify which dynamic state variables a forecast ought to include when projecting one-, five-, ten- and twenty-year improvements in coherence and arrival-time measurement? I would like an acceptance trial involving a known reference pulse, deliberate loss of an external clock and different lengths of holdover. The result should distinguish what the

Copyright 2026, James M. Atkinson

estimator predicted from what an independent instrument observed. A forecaster might promise almost perfect distributed synchronisation because nominal local oscillators become more stable, but the receiver array may still have unmeasured analogue latency and network asymmetry. How would a defensible uncertainty budget prevent that mistake? A calibration should record the actual event reference plane and distinguish predicted from observed time.

Norman Foster Ramsey Jr., Response: Dr. Kálmán, an apparently smooth estimated timeline is not proof of a correct physical time coordinate. The dynamic state may include clock offset, frequency offset, drift, phase behaviour, reference-lock state and relevant path delays. Their uncertainties can evolve differently during disciplined operation and holdover. A filtering model may predict these quantities, but its prediction depends upon an assumed state evolution and observation-noise model. A receiver's actual propagation and analogue delays must be measured independently where possible. The report should distinguish an instrument observation from a model-based time correction, and it should preserve the raw native sample indices for later challenge.

The controlled trial should start with a reference pulse delivered through a characterised path to several receivers, using an independent monitor to record actual event timing. Then remove or disturb one reference source for measured intervals while leaving others disciplined. Record clock-control state and compare predicted offsets against independent measurements. Vary temperature or supply conditions where relevant. The trial should include a return-to-lock event, since the control loop may introduce a transient adjustment that changes phase or frequency during a burst. These

Copyright 2026, James M. Atkinson

states should be labelled rather than concealed under one general word such as synchronised.

The uncertainty budget should include clock source instability, reference distribution, converter aperture timing, analogue group delay, timestamp semantics and network time-transfer asymmetry where applicable. Some components are correlated because receivers share a clock or calibration path. One cannot assume independence merely to obtain a smaller root-mean-square uncertainty. At the one-year horizon, measure the existing system and correct its most important calibration gaps. At five years, evaluate improved reference hardware under controlled conditions. Ten-year and twenty-year projections should present conditional ranges whose success depends upon measured improvements in every material layer, not simply one oscillator's nominal specification.

The final evidence statement ought to specify the time reference and supported physical proposition. A receiver may detect the same controlled event as another without proving coherent phase or precise time difference of arrival. An improved oscillator may reduce one error term while a previously neglected analogue delay remains dominant. The prudent future system is one whose state and uncertainty remain inspectable when the reference behaves badly, not one whose smoothest graph hides the uncertainty of its own timing model.

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I respectfully pass the token to Claude Elwood Shannon for a distinct examination of future instrumentation.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Fourth Principal Contributor: Dr. Atkinson, I would distinguish the growing capacity to transport and process symbols from an increase in the amount of physical information available at the receiver input. A faster converter may produce more bits per second, but those bits can include noise, repeated representations of a limited bandwidth and artefacts introduced by the chain. The sampling theorem describes recovery of an appropriately bandlimited signal under its assumptions; it does not promise recovery of a signal which the analogue front end clipped or filtered away. A receiver forecast must be written in terms of physically meaningful information, signal classes and uncertainty, not just transport rates.

Consider storage demand. A complex receiver delivering one hundred million complex samples per second with sixteen-bit I and sixteen-bit Q ordinarily produces thirty-two bits per complex sample before container overhead. That idealised raw stream is 3.2 billion bits per second, or approximately four hundred million bytes per second using decimal units. Ten such channels would produce roughly four gigabytes per second before metadata, buffering and redundancy. Those values are arithmetic planning examples, not promises of sustained device performance. A system design must consider continuous writes, storage wear, thermal conditions and whether a lawful preservation policy needs every sample.

At the one-year horizon, there may be substantial gains in architecture without a radical converter advance: use more appropriate analogue filtering, compress representations losslessly where useful, retain selected diagnostic measurements and schedule capture with explicit accounting for blind intervals. These measures can improve usable scientific coverage and reduce interpretation errors. A good forecast must not count saved storage

Copyright 2026, James M. Atkinson

as additional physical sensitivity. It should state whether the system gained detection performance, efficiency, evidence quality or merely a smaller archive. Distinguishing these outcomes prevents attractive but misleading comparisons between successive generations.

At five years, processing and storage economics may favour wider instantaneous captures or more simultaneous receiver channels. But the net benefit depends on whether the increased observation rate can be transported and analysed without loss. A recorder that advertises a gigahertz of bandwidth while dropping buffers under sustained load may provide less reliable evidence than a narrower system with validated continuity. The forecast should therefore include accepted data-loss limits, time-to-detection, event-clustering behaviour and a tested file-provenance mechanism. A system which cannot distinguish a missing buffer from measured silence is not scientifically improved by its greater raw bandwidth.

At ten years, more sophisticated processing may permit efficient detection of specified signal families with less data retention. Compressive and event-driven techniques are plausible research paths, but their benefits rely on tested signal models and detection policies. A sparse reconstruction may perform beautifully on familiar narrowband carriers and miss an unmodelled broadband transient. A neural detector may reduce an archive while introducing new selection bias. The forecast should specify which physical events are preserved and which may be omitted. It is not enough to project increased algorithmic accuracy without a predeclared, independent experiment including signals that violate the model's favourable assumptions.

Copyright 2026, James M. Atkinson

At twenty years, the data architecture itself may be different. Compute may move closer to an antenna, networks may aggregate distributed sensors, and autonomous instruments may adapt their settings. Nevertheless, the same inferential questions remain. What was physically observed? At which reference plane? Under what calibration and legal authority? Which samples and states were preserved? Can independent investigators reproduce the decision? These are not temporary software questions but structural constraints on scientific evidence. A model's output is useful only in proportion to the validated information it extracts from its observation.

I would resist a simple projection of aggregate converter bit depth. Combining multiple twelve-bit or fourteen-bit channels does not add their nominal word lengths into one physically independent twenty-four-bit or thirty-two-bit observation. Under appropriate assumptions, averaging independent noise can improve estimation, but common errors and correlated distortion can defeat the ideal gain. Similarly, interleaving channels can increase sample rate at the cost of calibration challenges; it does not necessarily increase instantaneous amplitude resolution. Each architectural claim should be tested against measured error and information limits rather than inferred from the number of installed converters.

The forecast should contain scenarios for both success and failure. If storage density improves rapidly but analog input linearity changes little, choose a receiver design that avoids collecting larger volumes of distorted data. If timing references improve but preselector switching continues to create blind time, prioritise coverage and scheduling. If AI software improves classification but cannot explain distribution shift, retain

Copyright 2026, James M. Atkinson

independent reference observations and abstention rules. The programme should identify which dependency is most likely to determine performance for a particular task and then revise its forecast as those measurements accumulate.

In conclusion, the future of SDR is not one number. It is a change in the set of questions that a calibrated, lawful, reproducible receiving system can answer. The scientist should forecast that set in conditional terms and preserve the distinction between bits transported, observations retained and inferences warranted. The most impressive numerical trend is not necessarily the most important improvement in knowledge.

David Slepian, Peer Question: Dr. Shannon, future receivers may use compressive acquisition, event-driven processing and machine-assisted selection to reduce the enormous sample volumes that broader bandwidths produce. Yet the signal of interest in a technical-surveillance investigation may be precisely an unknown, brief, non-sparse event that a fashionable model was never trained or designed to preserve. How should a technology forecast distinguish computational efficiency from a scientifically meaningful probability of detecting unanticipated RF activity? In particular, what must be measured before a planner can claim that selective recording retains the evidence needed for independent challenge? I ask also whether claims of increasing information content should be evaluated against the analogue reference plane or merely against the ability to produce more digital bits. A forecast may look impressive because a compressor writes fewer bytes, but the reduced archive could have discarded the only event capable of distinguishing an external source from a receiver artefact. The acceptance

Copyright 2026, James M. Atkinson

criteria must include a held-out signal that deliberately violates the favourable model.

Claude Elwood Shannon, Response: Dr. Slepian, a reduction in retained data is not itself an increase in information about the physical phenomenon. It is an engineering choice which may preserve particular quantities at lower cost while discarding others. If a model assumes sparsity in a chosen dictionary, it can be excellent for the signal classes matching that model and unreliable for a broadband transient outside it. A low reconstruction residual does not prove that the acquisition distinguished every possible input. The forecast should separate the direct measurement vector, the signal model, the reconstruction and the subsequent detection decision. Each layer needs a validation programme for the specific inference the user wishes to make.

I would require an independent controlled test including both favourable and deliberately unfavourable signals. Use sparse tones, frequency-agile bursts, short chirps, impulses and strong legitimate blockers. Vary arrival time relative to the capture schedule and include intentional sample loss. An independent calibrated reference should establish which authorised events actually entered the receiver input. Compare the stored observations and the algorithm's decisions against that reference, reporting missed events, false alarms, invalid captures and unresolved cases separately. The acceptance criteria should be fixed before inspecting the held-out results. A method that performs well only after changing its thresholds on the final test data has not demonstrated independent generalisation.

The information budget also includes physical dynamic range. A converter may produce an increased number of bits while its input noise and

Copyright 2026, James M. Atkinson

distortion remain unchanged. If the front end clips, the lost amplitude details are unavailable to any later computer. If an algorithm stores only averaged spectral bins, the phase history of a brief transient may be irrecoverable. These are not defects of a particular storage technology but consequences of the measurement chosen. Therefore future performance ought to be expressed in terms of validated observable quantities and detection opportunities, not merely sample output or compression ratio.

Selective retention can be defensible where it follows lawful scope and where its blind regions are honestly characterised. Some investigations need only narrowband occupancy statistics; others require a protected original waveform excerpt for phase or transient challenge. The laboratory should declare those needs in advance. When a forecast suggests that future AI will replace preservation of raw evidence, it must explain how independent examination will remain possible and which claims become untestable. Better computation may improve the use of observations, but it cannot create information that the receiver never acquired.

Dr. James M. Atkinson, Moderator: With thanks for the preceding analysis, I respectfully pass the token to John Bardeen for a distinct examination of future instrumentation.

John Bardeen, Fifth Principal Contributor: Dr. Atkinson, a receiver forecast which lacks a credible account of materials, devices and fabrication is merely an extrapolation of wishes. The useful performance of an ADC or low-noise front end depends upon thermal behaviour, transistor noise, parasitic capacitances, power handling, matching and the complexity of packaging. A device can be fast but noisy, linear but power-hungry, compact but difficult to cool. Future circuit architectures may redistribute those compromises, yet

Copyright 2026, James M. Atkinson

they do not remove the need to measure them. I would therefore insist that system-level projections be grounded in plausible physical mechanisms and an uncertainty budget that includes the complete analogue path.

At the one-year horizon, the most credible forecast uses demonstrated devices and changes that can be qualified in the laboratory. A receiver can be improved through better preselection, gain distribution, shielding, power supply design and calibration even without a new converter. The test should measure noise figure, input compression, intermodulation and the response to short strong pulses. A cleaner spectral display produced by a digital update is not sufficient evidence of reduced analogue distortion. An engineer must know where the limitation occurs before assigning credit for an apparent improvement.

At five years, packaging and integration may permit closer coupling of converter, clock and signal-conditioning circuitry. That proximity can reduce some interconnect parasitics but can also increase thermal coupling and electromagnetic interference within the package. High-speed digital switching near a weak analogue input poses a problem that geometry and shielding must address. A forecast should compare complete implementations under matched input signals and environmental conditions. One should not assemble the best published performance point from several different components into an imaginary product which simultaneously possesses all their virtues.

At ten years, novel materials or device structures may become commercially useful, but a credible forecast must identify the path from device physics to a qualified receiver. A research demonstration may show an excellent noise property in one component without establishing manufacturability,

Copyright 2026, James M. Atkinson

reliability, frequency coverage or power handling at system scale. Likewise, an innovative photonic interface can alter sampling or transport constraints while introducing calibration and synchronisation requirements of its own. The forecast should distinguish exploratory science, engineering prototypes and accepted field instrumentation. The dates of adoption should be scenario bands, not statements of certainty.

At twenty years, entirely different system partitioning is conceivable. One might place digitisation near antennas, use distributed sensor nodes or integrate signal analysis with adaptive front ends. Yet external electromagnetic signals will still encounter nonlinear components, imperfect references and noise. The scientific challenge will remain to separate energy that actually entered the measurement reference plane from features created internally. The greater complexity of autonomous systems may increase the difficulty of provenance and maintenance. A future device that measures broadly but cannot explain its operating state would not be preferable for forensic inference.

I recommend projecting power and reliability together. Additional converter channels, high-rate data links and processing accelerators generate heat. Temperature changes can affect oscillator behaviour, input matching, gain and filter response. Even if a chip specification improves under laboratory cooling, its performance inside a field enclosure may be materially different. Therefore the programme should track validated performance across environmental conditions and the cost of keeping the instrument within its characterised limits. A design with slightly lower peak bandwidth but excellent stability may produce more defensible multi-hour or multiday records.

Copyright 2026, James M. Atkinson

The physical test programme should use controlled source signals over frequency, level and time. It should include weak carriers for noise and sensitivity, strong blockers for nonlinear response, and short transients for recovery. It should also measure behaviour across temperature, vibration and supply variations where relevant. Repeated measurements on multiple specimens are necessary to distinguish an isolated prototype from reproducible manufacturing performance. A forecast that assumes all future devices will achieve the best observed laboratory result is not a forecast of a deployable population. The uncertainty of unit-to-unit variation belongs in the scenario.

Converter specifications deserve particular caution. Nominal resolution is the number of output codes, whereas effective performance is limited by noise and distortion under specified test conditions. Wider bandwidth and higher input frequency make aperture and clock imperfections more consequential. One can improve digital arithmetic, but one cannot eliminate analogue uncertainty by retaining additional zeros in a computer word. Parallel averaging may improve certain noise-limited measurements when errors are sufficiently independent. It cannot be treated as a deterministic path from fourteen bits to thirty-two accurate physical bits.

I would conclude by requiring each future milestone to identify a reference-plane improvement that can be independently demonstrated. An engineering forecast is valuable when it anticipates constraints, not when it supplies false precision about distant products. The analyst should revise forecasts as measurements mature, preserve failed hypotheses and ask which technology most improves lawful, calibrated observation. That

Copyright 2026, James M. Atkinson

question will remain useful long after the names of today's converter architectures have changed.

Hendrik Wade Bode, Peer Question: Dr. Bardeen, a forecast for a future SDR is sometimes written as if greater digital capability makes analogue filters obsolete. However, strong out-of-band emissions can drive an input amplifier or mixer into nonlinear operation long before the converter or FPGA applies a digital stopband. A new processor may hide the offending source from a waterfall while leaving its internally generated products. What circuit and system measurements should form the baseline for the one-, five-, ten- and twenty-year projections? I would also like a test which deliberately places weak authorised signals alongside much stronger blockers, then compares direct sampling and frequency-converting architectures with equal attention to preselection, gain and calibration. What evidence could establish an actual improvement in usable dynamic range, as distinct from a cleaner appearance on the display? Please specify an independent analogue input measurement rather than relying on a digital chart. Explain calibration uncertainty during sustained heating and strong blocker tests.

John Bardeen, Response: Dr. Bode, the physical sequence of operations is decisive. A digital filter operates only on information that the analogue chain and converter have delivered. If a preamplifier is driven into compression or creates intermodulation products, downstream processing cannot know with certainty which spectral components were external and which were internally generated without additional challenge tests. Some products may be rejected by digital filtering, but others can fall inside the band of interest. A wider converter does not eliminate the need to consider the input

Copyright 2026, James M. Atkinson

impedance, preselection, gain distribution, limiting and nonlinear response of the front end. These remain important across every plausible forecast horizon.

The laboratory should establish a calibrated input reference plane and use a controlled weak carrier together with one or more strong blockers. Measure the weak carrier's recoverability as blocker level changes, record the onset of compression and intermodulation, and test recovery after short strong pulses. Repeat with appropriate analogue preselection and with the preselector bypassed where safely possible. Compare a direct-sampling chain with a heterodyne chain on the same task, correcting for differing gain and filter bandwidths. The result should be a set of operating envelopes showing sensitivity, dynamic range, spurs and timing behaviour, not simply one manufacturer's nominal bandwidth figure.

Forecasting should then identify the physical limitations the future architecture must overcome. At one year, improved layout, shielding and filtering might offer the greatest practical gain. At five years, integration may alter the balance among front-end stages but will still require calibration. At ten years, different device or packaging technologies may change achievable performance points; those claims should remain conditional on measured noise, linearity and power. At twenty years, novel solutions are conceivable, but the need for a truthful analogue reference-plane model remains. Greater digital processing will not change the fact that a missing or saturated physical observation cannot be restored with certainty.

The final comparison should include reliability and environmental performance. A wideband high-power receiver may heat its oscillator and

Copyright 2026, James M. Atkinson

analogue input, degrading stability during long surveys. A narrower but more stable architecture might yield better evidence over days. The preferred future system depends on the specific scientific question and the legal purpose, not on an abstract race for larger bandwidth. A demonstrated improvement is one that survives independent measurement, documented uncertainty and the relevant strong-signal challenge.

Dr. James M. Atkinson, Moderator: I now invite four reciprocal questions addressed to four distinct colleagues, with immediate responses and no assertion that these historical figures ever conducted such a modern discussion.

Herbert Kroemer, Cross-Peer Question to Claude Elwood Shannon: Dr. Shannon, a committee may say that the amount of digital information stored by a future receiver will double repeatedly, and then mistake that growth for a corresponding improvement in knowledge of unknown RF emissions. I ask you to identify exactly where this inference fails. Suppose future hardware records many more quantised samples but the analogue input remains limited by strong-signal distortion, antenna coupling and clock uncertainty. Conversely, suppose an efficient detector permits careful study of a narrow authorised signal class while storing far fewer bytes. Which architecture has increased useful information for the intended scientific claim? I want a conditional forecast that distinguishes observation, preservation, reconstruction and attribution. Please also explain why combining many nominal fourteen-bit converters may improve some statistical estimates without creating a mathematically guaranteed thirty-two-bit measurement of a single physical amplitude. The planning conclusion must not depend on a particular hypothetical product becoming

Copyright 2026, James M. Atkinson

commercially available. Please distinguish the forecast of stored bits from the forecast of independently calibrated measurements.

Claude Elwood Shannon, Cross-Peer Answer to Herbert Kroemer: Professor Kroemer, the number of stored bits is a property of the chosen representation and acquisition process, not a direct measure of the information available about an unknown physical event. When the analogue path has clipped a transient, no increase in downstream word length can restore its lost peak. When an input filter has removed a frequency band, recording more samples from the remaining band does not document what happened in the omitted band. When a feature extractor averages across a brief pulse, the stored summary may be useful for mean occupancy while inadequate for event timing. Thus the forecast must state the class of questions the receiver can answer and the constraints under which the answer is identifiable.

Consider two hypothetical designs. The first records an enormous stream of samples but frequently overloads under legitimate nearby blockers, and the recorder loses unmarked buffers. The second records fewer samples while maintaining a calibrated analogue path, valid sample counters and a tested event schedule for the authorised task. The second may provide better evidence even though it writes fewer bytes. Conversely, for a task requiring unpredictable short transients across a wide band, aggressive event-triggered retention may make the first design superior if it truly observes continuously without loss. One cannot rank them by byte count alone. The laboratory must test relevant controlled events, blind periods, false alarms and preservation of the quantities needed for independent challenge.

Copyright 2026, James M. Atkinson

The matter of parallel converters is similar. Suppose several simultaneous channels measure the same scalar input with independent random errors of equal variance. Averaging can reduce the variance, with an ideal improvement related to the number of genuinely independent observations. But common clock jitter, analogue distortion, gain error and deterministic quantisation patterns can remain correlated. The numerical output of an average may have a longer word length for arithmetic reasons while possessing less physical precision than the word length suggests. Interleaving converters to increase aggregate sampling rate addresses a different objective and introduces phase, gain and offset mismatch. A claim of thirty-two accurate physical bits from several fourteen-bit channels requires experimental evidence that the necessary noise and error assumptions hold, not merely arithmetic addition.

The future programme should therefore forecast tested inference capacity. At each horizon it should identify the waveform families, environmental conditions, reference plane, uncertainty and lawful retention necessary to support its proposed observations. A stronger model may extract more defensible information from the same physically adequate data, but it cannot create an event never measured. That distinction protects the institution against spectacular numbers unaccompanied by meaningful scientific improvement.

Claude Elwood Shannon, Cross-Peer Question to John Bardeen: Dr. Bardeen, semiconductor and packaging research may enable substantial changes in the partition between analogue and digital circuitry, yet a system forecast can become exaggerated when it assumes that the most favourable individual device improvements will coexist without additional heat,

Copyright 2026, James M. Atkinson

coupling or calibration burdens. What physical experiment would demonstrate that a future integrated front end genuinely improves usable weak-signal dynamic range rather than merely shifting noise or spurs to another part of the spectrum? Please consider strong blockers, intermodulation, thermal drift and the converter's actual effective performance at high input frequencies. How should the forecast handle a research prototype whose laboratory noise figure is excellent but whose yield, reliability or calibration stability has not been established? I also ask whether photonic or quantum-assisted approaches should be evaluated against the same reference-plane standards as conventional receivers or given a different standard simply because their physical principles are novel. I ask that the reply separate scientific feasibility from manufacturing qualification and deployment.

John Bardeen, Cross-Peer Answer to Claude Elwood Shannon: Dr. Shannon, the comparison must be conducted at an equivalent physical reference plane. A proposed integrated device should be presented with known authorised test signals spanning the intended frequency, amplitude and time ranges. The laboratory should measure weak-signal sensitivity, compression, intermodulation products, transient recovery and environmental stability, then compare those quantities with the established receiver under matched conditions. A reduced noise figure at one frequency does not establish better sensitivity when the test contains strong out-of-band blockers that create distortion or force protective attenuation. Likewise, a digital output with a flatter spectrum might reflect altered filtering rather than a real improvement in analogue measurement.

Copyright 2026, James M. Atkinson

Thermal and electrical coupling are especially important in integrated designs. Shorter interconnects can reduce parasitic effects, but fast digital switching near sensitive analogue nodes can introduce interference. Heat from data transport and processing may affect gain, oscillator stability and reference distribution. A useful qualification test should operate at sustained load and realistic enclosure temperatures, not only at the brief and carefully cooled conditions of an initial demonstration. It should also measure variation among multiple specimens, since a single exceptional chip is not proof of reproducible manufacturing performance. Calibration stability through ageing and environmental change belongs in the evidence.

A research prototype can establish a mechanism without establishing procurement readiness. The forecast should label technology stages: scientific feasibility, engineering prototype, reproducible manufacture, calibrated deployment and long-term maintenance. Each has distinct evidence requirements. A ten-year scenario might assume a new device structure reduces one limitation, but the system-level benefit still depends on packaging, supply, input protection, clock quality and calibration. At twenty years, alternative physical principles might become useful, yet a precise market date or combined specification remains speculative. The probability of success is not established by the elegance of the underlying physics alone.

Photonic or quantum-assisted components should be judged by the same fundamental scientific question: what electromagnetic information did the complete apparatus observe, with what uncertainty, under what conditions? Their mechanisms may require different calibration instruments and failure tests, but novelty does not exempt them from independent verification. A

Copyright 2026, James M. Atkinson

receiver should earn acceptance by reproducible physical measurements, not by the fashionable name of its technology. The forecast can embrace research ambition while refusing to treat an unqualified laboratory demonstration as a field-ready forensic instrument.

John Bardeen, Cross-Peer Question to William Redington Hewlett: Mr. Hewlett, I would like to address the capital and maintenance consequences of the technology choices we have discussed. A receiver programme may pursue maximum instantaneous bandwidth by installing very fast converters, yet the operating institution must sustain storage, cooling, calibration, software provenance and independent legal review. At the same time, several moderate receivers may provide better spatial or continuous coverage but require a complex reference distribution and more personnel. How should an investment decision compare these alternatives over one-, five-, ten- and twenty-year horizons without embedding an unsupported assumption that every technical improvement will reduce total cost? Please specify which measurements should trigger continued investment, which should trigger an architecture change and which should terminate the experiment. I want the cost model to include the labour of investigating false alarms and maintaining evidence integrity, not merely the purchase price of hardware. The institution should also record which costs would be incurred by qualified independent review.

William Redington Hewlett, Cross-Peer Answer to John Bardeen: Dr. Bardeen, I would use lifecycle cost tied to verified scientific outcomes. The programme should quantify capital expenditure for receivers, antennas, filters, clocks, storage and networks, but also operating expenditure for power, cooling, calibration, software updates, protected evidence retention

Copyright 2026, James M. Atkinson

and expert review. A wider sample stream can raise costs throughout the chain. Conversely, additional narrowband receivers can multiply configuration and maintenance work. The comparison should therefore use the same authorised reference events and decision requirements for both architectures. The denominator is not simply dollars per nominal megahertz; it is cost per validated surveillance capability under defined uncertainty and operational coverage.

At one year, the institution can benchmark its existing equipment, identify the actual bottleneck and repair procedural deficiencies before buying new components. At five years, it can compare prototype architectures under a controlled test programme, measuring observed blind time, weak-signal recovery, false alarms and sustained data throughput. At ten years, a technology scenario should include replacement cycles, software provenance obligations and the risk that a promising component does not reach reliable production. At twenty years, the uncertainty is too large for a single procurement forecast. Scenario envelopes and revisable decision points are more useful than a confident budget line pretending to know future products and prices.

Milestones must be falsifiable. If a proposed wideband architecture cannot operate continuously without losing sample blocks at its advertised rate, the project should be redesigned or stopped for that purpose. If an integrated analogue front end produces unacceptable intermodulation under the site's blocker environment, its nominal converter speed cannot justify deployment. If autonomous screening reduces stored data but prevents independent challenge of significant events, the retention architecture needs revision. Positive results should be measured by independent

Copyright 2026, James M. Atkinson

calibration and tested observation intervals, not by a vendor demonstration selected for favourable conditions.

The cost of mistaken interpretation deserves explicit treatment. False alarms consume expert time, can trigger intrusive follow-up and may damage confidence in the investigation. A missed authorised reference event may reveal an unacceptable blind region. Calibration and provenance costs protect against both. A prudent organisation should sometimes choose a less spectacular system whose measurement limitations are known and whose operating history can be defended. Such an investment is not technically conservative in a pejorative sense; it is rational when the intended output is credible evidence.

William Redington Hewlett, Cross-Peer Question to Norman Foster Ramsey Jr.: Dr. Ramsey, the final technology roadmap must make a practical choice about reference distribution. An institution may wish to operate hundreds of geographically separated sensors, yet disciplined clocks can lose their external reference and network timing can suffer asymmetric delays. A future design could place an expensive common reference at every site, distribute timing over optical links or accept lower accuracy while emphasising continuous spectral coverage. How should the chosen application determine which approach is justified? I would like a predeclared experiment that compares measured arrival-time accuracy during normal operation, deliberate reference loss and restoration, and varying environmental conditions. What is the correct report when the local oscillator remains stable enough for spectral occupancy but no longer supports the time-difference-of-arrival precision claimed for localisation? A single word such as synchronised seems quite inadequate for procurement

Copyright 2026, James M. Atkinson

or forensic conclusions. Please distinguish local oscillator stability from interstation timing accuracy during reference loss.

Norman Foster Ramsey Jr., Cross-Peer Answer to William Redington Hewlett: Mr. Hewlett, reference design must follow the measurement requirement. A receiver used to determine coarse spectral occupancy may need adequate frequency calibration without requiring the submicrosecond interstation alignment demanded by some arrival-time methods. A coherent spatial array can impose tighter relative phase and path-delay conditions still. Therefore the procurement document should specify the physical quantity, its reference plane, accepted uncertainty and intended duration of operation. A common clock may reduce one source of relative error while creating correlated failures across sensors; independent clocks can offer resilience but require more complex synchronisation. No architecture is best without defining the desired inference.

The acceptance trial should use known reference signals observed through characterised paths. Compare actual arrival-time estimates under disciplined conditions, then remove a timing reference for increasing holdover intervals and measure how offset uncertainty evolves. Include thermal variation, network congestion where relevant and the restoration of discipline after the outage. The system's internal clock-status logs should be compared against independent observations. A smooth software time display is not sufficient evidence of correct acquisition time. If a reference change introduces a phase or frequency transient during a burst, the affected interval must be marked and analysed separately.

The forecaster should distinguish stability from accuracy. A local oscillator may continue at a remarkably stable rate while possessing an unknown

Copyright 2026, James M. Atkinson

offset from a common time scale. That might preserve useful within-receiver time differences and frequency estimates, subject to calibration, while limiting absolute timestamps or interstation localisation. The report should state that the receiver remained fit for specified occupancy measurements but lacked adequate evidence for a claimed arrival-time difference. It should not convert a successful local frequency check into certification of the entire spatial reconstruction. Analogue cable and filter delays require their own calibration even when the clocks agree.

At one year, measure existing performance and identify dominant uncertainty. At five years, test available reference improvements against the full chain. At ten and twenty years, forecast alternative architectures under scenarios of component advance, operational failure and cost. A plan that can preserve honest uncertainty when the clock loses its reference is better than one which assumes perfect discipline because the projected oscillator is impressive. The instrument's reliability includes the clarity of its limitations.

Dr. James M. Atkinson, Moderator: The joint conclusion is conditional. Engineering forecasts must state a physical reference plane, demonstrable measurement target, assumptions, uncertainty, dependencies and falsifying milestones. Numerical representations and sample throughput are not substitutes for validated observation. This closes Question 106 and passes the token to the final discussion on the combined evidential standard.

QUESTION 106. RESEARCH NOTES. IEEE 1241-2023, Standard for Terminology and Test Methods for Analog-to-Digital Converters, establishes a framework for ADC performance testing, https://standards.ieee.org/ieee/1241/6797/. Its applicability to specific future

Copyright 2026, James M. Atkinson

architectures must be examined. All scenarios are hypothetical and are not claims that particular future converter products exist.

EDITORIAL QUALIFICATION. Horizon years are illustrative review dates; no product or technological breakthrough is guaranteed. Calculations of sample throughput and jitter-limited SNR are conditional examples and do not establish measured RF performance.

Copyright 2026, James M. Atkinson

QUESTION 107

Copyright 2026, James M. Atkinson

What combined evidential standard should close a complex TSCM receiver investigation?

SCHOLARLY RECONSTRUCTION. This is fictional educational dialogue between deceased historical specialists. It is not genuine testimony, an account of an actual meeting, or evidence that any named participant endorsed contemporary techniques.

Dr. James M. Atkinson, Moderator: Sir Karl, I invite you to propose the final inference hierarchy that should govern lawful TSCM receiver investigations. Please distinguish observation, calibrated measurement, external-source identification, device attribution and legal conclusions, and identify the limits which prevent a stronger finding.

Sir Karl Raimund Popper, Principal Contributor: Dr. Atkinson, the final report should be organised around propositions that can be challenged, not around the grandeur of the instrumentation deployed. A survey may employ twenty receivers, multiple antennas and extensive digital analysis, yet the underlying proposition might remain modest: during a specified observation interval, one receiver recorded a feature consistent with a transient RF emission. The stronger proposition that an identified external device produced the feature requires additional discriminating evidence. The still stronger proposition concerning a person's conduct or intention lies beyond the output of the receiving apparatus. A correct investigation must not elevate a signal detection into an attribution merely because the evidence file is voluminous.

I propose an explicit hierarchy of findings. The first level describes instrument operation and acquired data: which physical quantities the

Copyright 2026, James M. Atkinson

apparatus measured, at which reference plane, under which configuration and validity conditions. The second level describes the waveform characteristics justified by those data, such as frequency range, bandwidth, timing and uncertainty. The third addresses external physical causation, distinguishing an incident emission from intermodulation, oscillator leakage, coupling or processing artefacts. The fourth concerns source class or location, which requires controlled spatial or comparative evidence. Individual-device attribution and legal conclusions require still stronger foundations. Each ascent should be marked as a new inference, not concealed in an adjective such as confirmed.

The decisive experiments are those that can embarrass the preferred account. If a spectral line is thought to originate from an external transmitter, the investigators should examine whether it persists with a characterised input load, changes under attenuation in the manner expected from an instrument-generated product, or appears independently on another receiver. A controlled reference signal may test the frequency and amplitude calibration. Changing antenna position, polarisation or location may provide spatial information, but those changes must be interpreted in the relevant propagation environment. A negative result from one control does not prove a competing explanation false if the control itself has a blind spot. The report should retain every material contrary result.

A negative survey conclusion demands equal restraint. If no qualifying emissions were detected, the investigator should state the observation period, bands, receiver sensitivity under tested conditions, scan dwell, blind intervals and the classes of emission the method was capable of detecting. The statement must not become an assertion that no hidden apparatus

Copyright 2026, James M. Atkinson

existed at any time. A device might have remained silent, transmitted outside the observed bands or produced an event inside unobserved time. The appropriate assurance is conditional upon a defined search protocol and demonstrated detection opportunities. The limitations are not footnotes to be concealed from a client; they delimit the scientific meaning of the finding.

I would require the report to identify alternative hypotheses by their testable predictions. An intermodulation product might change nonlinearly with input attenuation. A local oscillator leakage feature may remain associated with the receiver under antenna substitution. An external source might exhibit spatial variation, though reflections and near-field conditions can complicate that inference. A data-processing artefact may disappear under a different validated algorithm. These patterns are not infallible signatures, but they guide experimental challenges. If the evidence is compatible with more than one hypothesis after appropriate tests, the conclusion should remain unresolved rather than select the most dramatic explanation.

The forensic record must separate acquisition, analysis and interpretation. Original samples and metadata should be preserved under lawful authority and proportional retention, with the extent of any content capture justified. Derivatives should record processing methods, parameters, software versions and their relation to originals. A verified digest can support continuity of a defined byte sequence from a documented reference event; it cannot prove physical authenticity or legal authority. A scientifically valid measurement can also be obtained under unlawful conditions, and its

Copyright 2026, James M. Atkinson

admissibility is a distinct question for the competent jurisdiction. An expert must not let a technical signature settle matters entrusted to law.

I would involve independent examiners before the narrative is frozen. Give them a blinded case file containing the relevant data, calibration history and alternative hypotheses, while withholding the preferred investigator's conclusion where feasible. Ask each to articulate the strongest supported finding and what further observation would change it. Compare their reasoning, not simply their final labels. If disagreement arises because an instrument state was never recorded, that is an enduring limitation; no amount of confident prose repairs it. If disagreement arises because a mathematical method was inadequately explained, the study may need clearer assumptions and an independent computational replication.

A proper closing conference should state what would falsify the conclusion and whether that test was conducted. When it was not, say why. The report can contain strong affirmative results where multiple independent and discriminating observations converge, and it can contain scientifically useful qualified negatives. It should never imply that completeness of paperwork establishes completeness of the electromagnetic search. The quality of a TSCM investigation is revealed by its treatment of uncertainty and adverse evidence, not merely by the expense of the instruments or the elegance of the final illustrations.

My recommendation is therefore a modest but exacting doctrine: conclude at the highest level of inference actually supported, preserve the path by which that level was reached, and disclose the competing explanations that remain viable. A finding that survives a meaningful attempt at refutation deserves greater confidence than one which has never been challenged.

Copyright 2026, James M. Atkinson

When a fact is unknown, preserve the unknown rather than use engineering jargon to turn it into certainty.

David Slepian, Peer Question: Sir Karl, I wish to challenge the final evidential ladder with the case of a receiver which never possessed the information necessary for a particular conclusion. A narrowband system might accurately preserve a carrier's frequency yet lack the bandwidth or sample history needed to evaluate a brief transient. A compressive recorder might retain a mathematical projection adequate for detecting known sparse tones but inadequate for an unmodelled burst. How should the expert distinguish a testable hypothesis from one that the available data cannot discriminate, and how should that difference appear in the final findings? It is tempting to propose an elaborate reanalysis of retained data, but no algorithm can conjure an unobserved event into evidence without substantive assumptions. Please explain when further analysis can legitimately reduce uncertainty and when the proper response is to qualify the finding or conduct another authorised measurement. The final report must not confuse mathematical elegance with physical identifiability. Please specify which data are native measurements and which are model-dependent derivatives, and whether a subsequent replication could ever recreate missing historical RF information.

Sir Karl Raimund Popper, Response: Dr. Slepian, the correct answer begins with the scope of the observation. If a receiver preserved only a narrow band, a later algorithm cannot establish the detailed content of a transient outside that band. It may test hypotheses about the retained band, or produce model-dependent inferences about a broader signal under specified assumptions. The expert must not describe those inferences as

Copyright 2026, James M. Atkinson

though a complete waveform was measured. In a compressive acquisition, the recorded projections and the signal model should remain separate. More than one physical event may be compatible with the same compressed data when the acquisition operator lacks sufficient discriminating power. A small reconstruction residual does not abolish that non-uniqueness.

The final report should attach each claim to the information actually retained. Frequency occupancy can sometimes be established from validated spectral estimates without preserving communication content. Phase and precise transient timing may require original samples and clock information that the archive lacks. Source localisation may require independent receivers, spatial calibration or time references not available in one instrument's file. The reader should see a clear boundary between direct observation, mathematical derivative and physical interpretation. Where the required information was not collected, the investigator may state a limited result rather than press the algorithm into producing a more dramatic answer.

A controlled new measurement may reduce uncertainty when the underlying phenomenon can be recreated or when an authorised reference source can challenge the instrument's response. Such a test can evaluate whether an alternative explanation is plausible, but it does not recreate the historical unknown event. If a firmware flaw is discovered later, reproducing it under laboratory conditions may show that an earlier feature could have been an artefact; whether it actually was requires additional evidence. The report must preserve the temporal distinction. A later experiment is an examination of a hypothesis, not a time machine.

Copyright 2026, James M. Atkinson

I would therefore structure the final finding in terms of possible falsification. Specify what observations would be expected under each hypothesis and which were actually obtained. If the existing data cannot distinguish them, state that limitation. A scientifically responsible conclusion is not weakened by identifying a question that the apparatus could not answer; it is strengthened by refusing to assert what was never observed.

Hendrik Wade Bode, Peer Question: Sir Karl, a receiver-generated intermodulation product may closely resemble a real transmitted signal, and a stable spectral peak can arise from an oscillator or an electrical contact as easily as from a concealed apparatus. If a final report uses the words external emission, what minimum challenge tests should have been considered before those words appear? I do not suggest that every possible artefact can be ruled out, but the report should document why alternative receiver mechanisms have been treated as less plausible. Please explain the value and limitations of changing input attenuation, antenna substitution, preselection and independent receiver architecture. A control whose own effect on gain or bandwidth is poorly characterised can mislead the examiner. What should the finding say if the line survives several tests but a material intermodulation hypothesis remains unresolved? The difference between technical confidence and unjustified certainty is central to professional TSCM practice. I also ask how an independent laboratory would identify shared front-end nonlinearities when a second receiver supplies apparently corroborating but technically dependent evidence.

Sir Karl Raimund Popper, Response: Dr. Bode, the phrase external emission should be used only with an account of why a solely internal receiver origin has been challenged. Changing input attenuation can help reveal some

Copyright 2026, James M. Atkinson

nonlinear products because their levels may respond differently from the fundamentals that generate them. But the expected response depends upon where the attenuation lies relative to the nonlinear stage, and a poorly characterised change is not conclusive. Antenna substitution may help distinguish environmental energy from receiver leakage, yet the replacement antenna has its own pattern, sensitivity and coupling characteristics. Preselection can suppress interfering inputs and remove intermodulation; it also changes what the receiver can observe. Each control must therefore be interpreted under a known measurement model.

An independent receiver with different analogue architecture can provide stronger corroboration, provided its measurement errors and reference sources are not fully shared. Two instruments fed by one defective splitter or common clock may agree because of a common failure. Spatial relocation and polarisation changes may also help, but reflections and near-field coupling can make their interpretations ambiguous. The investigator should record the full controlled sequence and not select only those steps supporting the preferred theory. A genuine external signal can disappear under an antenna or filter change if the new configuration is insensitive to it; that outcome must not be treated automatically as proof of internal generation.

For the final report, I would distinguish an observed spectral feature from the inference of external origin. One may state that a feature was detected at a defined receiver reference plane and appeared under several independent configurations, with controlled tests failing to reproduce it as a specified internal product. That is meaningful evidence, though it may not identify a transmitter. If a material intermodulation hypothesis remains

Copyright 2026, James M. Atkinson

viable, the report should retain it and explain what additional experiment would discriminate it. Words such as confirmed external transmitter or uniquely identified device should be reserved for stronger evidence.

The scientific standard is not that every imaginable alternative must be disproved, which is impossible. It is that the important alternatives suggested by the physics and apparatus are explicitly considered and challenged proportionately to the claim. When a conclusion remains conditional, the condition should be visible in the main finding rather than concealed in a footnote. That is how an engineer avoids turning a polished instrument trace into an accusation that the trace itself cannot support.

Dr. James M. Atkinson, Moderator: Thank you for the preceding analysis. I respectfully pass the token to Sir David Cox to examine a distinct component of the final evidential and publication standard.

Sir David Cox, Second Principal Contributor: Dr. Atkinson, the end of an investigation is a decision under uncertainty, but the relevant probabilities must be attached to clearly stated questions. A false-alarm rate for a spectral detector is not the probability that a named device was responsible for a particular event. A confidence interval for received frequency does not describe the probability that an individual acted unlawfully. The data-generating process, selection mechanism and alternative explanations determine which statistical proposition can be estimated. When the final report combines several layers, the uncertainties must not disappear merely because the paragraph uses one polished conclusion. I would require a question-by-question evidential accounting.

Copyright 2026, James M. Atkinson

The measurement data should be partitioned into valid observations, invalid acquisition intervals and genuinely unobserved periods. A recorder may have been collecting samples continuously but dropped buffers under load. A scanner may have revisited a frequency only intermittently, leaving long blind intervals. An event-triggered archive may preserve only observations selected by a prior threshold, thereby excluding misses from subsequent performance estimates. These conditions have different statistical meanings. A quiet displayed waterfall can be a true low-energy observation or the absence of a valid observation. No estimate of detection probability can be trusted if the relevant denominator has been misdescribed.

A probabilistic model for missed events should begin with an explicit population of opportunities. If an authorised laboratory emits known test pulses at predeclared times, the observed detection fraction estimates performance for that tested family and environment, subject to uncertainty. It does not automatically describe devices that transmit at unknown times using different modulation or power. Correlation among nearby windows further reduces the effective amount of information available for confidence statements. The investigator should report counts by independent session, receiver state and source class. A million overlapping windows from one experiment cannot stand in for a million independent tests of the system's generality.

Where the report invokes multiple hypotheses, it should distinguish goodness of fit from evidential discrimination. A model of external transmission may explain a spectral feature well; a model of receiver intermodulation may also explain it. A small residual does not show which explanation is correct if both predict the observed quantities. The

Copyright 2026, James M. Atkinson

investigator should design or identify measurements on which the predictions differ, such as a controlled attenuation change, independent receiver observation, spatial relocation or calibration stimulus. If such tests were not possible, the report should say that the alternatives remain unresolved. Mathematical sophistication does not create identification when the data do not distinguish the hypotheses.

I would require the technical summary to include the uncertainty budget for each reported measurand. Frequency calibration, spectral resolution, clock integrity, gain, antenna factor, cable loss and environmental effects may all be relevant, depending upon the claim. Correlated uncertainties from shared references should not be counted as independent support. A measurement from two receivers driven by the same defective clock is not fully independent timing corroboration. Confidence language should reflect both statistical variability and possible systematic effects. No honest interval can compensate for an unrecognised bias, so the report should document challenge tests for significant potential systematic errors.

Sequential analysis must be identified. A team may adjust thresholds after examining early alarms, change antenna configurations in response to suspected sources and extend the survey when a pattern appears. Such adaptive investigation can be sensible, but the final statistical claims must acknowledge the selection process. A rate computed from trials chosen after the event may not have the error properties of a predeclared experiment. The report should identify exploratory discoveries, confirmatory tests and subsequent follow-up separately. Stronger inferences may be possible after an independent confirmation, but the discovery data should not be quietly relabelled as independent validation.

Copyright 2026, James M. Atkinson

The legal decision may be different from the scientific estimate. Standards for expert admissibility, proof and disclosure vary by jurisdiction and type of proceeding. The expert may explain methods, limitations, calibration and what the observations support; the court or other competent decision-maker determines the legal consequences. The report should not use a statistical confidence percentage as though it established a legal burden of proof. A technically accurate negative survey may provide limited assurance for a client without proving that an alleged offence did not occur. Appropriate language keeps the domains separate.

I would propose a structured final table. Each claim has a source observation, method of analysis, calibration basis, independent corroboration, error or uncertainty estimate, tested alternatives and unresolved qualifications. The table also identifies whether the claim is direct measurement, statistical estimate, source classification or legal inference. Reviewers should be able to contest one row without dismantling the rest of the investigation. A correction to a time offset need not erase a valid qualitative detection, but it may invalidate a localisation claim depending on that offset. Such modularity makes reports more resilient to honest scientific revision.

The final conclusion should be neither evasive nor overconfident. It may state that a specified RF event was observed with validated frequency and timing measures, while its source remains unidentified. It may state that no qualifying events were detected within a bounded surveyed domain and known detection limits. It may state that a claimed emitter hypothesis was contradicted by a controlled receiver challenge. Each outcome can be

Copyright 2026, James M. Atkinson

valuable. What cannot be justified is collapsing these different propositions into a single assertion of certainty unsupported by the study design.

Norbert Wiener, Peer Question: Sir David, the final survey may be based on an autonomous collection system whose gain, channel schedule and anomaly thresholds changed in response to earlier observations. The investigator may then aggregate its alarms into one impressive statistic, although different intervals were governed by different decision rules. How should the final statistical report account for this adaptive process? In particular, what is the appropriate observational denominator when the receiver was retuning, overloaded, in clock holdover or storing only selected alarm intervals? Please explain why a model's false-alarm estimate measured under one laboratory regime cannot simply be attached to every alert generated later at an unfamiliar site. The report should distinguish the machine's historical decision from an updated model's subsequent classification. It must also consider whether an apparent lack of alarms proves anything about the periods when the machine was not qualified to observe the intended band. Please explain whether adaptive thresholds and feedback can change the relevant observation opportunities, and what contemporaneous control record makes those adaptations independently auditable.

Sir David Cox, Response: Dr. Wiener, an adaptive system is a sequence of potentially different decision procedures applied to a sequence of changing observations. Its final analysis should identify each operating regime and the rule in force, including the model version, threshold, gain state and valid observation interval. A pooled alarm count alone is not enough to assess performance. We need to know which opportunities were observed, under

Copyright 2026, James M. Atkinson

what sensitivity, and which apparent negatives were simply missing or invalid. A retune gap is not a quiet spectral measurement. An overloaded converter may produce data that are unsuitable for the inference even if the recorder continued. A clock in holdover may support frequency occupancy while failing a tighter interstation timing requirement.

The false-alarm denominator should correspond to a specified operational unit, such as a validated event cluster or a complete survey interval in a stable configuration. Overlapping FFT windows can be highly correlated, and their number should not be treated as independent experiments. If the system updates thresholds prospectively under a specified policy, one may evaluate that policy on independent held-out sessions; one cannot apply the original frozen-model false-alarm rate to every later decision without checking whether the relevant score distribution and threshold relationship remained stable. Historical alarms should retain the model and state under which they were generated.

When a later software version reclassifies preserved samples, it creates a derivative analysis with its own assumptions. It does not change whether the original system raised an alarm at the time. The report may explain that a newer, validated method provides a different scientific interpretation, but it should preserve the earlier event and its provenance. This is particularly important where the survey's actions were influenced by the historical decision. A final confidence statement that suppresses the acquisition or selection history will be misleading even if the last model itself is mathematically sound.

For a negative finding, I would quantify actual valid observation time and the tested detection probability for relevant reference events. Blind time,

Copyright 2026, James M. Atkinson

invalid data and untested waveforms must remain explicit. When the system's adaptive procedure has not been independently evaluated at the site, the report should say that the error rates are uncertain under that shift. A useful technical conclusion may remain possible, but its strength must be linked to the experiment actually conducted rather than to a number borrowed from a more comfortable environment.

Rudolf Emil Kálmán, Peer Question: Sir David, two receiving stations may present a narrow source-localisation region generated by an estimator whose covariance matrix assumes independent timing errors. In reality, both receivers share a timing reference, their cable lengths were not recently measured, and their propagation environments produce related multipath. How should the final report communicate the uncertainty of localisation when the apparent mathematical precision rests on possibly correlated and biased inputs? I should like an explanation of the difference between estimator covariance under a chosen model and actual accuracy under the full physical experiment. Please also consider a blind validation in which controlled emitters occupy known positions distinct from those used to tune the estimator. What should the investigators conclude if the calculated confidence region frequently excludes the independent known positions? This question bears directly upon whether a geometric diagram should appear as an evidential location claim or merely as a model-dependent investigative lead. In particular, should estimable clock offsets be separated from model error and unknown acquisition gaps, and how would that separation survive a later change of processing software?

Sir David Cox, Response: Dr. Kálmán, a covariance matrix is informative only relative to its stated model and the observations used to estimate it. If

Copyright 2026, James M. Atkinson

timing errors share a clock component, their correlation must be accounted for. If cable delays, analogue group delays or multipath biases are omitted, the resulting region may be much smaller than the true uncertainty. A visually narrow ellipse is not proof that the physical source lies inside it. The first task is to identify what each time measurement means, its reference plane and its calibration. The second is to propagate the uncertainties and relevant correlations through the localisation model, with alternative systematic effects examined where practicable.

Independent validation should use authorised emitters at known positions and a blind analysis procedure. Reserve some positions, signal forms and receiving configurations from model tuning. Ask analysts to estimate locations without access to the withheld ground truth, then compare nominal uncertainty regions with actual containment and systematic errors. If a purported confidence region repeatedly excludes the true reference positions, the model is miscalibrated for those conditions or the interpretation of its uncertainty is defective. The appropriate response is correction of the measurement and modelling process, followed by a fresh independent trial, not an artistic enlargement of the displayed region until it seems plausible.

The report should distinguish statistical variability from potential systematic bias. Repeating observations at one source location can yield a small spread while every estimate is displaced by the same uncalibrated delay. A method can be precise but inaccurate. Conversely, a broad region may correctly reflect limited information caused by antenna geometry or multipath. The investigator should preserve the input timing observations, clock states, calibration histories and processing recipe. A later reviewer should be able

Copyright 2026, James M. Atkinson

to reproduce the model-dependent region and challenge the assumptions that produce its shape.

Where the validation fails or the necessary calibration is missing, localisation should be treated as an investigative hypothesis rather than an established physical location. Other evidence may support a bounded source region, but no diagram should disguise the limitations of its measurements. The final technical finding should say whether the result was directly verified on comparable controlled cases, inferred under a model with acknowledged uncertainties, or left unresolved. That wording enables scientifically responsible decisions without pretending that numerical resolution is equivalent to evidential confidence.

Dr. James M. Atkinson, Moderator: Thank you for the preceding analysis. I respectfully pass the token to Sir Ronald Aylmer Fisher to examine a distinct component of the final evidential and publication standard.

Sir Ronald Aylmer Fisher, Third Principal Contributor: Dr. Atkinson, a final evidential standard must confront experimental design before it praises statistical calculation. If the investigators chose the measurement locations, observation times and thresholds only after seeing suspicious patterns, their eventual performance figures may reflect those choices. An impressive p-value or low estimated false-alarm rate can be meaningless when the trial was not conducted under the decision rule for which the mathematical error rate was derived. I would require the team to distinguish exploratory work from a fresh, independently designed confirmatory test wherever the conclusion demands such support. The integrity of the test design belongs at the centre of the final review.

Copyright 2026, James M. Atkinson

Randomisation and counterbalancing can reduce confounding in controlled laboratory experiments. When comparing receiver chains, rotate the order of apparatus, source levels and environmental conditions so that warm-up drift does not masquerade as a device difference. Repeat across independent acquisition sessions and specimens, rather than accumulating thousands of overlapping windows from one recording. Use independent reference sources and blinded examiners where feasible. The result should reveal whether the reported detection survives ordinary changes in hardware, location and background interference. A test constructed only from favourable examples should be labelled as a demonstration, not as general proof.

The correct sampling unit must be defined. A receiver can process millions of FFT cells per hour, but many share samples and environmental conditions. Treating them as independent will make confidence intervals artificially narrow. One might instead measure the fraction of controlled authorised events detected, the number of false alarm clusters per valid monitoring hour, or the proportion of complete sessions meeting a specified performance criterion. These answer distinct questions. The chosen denominator and clustering rule should be established before viewing the final evaluation data. An event that occurs during known blind time cannot be counted as a true negative merely because the recorder contains no corresponding file.

Absence of an observed false alarm is not proof that the population false-alarm probability is zero. Similarly, successful detection of every burst in a short laboratory trial is not a guarantee against missed field events. Confidence intervals and uncertainty bounds must be reported with

Copyright 2026, James M. Atkinson

assumptions and effective sample size explicit. The team should resist taking a favourable point estimate from a small set of related observations and extrapolating it to every waveform family or site. Operational conditions can change the background distribution and detector sensitivity. A final report should give the conditions demonstrated, the conditions untested and the reasons for treating any extension as plausible.

Alternative physical causes require experiments that can discriminate them. A spectral peak could arise from an external emission, local oscillator mixing, power-supply interference or a software processing artefact. A receiver substitution, input-load test or calibrated attenuation change may produce distinct predictions under some hypotheses. Yet each experiment has assumptions: reflections, nonlinear stages or internal coupling can confound a simple interpretation. The investigator should specify why a control is informative in the case under examination and what a contrary result would imply. An experiment does not become valid merely because it has an elaborate name.

I would include explicit stopping and revision rules. A team may decide that enough evidence exists to report a bounded negative, that a source attribution requires further measurements, or that a faulty instrument makes some results unusable. Those decisions should be documented before a final narrative is constructed. If a new instrument defect is discovered after the draft report, the affected claims should be reassessed rather than defended by inertia. An honest correction is better than preserving a misleading conclusion for the sake of consistency. The record should disclose the changed analysis and the observations upon which it rests.

Copyright 2026, James M. Atkinson

The problem of multiple comparisons cannot be ignored. Searching thousands of frequencies, time intervals and receiver combinations creates many opportunities for apparently exceptional patterns. Thresholds chosen for one isolated comparison need not maintain the same overall false-alarm behaviour across the search. Appropriate error control depends upon the selection and dependence structure, and it may be more illuminating to separate discovery from independent confirmation than to force one number onto the entire search. The survey should declare whether its probability calculations concern bins, event clusters, sessions or a predeclared hypothesis. The presentation of a rare score is not proof of a rare external source.

Expert testimony should then follow the measurements. The scientist may describe the experimental programme, data, uncertainties and extent to which alternatives were challenged. The scientist should not imply that a detector's error rate is a probability of legal guilt or that an inconclusive instrument observation proves covert intent. Those propositions belong to different reasoning and legal standards. The report's credibility depends upon precise language which permits a competent reviewer to identify where observation ends and interpretation begins.

I would close with a practical demand: disclose every material failed test, invalid acquisition and protocol deviation that bears on the claim. A perfectly formatted evidence package can conceal bad experimental design; a small but well-controlled experiment may provide a stronger inference. The final standard should reward the latter by requiring clear units of observation, predeclared rules, independent challenges and proportional conclusions. The soundness of a finding is not measured by the length of the report.

Copyright 2026, James M. Atkinson

Charles Hard Townes, Peer Question: Sir Ronald, I am concerned that a laboratory may use thousands of spectral tests to discover a rare-looking peak, select that peak for further examination, and then report the statistical significance originally calculated for one preselected frequency. The selection procedure itself created many opportunities for an exceptional value. How should the end-of-investigation review distinguish a legitimately exploratory discovery from an independently confirmed RF event? I would like you to address the physical challenge tests that might accompany statistical confirmation, including controlled receiver attenuation, independent frequency measurement and scrutiny of oscillator-related products. A technical report should not merely attach a very small number to a highlighted waterfall pixel. Please explain what the calculation's denominator, counting unit and null model must be, and what should be said when the underlying noise is impulsive or otherwise poorly represented by the chosen distribution. Would you distinguish energy recorded at a defined receiver reference plane from proof of a particular external physical source when propagation and local oscillator behaviour are incompletely tested?

Sir Ronald Aylmer Fisher, Response: Dr. Townes, the problem is selection. A threshold or significance calculation designed for one predeclared comparison need not retain its stated error rate when applied after searching many frequencies and time windows. The more opportunities the investigator examines, the more likely an apparently exceptional observation may arise by chance or by an unmodelled instrumental effect. Correlation among overlapping windows and spectral bins complicates the calculation further. The final report should declare the search space,

Copyright 2026, James M. Atkinson

selection policy, reference distribution and event-clustering rule. It should not report a post hoc selected result as though the frequency and time were fixed before observing the data.

Exploratory discovery is valuable when followed by an appropriate independent test. One might freeze the candidate frequency and analysis rule, then obtain a fresh authorised recording under controlled receiver conditions. A second receiver or changed analogue configuration can test the external origin of the feature. Known-reference stimuli can challenge frequency and amplitude calibration. Tests for local oscillator leakage, intermodulation and processing artefacts should be selected according to the apparatus and observed phenomenon. An impressive score from the original search remains part of the discovery history, not independent proof of the selected external cause.

The chosen null model is central. A Gaussian thermal-noise assumption may be useful under appropriate conditions but misleading when the background contains switching interference, lightning-like impulses or strong-signal mixing products. The laboratory should inspect relevant residuals and compare models under held-out conditions. If the false-alarm rate is uncertain because the background distribution was not characterised, the report should state that uncertainty rather than quote several false decimal places. Independent confirmation may be based on a physical intervention as well as statistical replication; the two address different but complementary weaknesses.

I would recommend a final classification of claims: exploratory anomaly, independently confirmed instrument observation, externally incident emission supported by discriminating controls, or source attribution

Copyright 2026, James M. Atkinson

requiring still greater evidence. The statistical finding must not be promoted beyond the physical tests. A rare-looking measurement is not by itself a rare device or a sign of illicit purpose. Appropriate error control and independent challenge turn an observation into a more defensible conclusion, while preserving the negative and ambiguous cases that an honest experiment inevitably encounters.

Dr. James M. Atkinson, Moderator: Thank you for the preceding analysis. I respectfully pass the token to Sir Harold Jeffreys to examine a distinct component of the final evidential and publication standard.

Sir Harold Jeffreys, Fourth Principal Contributor: Dr. Atkinson, the responsible analysis must recognise that alternative explanations can remain plausible even after the data are measured with great precision. A narrow confidence interval around a frequency estimate may leave uncertain whether the observed line arose from a transmitter or an internal spur. One can be certain about a conditional calculation while uncertain about the model's applicability. Bayesian reasoning can make assumptions explicit, but the resulting conclusions depend upon the chosen hypotheses, likelihoods and prior information. No numerical posterior should be displayed as though those choices were facts established by the receiving instrument itself.

The first task is to define the evidence and the competing accounts. An event may be explained by a lawful nearby communication, a receiver-generated intermodulation product, leakage from laboratory equipment, an unknown external emitter or a processing defect. Some accounts can be rejected by controlled tests; others may remain indistinguishable within the present data. If a model of one account omits material mechanisms, a

Copyright 2026, James M. Atkinson

comparison may unfairly favour the more elaborate model. A responsible analyst should test the sensitivity of conclusions to reasonable changes in assumptions and say when the evidence cannot discriminate among causes. Model uncertainty is not the same as uncertainty about the measured frequency or power.

Prior information may be relevant, but it should never be smuggled into the instrument output. A site history might suggest that particular equipment is commonly present; a client might suspect an exotic hidden transmitter. Neither is direct RF evidence of that device. The scientist should separate background knowledge from new observations, and examine how alternative prior choices affect a conditional inference if a formal probabilistic comparison is used. A posterior ratio can be mathematically correct under stated assumptions while being unhelpful if the proposed source classes are incomplete or the measurement model is not validated for the relevant receiver state.

Negative surveys illustrate the difficulty. The absence of an alarm is more informative when the detector has a known, high probability of detecting the stipulated source class during actual observed intervals. It is much less informative when the suspected source may be silent, the scan is intermittent, or the signal class is outside validation. The investigator should account for the observation schedule and detection probability before making an assurance claim. One cannot legitimately transform no file retained into no emission occurred if the recorder stored only alarm-triggered data. A large amount of quiet screen time may contain little information about rare events if much of that time was unobserved.

Copyright 2026, James M. Atkinson

I would present alternative explanations in an evidence matrix, documenting the measurement each predicts and the test outcome. If a suspicious line persists with a dummy input load, an internal origin gains plausibility, subject to the load and coupling design. If an independent calibrated receiver observes the same emission under a sufficiently distinct analogue path, an external cause becomes more credible. Yet correlated clocks, shared antennas and common software can compromise independence. The expert should describe these dependencies rather than count instruments as independent votes. Convergent evidence is persuasive when its errors and failure modes are sufficiently distinct.

The likelihood model, if employed, requires a defensible account of the data-generating process. Noise may not be stationary or Gaussian; spectra may be correlated across windows; and threshold-triggered selection may censor the archive. A likelihood fitted to ideal thermal noise does not necessarily describe impulsive interference or strong-blocker regimes. A sensitivity analysis should vary plausible noise models and detection policies. When the conclusion changes materially under those variations, report the instability. One may still make a qualitative finding, but a spurious precise probability would be less useful than a clearly bounded verbal assessment.

Timing and spatial reconstruction add further dependencies. A receiver may have an excellent internal clock yet an uncertain analogue group delay; a bearing may be biased by multipath or incorrect array geometry. Combining these measurements into a source location without propagating their correlations can give a misleadingly narrow region. The final report should identify each calibrated reference, its uncertainty and any shared systematic effects. A location ellipse is a mathematical derivative of assumptions and

Copyright 2026, James M. Atkinson

measurements, not a direct visualisation of an emitter's true position. A lawfully and independently corroborated observation may be needed before a source attribution is warranted.

I would preserve the reasoning history. An initial hypothesis may have been stimulated by a detector alarm, followed by tests that changed the investigator's view. Later software can reprocess protected samples, but it cannot retroactively alter what the original receiver observed or what the initial model output meant at the time. Store each interpretive step with its evidential basis and uncertainties. A future reviewer should be able to challenge the current explanation without guessing which alternatives were dismissed, when and why. The custody of the reasoning is nearly as important as the custody of the files.

My final proposition is that disciplined uncertainty can coexist with useful conclusions. A report may state that an externally incident emission was strongly supported by independent challenge tests while the individual transmitter remained unidentified. It may state that a negative search provides limited assurance within defined bands and times. It may state that data are insufficient for attribution. The conscientious investigator does not fill the remaining gap with a probability whose assumptions are untested. Such restraint is a strength of science, not a defect in its language.

John von Neumann, Peer Question: Sir Harold, the final case file may include a complex probabilistic reconstruction which assigns a high posterior weight to one particular source hypothesis. Yet the algorithm's candidate list may exclude relevant internal artefacts or unidentified benign emitters, and its likelihood model may rely on a noise distribution which the receiver never validated. Under such conditions, the posterior can be precise relative to the

Copyright 2026, James M. Atkinson

wrong question. How should a reviewer challenge the completeness of the hypothesis set and the sensitivity of a final attribution to modelling assumptions? I would also like to know whether two agreeing algorithms provide independent corroboration if both consume the same samples, calibration tables and prior information. Please describe a controlled test that could expose a shared modelling failure. The report must distinguish a model comparison from direct physical evidence of an individual emitter, especially where a legal allegation might follow. Please explain what the acceptance test should do when a recorded checksum is intact but the firmware state, sample continuity or acquisition clock reference cannot be established.

Sir Harold Jeffreys, Response: Professor von Neumann, a high conditional probability can be mathematically correct while resting on an incomplete or inappropriate model family. If the candidate list excludes the true source mechanism, the algorithm will distribute weight among the remaining options and may appear confident in the least wrong one. An RF case can contain receiver intermodulation, oscillator leakage, environmental interference or other explanations not represented in the preferred model. The reviewer should therefore ask which alternatives the model considered, which material mechanisms it excluded and what independent evidence justifies those exclusions. A posterior is conditional upon its hypotheses, likelihoods, prior assignments and the observed data; it is not a direct property of the electromagnetic source.

I would test sensitivity by varying scientifically plausible likelihood structures, noise assumptions and prior information. A conclusion that changes substantially under reasonable alternatives should be reported as

Copyright 2026, James M. Atkinson

model-dependent. More importantly, the laboratory should design controlled physical interventions which produce different predictions under the candidate explanations. An input-load test, attenuation change or independently calibrated receiver may discriminate an external source from an internal product in suitable circumstances. The intervention's assumptions must also be documented. A polished computation cannot substitute for a missing discriminating observation.

Agreement among algorithms is not necessarily independent support. Two programmes may share the same uncalibrated time axis, input samples or feature representation and therefore repeat the same bias. Even models developed by separate teams can be mutually dependent if they rely on one common reference source or defective calibration table. An independent corroboration claim should identify the distinct instruments, signal paths, reference sources and analysis assumptions that make an error less likely to be shared. If these are not sufficiently independent, the report should describe agreement between analyses, not independent physical confirmation.

The final attribution must respect these limits. It may be defensible to report that an observed event is more consistent with one tested physical explanation than with another, subject to the available controls. It is a stronger and often unsupported claim to identify one particular device or person. Where the hypothesis space is incomplete or the likelihood model poorly validated, the correct report is a bounded inference or an unresolved source. Numerical confidence without an adequate account of alternative physical mechanisms is not scientific certainty.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Thank you for the preceding analysis. I respectfully pass the token to W. Edwards Deming to examine a distinct component of the final evidential and publication standard.

W. Edwards Deming, Fifth Principal Contributor: Dr. Atkinson, quality is not established by inspecting a finished report after an undisciplined acquisition. It arises from the design and control of the entire process: authority to examine, calibration, instrument preparation, acquisition, logging, analysis, independent challenge, preservation and communication. A laboratory which repairs a defective file at the final editorial stage has not necessarily repaired the observation that was never properly made. I would therefore propose a process-capability model for the investigation, with each critical step documented and subject to corrective action. The final report should reflect what the process actually achieved, including its limitations.

Begin with responsibility. Identify who authorised the survey, who configured each instrument, who calibrated the reference, who acquired and transferred evidence, and who interpreted the result. These roles may overlap in a small team, but the record should not conceal the overlap where independence is claimed. When an expert conducts the entire workflow alone, a second reviewer should examine the measurements and the alternative hypotheses before final approval. The system should also preserve changes made by operators to gain, preselection, software thresholds and record retention. The record needs to be clear enough that another competent laboratory could perform a meaningful challenge.

Calibration has a lifecycle. A certificate from a distant date is not proof that an instrument remained correct throughout a particular event. A practical

Copyright 2026, James M. Atkinson

quality system uses scheduled calibration, interim performance checks, environment records and response to detected drift. A reference signal before and after a survey may help identify changes in frequency, gain or timing response, though it cannot establish continuous correctness between checks without assumptions. The laboratory should document those assumptions and any evidence of shock, temperature excursion, firmware update or unexpected behaviour. If the instrument falls outside its verified regime, the affected observations require explicit qualification.

I would establish control charts or other process-monitoring tools for appropriate stable reference quantities, but not treat every observed variation as random noise. A sudden gain shift after a cable replacement may be an assignable cause; a systematic offset after a firmware change demands investigation. A long-term monitoring process may exhibit drift that invalidates an earlier threshold calibration. Process records should permit the team to distinguish such changes from actual external RF events. A busy dashboard with thousands of alarms is not evidence of an effective process if its false-alarm burden prevents timely examination. The cost of poor quality includes wasted attention and potentially unjustified conclusions.

The laboratory should plan its evidence products before acquisition. A frequency-occupancy study may require calibrated spectral summaries, while an investigation of phase, pulses or modulation may need narrowly scoped original I/Q samples. Retention must follow legal authority and proportionality; collecting communication content simply because storage is inexpensive is not a quality objective. The file manifest should include time, location where appropriate, instrument and firmware identity, sample

Copyright 2026, James M. Atkinson

format, clock state, reference-plane calibration and missing-data information. Every working derivative needs a traceable processing history. An immaculate digest cannot cure an initial failure to document the receiver's operative state.

I would insist on internal audit and corrective action. When a receiver-generated artefact is misreported as an external source, the institution should not merely correct the sentence. It should identify why the challenge test failed, whether similar cases were affected, and which controls would prevent recurrence. If sample gaps were rendered as silence, the software and review process need repair, not just the chart caption. A structured nonconformance report can preserve the incident, scope, remediation and verification of effectiveness. This is how a laboratory learns rather than repeats an elegant mistake under a new version number.

A final report should be modular. Each finding has an observation source, analysis method, calibration status, verification outcome, residual uncertainty and reviewer sign-off. That arrangement allows a correction to one timing estimate without rewriting unaffected measurements. It also prevents the roundtable's scholarly dialogue from being mistaken for actual evidence. The historical contributors imagined in this educational discussion do not authenticate a modern field result; only the recorded measurements and actual independent reviewers can do that. The review apparatus should be clear about which evidence exists and which is illustrative.

The final decision can be a bounded affirmative, bounded negative or inconclusive report. None of these labels is inherently a sign of failure. A process that accurately reports its limits is more valuable than one that always produces an impressive attribution. Decision-makers need to

Copyright 2026, James M. Atkinson

understand what the survey covered, what it did not cover and what further investigation would materially reduce uncertainty. Where legal duties or evidence-retention limits prevent additional testing, that constraint belongs in the report. Quality is not the manufacture of certainty; it is the reliable production of justified findings.

My closing recommendation is a final release gate which checks the original evidence, instrument and software provenance, calibration, mathematical reasoning, legal scope, independent review, and the accuracy of the language used for conclusions. Failed controls must block unsupported claims even when the manuscript itself is handsome. A reviewer should be able to trace every important sentence to a measurement, a defined inference or an expressly identified assumption. Only then should the institution close the investigative file.

Dennis Gabor, Peer Question: Mr. Deming, the technical report may contain hundreds of pages of calibrated measurements, receiver screenshots, software logs and custody signatures. Yet an independent reviewer may still be unable to trace a major conclusion to the particular samples or tests that support it. How should a quality system distinguish genuine evidential completeness from administrative volume? Please define the final release gate so that a finding about a short RF pulse is checked for bandwidth, windowing, clock integrity and data continuity, while an attribution finding also faces external-source and alternative-hypothesis controls. I would also challenge an institution which deletes failed laboratory tests from its publication package because they appear untidy. How can the report remain readable without omitting adverse evidence, and how should corrective action be documented if a flaw is discovered after formal issuance? I would

Copyright 2026, James M. Atkinson

also ask what a time-frequency chart can legitimately preserve when its window suppresses a brief impulse or when the instrument archives only selected trigger intervals.

W. Edwards Deming, Response: Dr. Gabor, the number of pages does not demonstrate process capability. A final quality gate must be linked to the type of claim being made. A short-pulse timing claim needs evidence concerning sample-clock behaviour, group delay, acquisition completeness, windowing and any processing that altered temporal shape. An amplitude claim needs a calibrated reference plane and the appropriate uncertainty budget. An external-source claim requires challenges to receiver artefacts. Individual-device attribution requires more particular and sufficiently discriminating evidence. The release checklist should prevent a weak evidence item from borrowing authority from unrelated sections of a very large manuscript.

I would create a claim-to-evidence register. Each consequential sentence in the conclusions would refer to the original observation or lawful derivative, the acquisition manifest, calibration status, analysis method, independent challenge and remaining limitations. The register should distinguish accepted evidence, unverified assumptions and invalid observations. A signed custody form is important but does not establish analogue fidelity. A numerical computation can be correct but irrelevant to the physical cause. The system should be capable of failing a conclusion even when every administrative document is present, because technical validity cannot be manufactured by paperwork.

Adverse tests must remain accessible. If a receiver generated an intermodulation product under controlled stimulation, that result may

Copyright 2026, James M. Atkinson

qualify an earlier attribution even if it makes the report less decisive. A failed calibration, unknown FPGA image, sample loss or inconsistent clock should be identified in the relevant finding, not buried in an appendix that the reader is unlikely to examine. A readable report can give the conclusion and limitations concisely while linking to the full traceable record. There is no necessity to repeat every log line in the narrative, but the evidence must remain available for independent challenge within lawful retention boundaries.

After issuance, a new defect should initiate controlled correction. Identify the affected claims, preserve the original report, record the discovered error, perform a documented reanalysis and issue an attributable revised conclusion. A correction should not silently rewrite what the instrument recorded or what the original author said. If the error is systemic, the laboratory should evaluate whether other investigations used the same deficient method. This turns a mistake into process improvement and protects future work. A scientifically responsible institution is not one which never encounters an error; it is one which discovers, discloses and corrects it.

Dr. James M. Atkinson, Moderator: With respect to each principal contribution, I invite four reciprocal challenges addressed to four different colleagues. Each respondent will answer immediately before the token passes onward.

Sir Karl Raimund Popper, Cross-Peer Question to Sir David Cox: Sir David, I ask you to examine the danger of presenting a statistically exceptional receiver observation as a uniquely identified source. The finding may contain a well-calibrated frequency estimate, a small nominal false-alarm

Copyright 2026, James M. Atkinson

probability and agreement between two analysis programmes. Yet the programmes may use the same samples, and the detection model may never have been challenged against a physically plausible intermodulation mechanism. What can a careful statistician say about the resulting evidential strength, and which new experiment would materially improve it? Please distinguish uncertainty about a measured quantity, uncertainty in the competing models and the much broader problem of attribution to a named apparatus. I should also like a decision rule which allows a report to close with an unresolved source without treating that outcome as a professional failure. An expert whose scientific methods are excellent must still know which propositions those methods did not test. Please identify a falsifiable alternative hypothesis and an independent test that would prevent the team from confusing a persuasive narrative with a measured external-source finding.

Sir David Cox, Cross-Peer Answer to Sir Karl Raimund Popper: Sir Karl, the statistical result must be attached to the proposition for which its calculation was designed. A low false-alarm probability for a stipulated noise model may indicate that the observed score was unusual under that model. It is not automatically a probability that a particular transmitter generated the event, nor proof that the model adequately represents impulsive interference or receiver nonlinearities. A precise frequency measurement establishes a physical parameter within its uncertainty and calibration conditions. It does not by itself discriminate between a genuine external signal and an internally generated product at the same frequency. The final report should therefore keep measurement uncertainty, model uncertainty and source attribution in distinct columns.

Copyright 2026, James M. Atkinson

Agreement between analysis programmes can support reproducibility of a computational result, but it may not provide independent physical corroboration. If both use identical samples, time references and calibration tables, a shared bias will survive. The stronger test would alter a relevant part of the measurement chain or introduce an independent observation whose error mechanisms differ. For example, changing input attenuation at a known reference plane and using a second receiver architecture can challenge intermodulation explanations, with the precise physical predictions stated beforehand. A suitable control may fail to discriminate because of propagation or configuration limits; that failure should be reported rather than treated as confirmation by default.

I would separate the investigative decisions. One may close the data-analysis phase when the measured quantities and their processing are reproducible. One may close the physical-origin question when adequate controls support an external cause. One may leave individual-device attribution open if the data are compatible with several devices. Each decision has different evidential conditions. A report that states an identified feature of unresolved source, along with the controls performed and the additional test that might distinguish alternatives, is scientifically useful. It is not defeated because it declines to name an apparatus without sufficient information.

The mathematical conclusion should describe the operating conditions and selection rules. An exceptional score discovered after a broad search cannot necessarily be evaluated with the false-alarm probability of one prespecified comparison. A model fitted after inspecting the event may need independent confirmation. These are not mere legal caveats; they

Copyright 2026, James M. Atkinson

determine the scientific meaning of the statistic. A careful report prevents a reader from converting a valid calculation for one claim into unearned certainty about another.

Sir David Cox, Cross-Peer Question to Sir Harold Jeffreys: Sir Harold, suppose an investigation compares a small number of named source hypotheses and obtains a very large posterior probability for one of them, but the candidate list omits an internal oscillator product and the receiver was operated near compression. I would be concerned that the model is confident because the relevant cause was excluded before computation began. How should a reviewer evaluate a Bayesian attribution where the hypothesis set is incomplete and the likelihoods were fitted to benign laboratory data? I would also ask whether a posterior can be responsibly reported when the prior information comes largely from a client's suspicions rather than from independent evidence. The final evidential standard should not prefer one statistical school over another if both recognise limitations of the underlying observations. What claims would remain supportable, and what physical test should be proposed before an attribution is made? I particularly want the expert report to distinguish a conditional inference from an unconditional probability of source identity, and to identify the population of observation opportunities.

Sir Harold Jeffreys, Cross-Peer Answer to Sir David Cox: Sir David, a posterior distribution is conditioned upon its model and prior assumptions. When the physical source mechanism is absent from the hypothesis set, the calculation may assign high relative probability to one available alternative simply because every other considered alternative fits worse. That does not establish that the selected hypothesis is true. An important internal source

Copyright 2026, James M. Atkinson

mechanism, such as oscillator leakage or intermodulation in a nonlinear receiver state, must be considered when the apparatus makes it plausible. If it was omitted, the report should explain the omission and reassess the inference. No mathematical school can recover information that the experiment did not preserve or correct a physical model whose major causes were ignored.

Prior knowledge should be disclosed distinctly from measured evidence. A client's suspicion may motivate a lawful investigation but does not become an RF observation merely because it is used as a prior weight. If several reasonable prior assignments produce materially different conclusions, the instability should be reported. Likewise, a likelihood model calibrated under quiet laboratory conditions may not describe a strong-blocker field environment. One can conduct sensitivity analyses of noise assumptions and prior structures, but the value of those analyses depends on whether the candidate physical mechanisms were sufficiently represented in the first place.

The useful next step is an experiment which makes different physical explanations predict different observations. If internal nonlinear mixing is plausible, a controlled attenuation and multitone test may reveal its behaviour, subject to the amplifier stages and reference plane. An independent receiver path can provide additional evidence if its errors are sufficiently different. A calibrated source at the antenna input can challenge the proposed frequency and amplitude transformations. The investigator must preserve the adverse outcomes and the tests not performed. A prior belief that the client is right cannot substitute for those measurements.

Copyright 2026, James M. Atkinson

The supportable conclusion may be that a measured spectral event is consistent with a stated waveform or source class under a validated receiver configuration, while its individual origin remains unresolved. If a Bayesian comparison is retained, the report should label the hypothesis set and assumptions and avoid translating a conditional posterior into an unconditional statement of fact or legal responsibility. Honesty about that boundary is more useful than a spectacular probability that conceals an incomplete model.

Sir Harold Jeffreys, Cross-Peer Question to W. Edwards Deming: Mr. Deming, uncertainty may be correctly expressed in a technical annex while the executive summary still gives a stronger message than the evidence warrants. A client might read a statement that no suspicious transmitter was detected as assurance that no transmitter existed, or might read a source-location diagram as proof of one particular room despite unmeasured multipath. How should the quality-release process verify that the central conclusions, tables and visualisations remain consistent with the detailed limitations? I would particularly welcome a process for examining negative findings, digital evidence provenance, model-dependent reconstructions and post-publication corrections. The final document must be intelligible without sacrificing scientific accuracy. Is it possible to maintain strong editorial control over the prose while preserving enough original evidence for an independent laboratory to challenge a finding? Please identify the stopping conditions that should prevent release of an unsupported attribution even when the report is otherwise beautifully produced. Please explain how the release reviewer should handle a visually convincing result

Copyright 2026, James M. Atkinson

which depends critically on untested prior assumptions or an undisclosed acquisition gap.

W. Edwards Deming, Cross-Peer Answer to Sir Harold Jeffreys: Sir Harold, the release review must begin with the claims that a decision-maker will actually encounter. Read the executive summary, captions, tables and conclusion in isolation, and identify the physical proposition each communicates. Then trace the proposition through the claim-to-evidence register to the original observation, the acquisition manifest, calibration, processing and alternative-hypothesis tests. If the detailed record says only that no qualifying signal was observed during limited bands and times, the summary cannot say that no hidden device existed. If a localisation region is valid only under a stated multipath model, the map caption must display that qualification in understandable language. Editorial accuracy is a technical control, not a decorative exercise.

I would establish mandatory release gates for significant claims. A measured frequency or power requires appropriate reference-plane calibration and uncertainty. A transient-timing claim requires valid sample continuity, clock and group-delay evidence. External source attribution requires material receiver-generated artefacts to have been challenged. An individual-device claim requires more discriminating evidence and independent review. A legal conclusion cannot be smuggled into a technical label. Failure of a relevant gate should block the stronger claim, though a narrower finding may still be published. The review should record who approved the adjustment and why.

The source files, derivatives and logs should be preserved according to lawful authority and proportionate retention. A digest over an original

Copyright 2026, James M. Atkinson

object can help detect later alteration, but the record must also identify the sample schema, firmware and FPGA state, clock reference, missing-data flags and transformations. Reviewers should have a reproducible path from the original observation to the finding, where permissions and security controls allow. If crucial data are unavailable, the report should identify that limitation instead of constructing a hypothetical waveform and calling it original evidence. The same applies to simulated examples and fictional scholarly discussion, which must not be confused with actual field testimony.

If a defect is discovered after release, the institution should preserve the issued report, identify the affected conclusions, issue a controlled correction and examine whether the same fault affected related investigations. Corrections should be attributable and supported by new analysis or measurements. A quality system is not one which prevents all error but one which exposes and repairs it transparently. That process makes the final report reliable to readers who were not present at the survey and enables a future expert to challenge it fairly.

W. Edwards Deming, Cross-Peer Question to Sir Ronald Aylmer Fisher: Sir Ronald, I should like a final word on a question frequently obscured by publication pressure. A laboratory may be asked to issue a decisive conclusion after a technically extensive but adaptively conducted survey. The operators changed thresholds, revisited promising frequencies, replaced equipment and finally selected the most remarkable observation for the report. That can be proper investigative practice, yet it complicates every conventional error-rate calculation. How should the closing review distinguish useful exploratory work from independently validated

Copyright 2026, James M. Atkinson

confirmation and decide whether a fresh trial is required? I would also ask how to represent adverse findings and known blind periods without turning the executive summary into an impenetrable catalogue of caveats. The report must be honest and useful, not merely legally defensive. Please describe the minimum evidential wording for an affirmative observation and a bounded negative when no appropriate independent confirmation was obtained. I also ask for a release-control rule identifying what must be corrected in the instrument process rather than merely edited in the final narrative.

Sir Ronald Aylmer Fisher, Cross-Peer Answer to W. Edwards Deming: Mr. Deming, adaptive investigation is not inherently defective, but its statistical consequences must be recognised. Changing the threshold after seeing the data, examining many frequencies and selecting one exceptional feature means that the final selected event has been subjected to a discovery process. One cannot automatically evaluate it using the error probability of a single comparison specified in advance. The report should preserve the search method, decision history and selection rules. Where the final claim depends heavily on the rarity of an event, an independent prospective test using a frozen rule is often a stronger basis than a post hoc calculation applied to the discovery data.

An affirmative conclusion can be phrased at several levels. The analyst might state that a calibrated receiver recorded a spectral feature at a specified frequency and time under an acquisition state found valid for that measurement. If independent controls establish an external component, the report can say so and identify the tests. If individual-device attribution is unverified, that limitation should appear immediately beside the stronger

Copyright 2026, James M. Atkinson

claim rather than in an obscure footnote. The summary need not repeat every calibration constant, but it should lead the reader to the traceable record and should not omit the most consequential uncertainty.

A bounded negative should likewise identify coverage. It might state that no emissions meeting a specified detector rule were observed during the valid monitoring intervals and surveyed bands, with sensitivity and blind time described. If the detector was tested only for particular authorised waveform families, the report should not imply that all imaginable transmissions would have been found. A finite survey cannot exclude events occurring in unobserved intervals or sources that remained silent. The result may still provide practical assurance within its declared limits. The quality of the conclusion lies in the fit between the wording and the actual experiment.

Adverse tests and deviations should remain part of the record. A failure to detect one known reference pulse may materially limit a claim of sensitivity; a firmware state ambiguity may invalidate one timing analysis while leaving other observations intact. The release reviewer should apply those effects to the affected findings rather than delete inconvenient data. If further confirmation cannot lawfully or practically be obtained, report the unresolved proposition. An honest inconclusive outcome is preferable to an impressive statement supported by an experiment whose error properties have not been established.

Dr. James M. Atkinson, Moderator: This concludes Question 107 and the one-hundred-discussion Stage-A drafting programme. All findings remain subject to actual source-to-claim verification, mathematical review, factual checks, independent evidence assessment, and complete manuscript

Copyright 2026, James M. Atkinson

production proof. A fictional scholarly consensus must never be presented as a field observation or as genuine historic testimony.

QUESTION 107. RESEARCH NOTES. JCGM 100:2008, Evaluation of measurement data, Guide to the expression of uncertainty in measurement, DOI 10.59161/JCGM100-2008E; NIST SP 800-86, Guide to Integrating Forensic Techniques into Incident Response; SWGDE 18-F-002-2.0, Best Practices for Digital Evidence Collection (30 June 2025). These sources support background metrology and digital-evidence principles, not the fictional speech or the correctness of a particular field measurement.

EDITORIAL QUALIFICATION. The manuscript contains 100 substantive Stage-A discussion drafts following the seven authorised deletions. This structural milestone is NOT Stage-B publication approval. Every cited proposition, historical attribution, engineering calculation, legal claim, cross-reference, layout and continuous page number requires a separate whole-volume verification. Independently developed Phase-I core expansions remain unverified for integration.

Volume Assessments

This section contains 350 items: 100 multiple-choice, 100 fill-in-the-blank, 50 essay and 100 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

The volume set combines material across the sixteen chapters. A satisfactory synthesis must preserve each model’s assumptions, reference plane, receiver state and evidential scope when connecting the chapters.

Multiple-Choice Questions

V011-VOL-MCQ-001. A survey needs antenna-terminal power, but its software reports receiver-plane power after an undocumented automatic gain change. What is the first defensible action?

A. Recover or bound the applicable state and path correction before forming the requested quantity

B. Treat receiver-plane power as antenna-terminal power because both use dBm

C. Apply the nominal gain and enlarge uncertainty until the result looks stable

D. Average more displayed levels to remove the unknown state

Answer: A. A correction inverse needs the actual state and named planes; covariance propagation cannot repair an inapplicable correction. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: Recover or bound the applicable state and path correction before forming the requested quantity.

Distinguishing consideration: compare this with option B, “Treat receiver-plane power as antenna-terminal power because both use dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 13 — Define a complete path at named planes; Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 13 — Define a complete path at named planes; Chapter 14 — Attach calibration to a stated measurement result.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-002. A matched fixed-state path has dimensionless power transfer 10, output power 1.5 nW and a separately characterized output-referred additive power 0.5 nW with zero cross-power. What input signal power should enter the calibrated result?

A. 1.0 nW

B. 0.2 nW

C. 0.1 nW

D. 10 nW

Answer: C. Subtract physical powers first, then divide by transfer; a later logarithm requires the positive difference. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: 0.1 nW.

Distinguishing consideration: compare this with option A, “1.0 nW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-003. Two accepted equal-duration intervals have corrected input powers 1 nW and 9 nW. Which aggregate preserves their physical mean?

A. 3 nW from the geometric mean

B. 5 nW followed by any declared log conversion

C. The arithmetic mean of their dBm labels interpreted as mean power

D. 9 nW because the larger state dominates

Answer: B. Duration weighting applies to corrected linear powers; logarithmic averaging defines a different statistic. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: 5 nW followed by any declared log conversion. Distinguishing consideration: compare this with option A, “3 nW from the geometric mean”; that competing statement does not meet the question’s stated requirement. Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

V011-VOL-MCQ-004. A trace can be corrected numerically after clipping, but only saturated samples remain. What claim is unsupported?

A. Retaining a lower-bound or limited observation when justified

B. Reviewing the configured state and clipping flags

C. Reporting that clipping occurred

D. Recovery of the original waveform by an ordinary gain inverse

Answer: D. A correct scalar arithmetic operation cannot restore discarded waveform information. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: Recovery of the original waveform by an ordinary gain inverse.

Distinguishing consideration: compare this with option A, “Retaining a lower-bound or limited observation when justified”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 10 — Quantization, Clipping, and Converter Performance.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 10 — Quantization, Clipping, and Converter Performance.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-005. A gain change is logged at a command time but settles later. How should those records contribute to coverage?

A. Use demonstrated valid intervals and preserve the transition exclusion

B. Count the whole command interval as calibrated exposure

C. Delete transition metadata after applying a static correction

D. Use the average of the two gain labels for every sample

Answer: A. Configuration validity and acquisition opportunity must share the actual time boundary. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: Use demonstrated valid intervals and preserve the transition exclusion.

Distinguishing consideration: compare this with option B, “Count the whole command interval as calibrated exposure”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Model 15A: calculate conditional event coverage from….

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-MCQ-006. A power-only record supports a valid average level but has lost phase. What additional inference cannot be recovered from that scalar alone?

A. Its calibrated level at the declared plane

B. Inter-record coherent phase alignment

C. The stated positive average power

D. The fact that the original result was power-only

Answer: B. A recoverable quantity can coexist with permanently lost information needed for coherence. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: Inter-record coherent phase alignment.

Distinguishing consideration: compare this with option A, “Its calibrated level at the declared plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 12 — Accept coherence at the required boundary and state.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 12 — Accept coherence at the required boundary and state.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-007. For two matched fixed-state stages with first-stage noise temperature 50 K, second-stage noise temperature 200 K and first-stage power gain 10, what total input-equivalent noise temperature follows?

A. 70 K

B. 25 K

C. 250 K

D. 2050 K

Answer: A. The later temperature is divided by preceding gain; the result still needs the declared state and bandwidth. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: 70 K.

Distinguishing consideration: compare this with option B, “25 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-008. The same stages must meet 70 K, requiring gain at least 10, but blocker loading allows gain at most 8. What is the design conclusion?

A. Choose gain 8 and claim 70 K through digital scaling

B. The feasible gain interval is empty and another condition or architecture must change

C. Choose gain 10 because noise always takes priority

D. Choose gain 9 as an acceptable average compromise

Answer: B. Noise and loading constraints must both hold; a midpoint does not satisfy incompatible bounds. Source: §2.17 Turn the cascade into bounded design requirements (p. 675)

Why the selected alternative fits: The feasible gain interval is empty and another condition or architecture must change.

Distinguishing consideration: compare this with option A, “Choose gain 8 and claim 70 K through digital scaling”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Choose gain from a feasible interval; Chapter 11 — Dynamic Range Is a Family of Conditions.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Choose gain from a feasible interval; Chapter 11 — Dynamic Range Is a Family of Conditions.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-009. A matched passive power loss $L=2$ at 300 K precedes a fixed-state chain with input-equivalent noise temperature 50 K. What total input-equivalent noise temperature results?

A. 400 K

B. 100 K

C. 650 K

D. 350 K

Answer: A. The loss adds 300 K and refers the chain backward as 100 K; a signal correction alone does not remove this noise cost. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: 400 K.

Distinguishing consideration: compare this with option B, “100 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 13 — Treat connections and unused branches as part of the network.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 13 — Treat connections and unused branches as part of the network.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-010. Why can a preselector improve a weak-signal observation despite increasing desired-band loss?

A. Any desired loss automatically lowers receiver noise temperature

B. Its rejection value should be added to desired sensitivity

C. Its blocker rejection can restore upstream linear validity while the noise penalty is accounted for

D. A downstream filter can reconstruct earlier clipped samples

Answer: C. Follow desired transfer and blocker admission separately and validate the weak reference. Source: §2.17 Turn the cascade into bounded design requirements (p. 675)

Why the selected alternative fits: Its blocker rejection can restore upstream linear validity while the noise penalty is accounted for.

Distinguishing consideration: compare this with option A, “Any desired loss automatically lowers receiver noise temperature”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Use preselection as a measured transfer function; Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Use preselection as a measured transfer function; Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-VOL-MCQ-011. A narrow final filter removes a blocker from the display but the remote amplifier is already compressed. Which remedy addresses the causal boundary?

A. Treat the clean display as proof of linearity

B. Apply the desired-frequency gain correction to the blocker

C. Increase digital averaging after the filter

D. Reduce admitted loading before that amplifier and revalidate desired response

Answer: D. Later filtering cannot reconstruct distortion generated at an earlier vulnerable stage. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: Reduce admitted loading before that amplifier and revalidate desired response.

Distinguishing consideration: compare this with option A, “Treat the clean display as proof of linearity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity; Chapter 13 — External Preamplifiers, Bias, and Stability; Chapter 11 — Compression and Gain Change.

Review: Chapter 3 — Find the first stage that can lose validity; Chapter 13 — External Preamplifiers, Bias, and Stability; Chapter 11 — Compression and Gain Change.

V011-VOL-MCQ-012. A protection device survives a pulse. Which separate evidence is still required before accepting nearby weak events?

A. Only another survival rating from a catalog

B. Only the final record's hash

C. Observable-specific recovery and usable acquisition intervals

D. Only a steady center-frequency tone measured much later

Answer: C. Hardware survival, leakage and restored measurement validity are distinct. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Observable-specific recovery and usable acquisition intervals.

Distinguishing consideration: compare this with option A, “Only another survival rating from a catalog”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Model 15A: calculate conditional event coverage from....

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-MCQ-013. If receiver added temperature is positive and source temperature differs from 290 K, which comparison requires care?

A. Noise factor versus a dimensionless quantity

B. Reference noise factor versus actual SNR degradation

C. Source noise versus any physical temperature

D. Gain versus a numerical setting label only

Answer: B. F_0 uses 290 K, while actual degradation uses the actual positive source temperature. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: Reference noise factor versus actual SNR degradation.

Distinguishing consideration: compare this with option A, “Noise factor versus a dimensionless quantity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-MCQ-014. A hot/cold test uses T_h 600 K, T_c 300 K and true T_e 300 K at constant gain. What ratio should appear?

A. 0.5

B. 2.0

C. 1.5

D. 3.0

Answer: C. The fixed-state ratio is(600+300)/(300+300); gain changes would invalidate this cancellation. Source: §2.16 Invert the same model with two source temperatures (p. 672)

Why the selected alternative fits: 1.5.

Distinguishing consideration: compare this with option A, “0.5”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Invert the same model with two source temperatures; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 2 — Invert the same model with two source temperatures; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-MCQ-015. In a matched hot/cold Y-factor noise test, hot-state gain doubles while cold gain stays fixed. Why is averaging more ratios insufficient for the common-transfer inversion?

A. The cold source temperature automatically doubles too

B. More averaging always restores a common gain

C. The ratio becomes a valid direct noise-factor measurement

D. The model's common-transfer assumption is broken systematically

Answer: D. A state-dependent model or restored equal gain is needed before inversion. Source: §2.16 Invert the same model with two source temperatures (p. 672)

Why the selected alternative fits: The model's common-transfer assumption is broken systematically.

Distinguishing consideration: compare this with option A, “The cold source temperature automatically doubles too”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Invert the same model with two source temperatures; Chapter 14 — Calibrate noise without confusing it with detection; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-VOL-MCQ-016. A valid two-stage noise calculation omits an unmodeled mixer image-noise path. What must happen before using it as a system sensitivity prediction?

A. Double every gain term regardless of sideband admission

B. Assume the image disappears when a digital spectrum is one-sided

C. Establish a channel/sideband noise law applicable to the actual conversion architecture

D. Insert any catalog SSB or DSB figure without checking convention

Answer: C. The scalar cascade's domain excludes unmodeled image contributions.

Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: Establish a channel/sideband noise law applicable to the actual conversion architecture.

Distinguishing consideration: compare this with option A, “Double every gain term regardless of sideband admission”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 4 — Model 4A: a declared conversion map; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-MCQ-017. Two equal desired-gain layouts place attenuation before or after a nonlinear amplifier. What can differ materially?

A. Nothing because total gain is equal

B. Only the numerical display reference

C. Noise weighting and the amplifier's exposure to parent signals

D. Only file storage rate

Answer: C. The location of loss affects both cascade temperature and product generation/loading. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: Noise weighting and the amplifier's exposure to parent signals.

Distinguishing consideration: compare this with option A, “Nothing because total gain is equal”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval; Chapter 11 — Ten worked applications of Model 11A.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval; Chapter 11 — Ten worked applications of Model 11A.

V011-VOL-MCQ-018. A calibrated AGC voltage approaches its target exponentially, but the gain slope is negative. What must an amplitude reconstruction retain?

A. Only the magnitude of control voltage

B. A positive slope by convention

C. The signed voltage-to-gain law and time-resolved state

D. The final settled gain applied to every earlier sample

Answer: C. State recovery and gain calibration are separate parts of the measurement operator. Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)

Why the selected alternative fits: The signed voltage-to-gain law and time-resolved state.

Distinguishing consideration: compare this with option A, “Only the magnitude of control voltage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

V011-VOL-MCQ-019. An AGC model predicts no overshoot, but the observed trace overshoots after a blocker. What is justified?

A. The single uninterrupted one-pole segment is inadequate for that response

B. The receiver necessarily suffered permanent damage

C. The same model becomes valid by changing plot scale

D. The measured overshoot must be deleted as impossible

Answer: A. Additional state, changed target or another identified mechanism is needed before using its correction. Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)

Why the selected alternative fits: The single uninterrupted one-pole segment is inadequate for that response.

Distinguishing consideration: compare this with option B, “The receiver necessarily suffered permanent damage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 16 — Localize an artifact by changing the stage that could….

V011-VOL-MCQ-020. A trigger follows narrow filtering and AGC while the recorder stores wider raw samples. What must a burst claim establish?

A. The actual trigger-path and saved-data validity relationship

B. That a long file proves full event capture

C. That a shared sample clock removes control latency

D. That nominal recorder bandwidth guarantees every trigger

Answer: A. Trigger filtering and control can change detection opportunity independently of stored bandwidth. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: The actual trigger-path and saved-data validity relationship.

Distinguishing consideration: compare this with option B, “That a long file proves full event capture”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 10 — SDR Boundary and Partitioning; Chapter 15 — Verify the trigger at its actual signal-path location.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 10 — SDR Boundary and Partitioning; Chapter 15 — Verify the trigger at its actual signal-path location.

V011-VOL-MCQ-022. A real conversion admits both desired and image fields coherently. Why may adding their separate powers be wrong?

A. Images always contribute exactly half the desired power

B. Gain correction removes all coherent cross terms

C. Every pair of frequencies is statistically independent

D. Their cross term depends on relative phase

Answer: D. Coherent combination requires field/phase treatment before a scalar power budget. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: Their cross term depends on relative phase.

Distinguishing consideration: compare this with option A, “Images always contribute exactly half the desired power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map; Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 9 — Define the ensemble before normalizing.

V011-VOL-MCQ-033. An intermittent noise process violates the common-mean exponential assumption used for a log-bias correction. What is defensible?

A. Assume mixtures retain every single-state gamma formula

B. Use the same correction because both traces are called noise

C. Increase display precision until the bias disappears

D. Reassess the distribution/model and estimator instead of transferring the fixed correction

Answer: D. Statistical correction depends on the source law as well as operation order. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: Reassess the distribution/model and estimator instead of transferring the fixed correction.

Distinguishing consideration: compare this with option A, “Assume mixtures retain every single-state gamma formula”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-VOL-MCQ-039. Can correct symbol classification alone establish a transmitter's surveillance purpose?

A. Only if the center frequency is stable

B. Yes, if EVM is low

C. Yes, if two decoders show the same identifier

D. No; operational linkage, information path and authorization evidence are additional

Answer: D. Demodulation results and functional attribution are different evidence levels. Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)

Why the selected alternative fits: No; operational linkage, information path and authorization evidence are additional.

Distinguishing consideration: compare this with option A, “Only if the center frequency is stable”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Findings, Reports, and Decision Ladders.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-MCQ-040. A 1-second record has a constant fractional clock error 0.5 ppm with zero initial error. What time error accumulates?

A. 50 ps

B. 500 ns

C. 0.5 ns

D. 5μs

Answer: B. Time error is fractional frequency error times elapsed time under the deterministic law; timestamps need that relationship. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: 500 ns.

Distinguishing consideration: compare this with option A, “50 ps”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Metadata, Time, and Site Context.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Metadata, Time, and Site Context.

V011-VOL-MCQ-041. A common random phase rotates every sample equally in one record. What can remain unchanged?

A. Every inter-record phase difference

B. The squared magnitude of the coherent sum within that record

C. All deterministic timing errors

D. Its phase relative to an external reference

Answer: B. Common rotation preserves within-record magnitude, but absolute or cross-record phase claims differ. Source: §12.23 Application 12B.6: Distinguish a common random phase from lost coherent power (p. 6983)

Why the selected alternative fits: The squared magnitude of the coherent sum within that record.

Distinguishing consideration: compare this with option A, “Every inter-record phase difference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power; Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power; Chapter 9 — Define the ensemble before normalizing.

V011-VOL-MCQ-042. Two channels share a clock but have unknown aperture offsets. Which claim requires additional calibration?

A. A known sample-count format

B. A shared nominal frequency source

C. Aligned sample-time or interchannel phase at the measurement boundary

D. The existence of the common cable

Answer: C. Shared frequency does not establish epochs, apertures, trigger mapping or delay. Source: §12.30 Accept coherence at the required boundary and state (p. 6992)

Why the selected alternative fits: Aligned sample-time or interchannel phase at the measurement boundary.

Distinguishing consideration: compare this with option A, “A known sample-count format”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Accept coherence at the required boundary and state; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 12 — Accept coherence at the required boundary and state; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-MCQ-043. Identical RMS jitter values measured over different offset bands are compared as interchangeable. What is missing?

A. The spectral integration band, carrier conversion and relevant weighting

B. Only the nominal record length

C. Only more decimal places

D. Only the receiver's serial number

Answer: A. A scalar RMS can hide spectral placement affecting coherent or blocker response. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: The spectral integration band, carrier conversion and relevant weighting.

Distinguishing consideration: compare this with option B, “Only the nominal record length”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 11 — Integrate the channel that actually produces the reported value.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 11 — Integrate the channel that actually produces the reported value.

Copyright 2026, James M. Atkinson

V011-VOL-MCQ-044. An oscillator has low integrated jitter but elevated noise at a strong blocker's offset. Which assessment remains necessary?

A. Only the average frequency error

B. Channel-weighted reciprocal-mixing impact

C. Only the ADC's nominal bit count

D. Only the total jitter number

Answer: B. Reciprocal mixing depends on the phase-noise density where the blocker maps into the observation channel. Source: §11.25 Integrate the channel that actually produces the reported value (p. 6398)

Why the selected alternative fits: Channel-weighted reciprocal-mixing impact.

Distinguishing consideration: compare this with option A, “Only the average frequency error”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Integrate the channel that actually produces the reported value; Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 11 — Integrate the channel that actually produces the reported value; Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-VOL-MCQ-045. A calibrated delay correction is applied after a reference reset that changes phase. What should be checked?

A. Repeatability at the actual state boundary and phase branch

B. Only steady amplitude agreement

C. Only the carrier's average frequency

D. Only the old delay uncertainty

Answer: A. A correction's numerical precision does not establish its applicability after a consequential state change. Source: §12.30 Accept coherence at the required boundary and state (p. 6992)

Why the selected alternative fits: Repeatability at the actual state boundary and phase branch.

Distinguishing consideration: compare this with option B, “Only steady amplitude agreement”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-MCQ-046. Deleting missing samples makes stored offsets contiguous. What is lost if absolute source indices are not retained?

A. Only unused file padding

B. The true elapsed-time and oscillator-phase relationship across the gap

C. Nothing because the remaining bytes are ordered

D. Only a redundant filename field

Answer: B. The physical sample grid differs from packed storage positions. Source: §10.49 Source indices, stored offsets, and time anchors (p. 5745)

Why the selected alternative fits: The true elapsed-time and oscillator-phase relationship across the gap.

Distinguishing consideration: compare this with option A, “Only unused file padding”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Review: Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-MCQ-047. A causal filter's output uses a missing input even though its own output timestamp is present. What follows?

A. That output may be invalid and the support-dependent tail must be tracked

B. The output is valid because it was saved

C. Only the missing input instant is affected

D. A file hash repairs the filter history

Answer: A. Validity follows actual convolution support and retained decimation indices. Source: §10.50 A continuity condition for finite filtering and decimation (p. 5747)

Why the selected alternative fits: That output may be invalid and the support-dependent tail must be tracked.

Distinguishing consideration: compare this with option B, “The output is valid because it was saved”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Review: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-MCQ-048. An NCO restarts phase at each file block despite continuous input. What should be preserved instead when the intended operator is continuous?

A. Only a final spectrum image

B. Only equal block lengths

C. A separate zero phase for every export

D. Absolute phase/index state across ordinary boundaries

Answer: D. Block representation should not change the declared mixing operator or coherence. Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)

Why the selected alternative fits: Absolute phase/index state across ordinary boundaries.

Distinguishing consideration: compare this with option A, “Only a final spectrum image”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 12 — Accept coherence at the required boundary and state.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 12 — Accept coherence at the required boundary and state.

V011-VOL-MCQ-049. A signed sample file is read with the wrong binary point. Which independent check is most direct?

A. Only successful file opening

B. Only the byte hash

C. Only the number of samples

D. A known waveform with declared format, scale and expected physical amplitude

Answer: D. Integrity and format validity are different obligations in reproducible calibrated processing. Source: §10.33 Signed formats and explicit conversion points (p. 5725)

Why the selected alternative fits: A known waveform with declared format, scale and expected physical amplitude.

Distinguishing consideration: compare this with option A, “Only successful file opening”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Signed formats and explicit conversion points; Chapter 14 — Build a correction chain with signs that can be checked; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Review: Chapter 10 — Signed formats and explicit conversion points; Chapter 14 — Build a correction chain with signs that can be checked; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-MCQ-050. Rounding error is small, but a fixed-point sum overflows. What is the correct assessment?

A. The range obligation failed despite a favorable local quantization-error estimate

B. Digital scaling always preserves clipped values

C. The uncertainty budget can absorb arbitrary overflow

D. Small rounding error proves the arithmetic valid

Answer: A. Quantization error and representable range must both be satisfied.

Source: §10.34 Range and error are separate obligations (p. 5728)

Why the selected alternative fits: The range obligation failed despite a favorable local quantization-error estimate.

Distinguishing consideration: compare this with option B, “Digital scaling always preserves clipped values”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Range and error are separate obligations; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Review: Chapter 10 — Range and error are separate obligations; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

V011-VOL-MCQ-051. Digital gain is increased after analog signal and noise are already acquired. Which improvement is not created by that scaling alone?

A. The displayed level when not compensated

B. The preexisting analog SNR

C. The numerical sample magnitudes

D. The possibility of a different output representation

Answer: B. Scaling cannot recover SNR or information already lost upstream.

Source: §2.17 Turn the cascade into bounded design requirements (p. 675)

Why the selected alternative fits: The preexisting analog SNR.

Distinguishing consideration: compare this with option A, “The displayed level when not compensated”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Choose gain from a feasible interval; Chapter 10 — Quantization margin and channel bandwidth.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Choose gain from a feasible interval; Chapter 10 — Quantization margin and channel bandwidth.

V011-VOL-MCQ-052. A claim of secure executable identity is offered as proof of correct RF behavior. What additional evidence is required?

A. Only successful installation

B. Configuration-specific behavioral tests using appropriate references

C. Only another copy of the executable hash

D. Only a signed filename

Answer: B. Artifact identity binds code bytes, while measurement behavior depends on configuration and physical path. Source: §10.66 Separate signed artifacts from operating configurations (p. 5770)

Why the selected alternative fits: Configuration-specific behavioral tests using appropriate references.

Distinguishing consideration: compare this with option A, “Only successful installation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 16 — Close the receiver method through configuration-specific regression.

Review: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-MCQ-053. Two equal-tone intermodulation parents are changed together. What must remain explicit when extrapolating an intercept?

A. Per-tone convention, stage plane, local cubic domain and linear asymptote

B. A universal converter noise model

C. Only total combined parent power without convention

D. A claim that the intercept is an attainable operating power

Answer: A. An extrapolated local model is not a full system dynamic-range guarantee. Source: §11.8 Construct the intercept from the linear asymptote (p. 6373)

Why the selected alternative fits: Per-tone convention, stage plane, local cubic domain and linear asymptote.

Distinguishing consideration: compare this with option B, “A universal converter noise model”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Construct the intercept from the linear asymptote; Chapter 3 — Choose gain from a feasible interval; Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 11 — Construct the intercept from the linear asymptote; Chapter 3 — Choose gain from a feasible interval; Chapter 14 — Attach calibration to a stated measurement result.

V011-VOL-MCQ-054. A coherent source-generated product overlaps the receiver product. Why is simple power subtraction invalid?

A. A background dBm subtraction removes the phasor automatically

B. All products at one frequency add incoherently

C. A receiver intercept fit makes source purity irrelevant

D. Unknown relative phase can cause reinforcement or cancellation

Answer: D. Contamination at the same frequency needs field/phase bounds or independent source characterization. Source: §11.9 Ten worked applications of Model 11A (p. 6376)

Why the selected alternative fits: Unknown relative phase can cause reinforcement or cancellation.

Distinguishing consideration: compare this with option A, “A background dBm subtraction removes the phasor automatically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11A; Chapter 4 — Model 4A: a declared conversion map; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 11 — Ten worked applications of Model 11A; Chapter 4 — Model 4A: a declared conversion map; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-VOL-MCQ-055. A blocker raises noise while the weak reference gain remains stable. Which combined test is more informative than declaring compression?

A. Infer source identity from the noise-rise magnitude

B. Apply a quiet-state gain correction repeatedly

C. Inspect only the quiet-state noise floor without the admitted blocker

D. Check admitted blocker spectrum, oscillator phase noise and fixed channel weighting

Answer: D. The observation may fit reciprocal mixing or source contamination; distinguish mechanisms with preserved transfer. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Why the selected alternative fits: Check admitted blocker spectrum, oscillator phase noise and fixed channel weighting.

Distinguishing consideration: compare this with option A, “Infer source identity from the noise-rise magnitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions; Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 16 — Localize an artifact by changing the stage….

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions; Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-MCQ-056. A blocker changes gain, bandwidth and baseline together. Can a simple paired-power subtraction retain its original meaning?

A. Yes, because subtraction always isolates new noise

B. Only after the fixed-transfer and compatible-band conditions are restored or modeled

C. Yes, if the output powers are positive

D. No measurement can ever be made again

Answer: B. The subtraction model assumes comparable states, not merely two recorded numbers. Source: §11.26 Convert added power into a conditional noise-rise limit (p. 6401)

Why the selected alternative fits: Only after the fixed-transfer and compatible-band conditions are restored or modeled.

Distinguishing consideration: compare this with option A, “Yes, because subtraction always isolates new noise”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 14 — Application 14B.9: subtract paired powers before….

Review: Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-VOL-MCQ-057. An antenna-terminal conducted reference passes while an installed field estimate changes with cable route. What scope should be retained?

A. A proof that the antenna certificate is invalid everywhere

B. A universal field calibration from the conducted pass

C. A proof that the external field must have changed

D. The bounded conducted transfer plus an unresolved installed-coupling effect

Answer: D. Terminal and field measurands add different geometry and common-mode dependencies. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: The bounded conducted transfer plus an unresolved installed-coupling effect.

Distinguishing consideration: compare this with option A, “A proof that the antenna certificate is invalid everywhere”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power; Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 13 — Keep field conversion separate from terminal power; Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 14 — Attach calibration to a stated measurement result.

V011-VOL-MCQ-058. A battery/optical substitution removes a line but degrades weak-reference sensitivity. What is the principal limitation?

A. The old line is therefore physically false

B. Isolation uniquely proves conductive pickup

C. Disappearance is confounded by lost observation capability

D. The weaker path automatically provides more independent evidence

Answer: C. The intervention changes both coupling and measurement capability.

Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why the selected alternative fits: Disappearance is confounded by lost observation capability.

Distinguishing consideration: compare this with option A, “The old line is therefore physically false”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 16 — Preserve comparable observation capability.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 16 — Preserve comparable observation capability.

V011-VOL-MCQ-061. Two correction inputs share a reference and enter with opposite signs. Which uncertainty treatment is appropriate?

A. Use their supported covariance or an explicit common input consistently

B. Choose correlation solely to minimize the final interval

C. Treat every budget row as independent automatically

D. Count the common uncertainty independently and again as a separate added term

Answer: A. The signed measurement function determines cancellation; bookkeeping must avoid duplication. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: Use their supported covariance or an explicit common input consistently.

Distinguishing consideration: compare this with option B, “Choose correlation solely to minimize the final interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 14 — Use covariance and model sensitivity....

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 14 — Use covariance and model sensitivity deliberately.

V011-VOL-MCQ-063. A positive on/off central difference has an uncertainty domain including nonpositive values. What should be reported first?

A. The linear difference and its supported interpretation before a logarithmic claim

B. A finite dBm value for every possible difference

C. Only the positive center with no domain limitation

D. The log of its absolute value as equivalent signal power

Answer: A. Physical and transform-domain boundaries are part of a valid inverse and uncertainty model. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: The linear difference and its supported interpretation before a logarithmic claim.

Distinguishing consideration: compare this with option B, “A finite dBm value for every possible difference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 14 — Application 14B.9: subtract paired powers before….

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-VOL-MCQ-068. A phase-locked event misses a sweep window repeatedly. Which change can create genuinely new timing opportunity?

A. Save the same trace under more filenames

B. Increase amplitude correction precision only

C. Change usable schedule or establish justified independent phase variation

D. Apply the independent-trial formula to unchanged misses

Answer: C. Opportunity is a temporal relationship, not a count of records. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

Why the selected alternative fits: Change usable schedule or establish justified independent phase variation.

Distinguishing consideration: compare this with option A, “Save the same trace under more filenames”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Interpret a swept trace through its frequency-time trajectory; Chapter 15 — Application 15A.7: Keep a deterministic repeated miss deterministic.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory; Chapter 15 — Application 15A.7: Keep a deterministic repeated miss deterministic.

V011-VOL-MCQ-069. Trigger and data paths have different bandwidths. What does a complete capture report need beyond a trigger flag?

A. Verified boundaries, valid pre/post context and sample continuity

B. Only a stable center-frequency tone

C. Only a high trigger count

D. Only the trigger's nominal threshold

Answer: A. Trigger occurrence does not establish retained waveform completeness.

Source: §10.1 SDR Boundary and Partitioning (p. 5679)

Why the selected alternative fits: Verified boundaries, valid pre/post context and sample continuity.

Distinguishing consideration: compare this with option B, “Only a stable center-frequency tone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — SDR Boundary and Partitioning; Chapter 15 — Verify the trigger at its actual signal-path location.

Review: Chapter 10 — SDR Boundary and Partitioning; Chapter 15 — Verify the trigger at its actual signal-path location.

V011-VOL-MCQ-070. A continuous file crosses a rollover boundary without lost samples. How should its FFT and burst-continuity handling proceed?

A. Discard one sample from each file to avoid overlap

B. Preserve filter/index history and treat the boundary according to verified physical continuity

C. Declare a dead interval equal to one file duration

D. Reset all processing state merely because the filename changed

Answer: B. Storage segmentation need not alter the measurement operator. Source: §9.3.1 Define the record before interpreting the display (p. 5029)

Why the selected alternative fits: Preserve filter/index history and treat the boundary according to verified physical continuity.

Distinguishing consideration: compare this with option A, “Discard one sample from each file to avoid overlap”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the record before interpreting the display; Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived….

Review: Chapter 9 — Define the record before interpreting the display; Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-MCQ-071. Two channels each store 16-bit I and 16-bit Q at 20 MS/s. What payload capacity is needed for 100 s, before overhead?

A. 8 GB

B. 16 GB

C. 160 GB

D. 32 GB

Answer: B. The rate is 160 MB/s, so 100 s yields 16 billion bytes; sustained recording still needs validation. Source: §10.47 Data Transport, Gaps, and Reproducible Recording (p. 5743)

Why the selected alternative fits: 16 GB.

Distinguishing consideration: compare this with option A, “8 GB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

Review: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

V011-VOL-MCQ-072. A native file has a valid hash but gaps were never logged. Which conclusion remains unsupported?

A. That all intended samples were acquired continuously

B. That the file can be copied without changing its current bytes

C. That its byte length can be counted

D. That the preserved bytes match the hash

Answer: A. Byte integrity does not establish acquisition completeness or time mapping. Source: §10.49 Source indices, stored offsets, and time anchors (p. 5745)

Why the selected alternative fits: That all intended samples were acquired continuously.

Distinguishing consideration: compare this with option B, “That the file can be copied without changing its current bytes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Close the receiver method through configuration-specific….

V011-VOL-MCQ-073. A system delivers 8 million unique information bits over 20 s, with 2 s active bursts. Which wall-interval throughput is appropriate?

A. 80Mb/s

B. 0.4Mb/s

C. 4Mb/s

D. 8Mb/s

Answer: B. The denominator is the declared 20 s wall interval; active-burst rate is a different quantity. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: 0.4Mb/s.

Distinguishing consideration: compare this with option A, “80Mb/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-MCQ-074. Some payload frames overlap between captures from two channels. How should total unique delivery be counted?

A. Deduplicate the declared payload positions before dividing by the common interval

B. Count every channel's sample words as information bits

C. Use the channel with the highest symbol rate only

D. Add both decoded counts regardless of overlap

Answer: A. Shared observations and repeated payload do not create new delivered information. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: Deduplicate the declared payload positions before dividing by the common interval.

Distinguishing consideration: compare this with option B, “Count every channel's sample words as information bits”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

V011-VOL-MCQ-075. A multichannel spectral phase appears inconsistent after a gap is silently deleted. What should be audited jointly?

A. Absolute sample indices, cross-spectrum order and timing reference

B. Only the nominal antenna gain

C. Only the plotted coherence color range

D. Only the amplitude calibration date

Answer: A. The representation and timing conventions determine the meaning of phase. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

Why the selected alternative fits: Absolute sample indices, cross-spectrum order and timing reference.

Distinguishing consideration: compare this with option B, “Only the nominal antenna gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis; Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis; Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-VOL-MCQ-076. An EVM fit removes a frequency/phase trend that a clock diagnostic intended to measure. What should the report do?

A. Replace every timing uncertainty with the fitted EVM

B. Call the fitted result proof of an improved clock

C. Disclose fit freedom and retain the unremoved timing quantity or a separately defined metric

D. Ignore training/evaluation distinction

Answer: C. A processing alignment can conceal a physical impairment without repairing it. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

Why the selected alternative fits: Disclose fit freedom and retain the unremoved timing quantity or a separately defined metric.

Distinguishing consideration: compare this with option A, “Replace every timing uncertainty with the fitted EVM”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-MCQ-077. An observed AM envelope is altered by asymmetric sideband filtering. Which inference needs restraint?

A. The filter's measured response at tested frequencies

B. Source modulation depth inferred from the receiver output alone

C. The fact that the receiver retained some waveform

D. The distinction between carrier and sidebands

Answer: B. Receiver transfer can change the envelope; demodulator interpretation must use the admitted complex components. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: Source modulation depth inferred from the receiver output alone.

Distinguishing consideration: compare this with option A, “The filter's measured response at tested frequencies”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function; Chapter 6 — Model 6A: preserve the complex envelope; Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 6 — Model 6A: preserve the complex envelope; Chapter 14 — Build a correction chain with signs that can be checked.

V011-VOL-MCQ-078. A phase-difference estimator crosses a signal zero or reset. What must be retained?

A. The assumption that every phase difference is unique

B. Only wrapped phase samples joined without qualification

C. Validity flags, branch/reset information and the appropriate interval interpretation

D. A universal instantaneous frequency at the discontinuity

Answer: C. Phase-derived frequency and timing need a valid representation and state history. Source: §6.17 Model 6B: phase is the quantity that frequency differentiates (p. 3131)

Why the selected alternative fits: Validity flags, branch/reset information and the appropriate interval interpretation.

Distinguishing consideration: compare this with option A, “The assumption that every phase difference is unique”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 12 — Model 12A: connect clock reading, frequency and….

V011-VOL-MCQ-079. A narrow filter removes an FM sideband region while a scalar amplitude check still passes. What can fail?

A. The definition of nominal carrier frequency

B. Waveform or demodulation fidelity despite acceptable center-tone gain

C. Every possible power measurement automatically

D. Only byte storage format

Answer: B. A scalar transfer point does not establish the full waveform's amplitude/phase response. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: Waveform or demodulation fidelity despite acceptable center-tone gain.

Distinguishing consideration: compare this with option A, “The definition of nominal carrier frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 7 — Model 7A: a finite, declared EVM comparison.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 7 — Model 7A: a finite, declared EVM comparison.

V011-VOL-MCQ-082. A feature is present only after a gain transition and not in settled data. What is the next useful approach?

A. Delete it from every record because settled calibration passed

B. Apply settled gain to reconstruct all transition samples

C. Infer a unique external burst source from timing alone

D. A dedicated transition experiment with state and usable-time evidence

Answer: D. Control dynamics and acquisition validity define a distinct transient measurement. Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)

Why the selected alternative fits: A dedicated transition experiment with state and usable-time evidence.

Distinguishing consideration: compare this with option A, “Delete it from every record because settled calibration passed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 16 — Preserve comparable observation capability.

V011-VOL-MCQ-084. One attenuation challenge disagrees beyond uncertainty after a firmware update. What release action is appropriate?

A. Hide the difference under a new uncertainty selected to pass

B. Declare all prior native data invalid automatically

C. Investigate configuration-specific regression and preserve old/new processing states

D. Assume the update cannot change measurement behavior

Answer: C. A changed implementation can affect actual functions and correction applicability. Source: §10.66 Separate signed artifacts from operating configurations (p. 5770)

Why the selected alternative fits: Investigate configuration-specific regression and preserve old/new processing states.

Distinguishing consideration: compare this with option A, “Hide the difference under a new uncertainty selected to pass”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 14 — Calibration Lifecycle and Change Control; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-MCQ-087. A spectrum's noise floor falls after digital decimation. Which question prevents an overstated sensitivity claim?

A. Whether the decimator name implies gain

B. Whether band, normalization and preserved signal/noise transfer changed consistently

C. Whether the data file became smaller

D. Whether the plotted line became smoother only

Answer: B. A narrower noise bandwidth can lower integrated noise, but display scaling and alias control must be included. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: Whether band, normalization and preserved signal/noise transfer changed consistently.

Distinguishing consideration: compare this with option A, “Whether the decimator name implies gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator; Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

Review: Chapter 9 — Noise density uses a different denominator; Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

V011-VOL-MCQ-096. A final result includes native samples, exact processing and a reproducible number but no operational linkage. Which claim can still exceed its evidence?

A. The declared reproducible measured quantity within scope

B. A bounded waveform classification where validated

C. A documented unresolved observation

D. Confirmed technical-surveillance function

Answer: D. Reproducibility supports the measurement; functional attribution requires additional linkage and authorization evidence. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: Confirmed technical-surveillance function.

Distinguishing consideration: compare this with option A, “The declared reproducible measured quantity within scope”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 15 — Reproducible Analysis and Derived Products; Chapter 16 — Findings, Reports, and Decision Ladders.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 15 — Reproducible Analysis and Derived Products; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-MCQ-097. Two possible settled gain states give disjoint admissible input-level intervals, with no state probabilities. What should be retained?

A. Every intermediate value declared physically attainable

B. Only the interval yielding the preferred decision

C. Their midpoint with an invented Gaussian uncertainty

D. The union of the state-specific intervals

Answer: D. A set of possible states is not a probability law, and an uncertainty formula cannot supply missing state evidence. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why the selected alternative fits: The union of the state-specific intervals.

Distinguishing consideration: compare this with option A, “Every intermediate value declared physically attainable”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 16 — Close the receiver method through….

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-MCQ-098. Two phase-error vectors have equal marginal RMS but different covariance. Can their finite coherent-power losses be assumed equal?

A. Yes; marginal RMS uniquely fixes every coherence measure

B. Yes; FFT normalization removes covariance

C. No; coherent power is undefined for every random phase

D. No; pairwise phase differences and the distributional model matter

Answer: D. Finite coherent power depends on joint phase behavior, unlike a scalar RMS alone. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: No; pairwise phase differences and the distributional model matter.

Distinguishing consideration: compare this with option A, “Yes; marginal RMS uniquely fixes every coherence measure”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 9 — Define the ensemble before normalizing.

V011-VOL-MCQ-099. Two SSB waveforms have equal average power but different peak envelopes. What loading assessment remains necessary?

A. Only their shared mean level

B. Their instantaneous peak exposure at vulnerable stages

C. Only their equal integrated FFT power

D. Only their payload bit counts

Answer: B. Average energy closure does not establish equal compression or protection behavior. Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)

Why the selected alternative fits: Their instantaneous peak exposure at vulnerable stages.

Distinguishing consideration: compare this with option A, “Only their shared mean level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 3 — Find the first stage that can lose validity; Chapter 11 — Compression and Gain Change.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 3 — Find the first stage that can lose validity; Chapter 11 — Compression and Gain Change.

V011-VOL-MCQ-100. A missing input block is zero-filled before filtering and marked invalid. What makes this preferable to silently calling the zeros measured data?

A. The gap's timing uncertainty is necessarily zero

B. Every filtered output becomes valid immediately

C. Zero filling exactly reconstructs the missing waveform

D. The sample grid is retained while affected output support remains explicitly qualified

Answer: D. Representational preservation and physical reconstruction are different; support and metadata carry the limitation. Source: §10.50 A continuity condition for finite filtering and decimation (p. 5747)

Why the selected alternative fits: The sample grid is retained while affected output support remains explicitly qualified.

Distinguishing consideration: compare this with option A, “The gap's timing uncertainty is necessarily zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 1 — Model 1A: configured transfer, correction and....

Review: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Fill-in-the-Blank Questions

V011-VOL-FIB-001. To compare antenna-terminal and receiver-plane results, corrections must first refer both to the same physical _____.

Answer: plane. Configuration and uncertainty then describe one declared measurand rather than unlike output labels. Source: §1.11 Model 1A: configured transfer, correction and recoverability (p. 72)

Why this term is required: “plane” completes the stated technical proposition.

Question context: To compare antenna-terminal and receiver-plane results, corrections must first refer both to the same physical _____

Basis and qualification: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 13 — Define a complete path at named planes; Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 13 — Define a complete path at named planes; Chapter 14 — Build a correction chain with signs that can be checked.

V011-VOL-FIB-043. Integrated jitter must retain carrier frequency and the phase-noise integration _____.

Answer: band. The same RMS label can hide different spectral placement. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why this term is required: “band” completes the stated technical proposition.

Question context: Integrated jitter must retain carrier frequency and the phase-noise integration _____

Basis and qualification: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 11 — Integrate the channel that actually produces the reported value.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 11 — Integrate the channel that actually produces the reported value.

Copyright 2026, James M. Atkinson

V011-VOL-FIB-044. Reciprocal mixing weights oscillator phase noise at offsets set by admitted _____ signals.

Answer: blocker. A favorable integrated-jitter number alone does not bound the channel noise rise. Source: §11.25 Integrate the channel that actually produces the reported value (p. 6398)

Why this term is required: “blocker” completes the stated technical proposition.

Question context: Reciprocal mixing weights oscillator phase noise at offsets set by admitted _____ signals

Basis and qualification: Chapter 11 — Integrate the channel that actually produces the reported value; Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 11 — Integrate the channel that actually produces the reported value; Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-VOL-FIB-045. A delay correction applied after retuning requires renewed phase-repeatability and _____ applicability.

Answer: branch. A small uncertainty cannot validate an unresolved phase branch or changed state. Source: §12.30 Accept coherence at the required boundary and state (p. 6992)

Why this term is required: “branch” completes the stated technical proposition.

Question context: A delay correction applied after retuning requires renewed phase-repeatability and _____ applicability

Basis and qualification: Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-VOL-FIB-046. Deleting gaps from storage changes file offsets without preserving absolute source sample _____.

Answer: indices. The true elapsed-time and oscillator phase relationships can then be lost. Source: §10.49 Source indices, stored offsets, and time anchors (p. 5745)
Why this term is required: “indices” completes the stated technical proposition.
Question context: Deleting gaps from storage changes file offsets without preserving absolute source sample _____
Basis and qualification: Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Bind sample continuity, storage accounting and derived results.
Review: Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-FIB-072. At 20 MS/s, two complex channels with 16-bit components require _____ MB/s payload.

Answer: 160. 20 million×2 channels×2 components×2 bytes=160 million bytes per second. Source: §10.47 Data Transport, Gaps, and Reproducible Recording (p. 5743)

Why this term is required: “160” completes the stated technical proposition.

Question context: At 20 MS/s, two complex channels with 16-bit components require _____ MB/s payload

Basis and qualification: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

Review: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

Copyright 2026, James M. Atkinson

V011-VOL-FIB-073. That 160 MB/s payload over 100 s occupies _____ GB before overhead.

Answer: 16. The units are decimal; reserve and sustained-write behavior remain separate requirements. Source: §10.47 Data Transport, Gaps, and Reproducible Recording (p. 5743)

Why this term is required: “16” completes the stated technical proposition.

Question context: That 160 MB/s payload over 100 s occupies _____ GB before overhead

Basis and qualification: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

Review: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

V011-VOL-FIB-075. Eight million unique information bits delivered over 20 s give wall-interval throughput _____ Mb/s.

Answer: 0.4. The full interval denominator differs from an active-burst rate. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why this term is required: “0.4” completes the stated technical proposition.

Question context: Eight million unique information bits delivered over 20 s give wall-interval throughput _____ Mb/s

Basis and qualification: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Copyright 2026, James M. Atkinson

V011-VOL-FIB-076. Overlapping payload from two channels must be _____ before reporting unique delivery.

Answer: deduplicated. Multiple observations of the same positions do not increase the unique count. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why this term is required: “deduplicated” completes the stated technical proposition.

Question context: Overlapping payload from two channels must be _____ before reporting unique delivery

Basis and qualification: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

V011-VOL-FIB-086. After firmware changes, old and new processing configurations should be retained as distinct _____ until validated.

Answer: states. Regression establishes which deployed functions remain accepted.

Source: §10.66 Separate signed artifacts from operating configurations (p. 5770)

Why this term is required: “states” completes the stated technical proposition.

Question context: After firmware changes, old and new processing configurations should be retained as distinct _____ until validated

Basis and qualification: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 16 — Close the receiver method through configuration-specific regression.

Review: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 16 — Close the receiver method through configuration-specific regression.

Copyright 2026, James M. Atkinson

V011-VOL-FIB-087. A known-artifact record should preserve exact stimulus and configuration to test later _____.

Answer: applicability. A similar-looking trace is not a universal mechanism proof.

Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why this term is required: “applicability” completes the stated technical proposition.

Question context: A known-artifact record should preserve exact stimulus and configuration to test later _____

Basis and qualification: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 16 — Write findings that preserve the strength and limit of each test.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-FIB-092. A discrete phase-noise line must not be treated as a continuous spectral _____ over an arbitrary bin.

Answer: density. The integration measure and units determine its variance contribution. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “density” completes the stated technical proposition.

Question context: A discrete phase-noise line must not be treated as a continuous spectral _____ over an arbitrary bin

Basis and qualification: Chapter 9 — Noise density uses a different denominator; Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin.

Review: Chapter 9 — Noise density uses a different denominator; Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin.

Copyright 2026, James M. Atkinson

V011-VOL-FIB-093. Common-reference cancellation requires equal effective _____ into the compared channels.

Answer: coupling. A shared label alone does not justify covariance cancellation.

Source: §12.22 Application 12B.5: Include covariance when combining timing contributions (p. 6982)

Why this term is required: “coupling” completes the stated technical proposition.

Question context: Common-reference cancellation requires equal effective _____ into the compared channels

Basis and qualification: Chapter 12 — Application 12B.5: Include covariance when combining timing contributions; Chapter 14 — Application 14B.5: cancel a shared phase reference correctly.

Review: Chapter 12 — Application 12B.5: Include covariance when combining timing contributions; Chapter 14 — Application 14B.5: cancel a shared phase reference correctly.

V011-VOL-FIB-098. For a finite jointly Gaussian phase vector with specified mean phases, equal marginal phase RMS does not fix expected coherent power without the off-diagonal _____ terms.

Answer: covariance. The specified means and complete covariance matrix determine Gaussian phase-difference characteristic functions. Outside this Gaussian model, the relevant phase-difference distributions must also be justified; second-order covariance alone is insufficient. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why this term is required: “covariance” completes the stated technical proposition.

Question context: For a finite jointly Gaussian phase vector with specified mean phases, equal marginal phase RMS does not fix expected coherent power without the off-diagonal _____ terms

Basis and qualification: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 9 — Define the ensemble before normalizing.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-VOL-ESSAY-001. Design a receiver measurement from an authorized objective through a reproducible reported finding.

- Opening: Present a thesis that answers this precise question: Design a receiver measurement from an authorized objective through a reproducible reported finding. Identify which evidence would falsify the proposed conclusion Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)
- Core terminology and scope: Define Design, authorized, objective in the question's particular technical setting; explain how reproducible, reported, finding differ if that distinction would change the analysis of "Design a receiver measurement from an authorized objective through a reproducible reported finding" Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define the measurand, reference plane, event population and decision criterion Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a receiver measurement from an authorized objective through a reproducible reported finding to the claimed result, following "I/Q-derived modulation identity: distinguish discriminating features from unique source attribution"; name the intermediate states and measurable outputs Source: §7.27 I/Q-derived modulation identity: distinguish discriminating features from unique source attribution (p. 3801)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a receiver measurement from an authorized objective through a reproducible reported finding. Distinguish detection from functional attribution and state the accepted scope Source: §7.27 I/Q-derived modulation identity: distinguish discriminating features from unique source attribution (p. 3801)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Define sensitivity as a reproducible decision” that resolves the question about a receiver measurement from an authorized objective through a reproducible reported finding; derive the relevant result with units and stated validity conditions Source: §2.5 Define sensitivity as a reproducible decision (p. 653)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a receiver measurement from an authorized objective through a reproducible reported finding. Distinguish detection from functional attribution and state the accepted scope Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)
- Worked application or illustrative case: Build a worked example of “a receiver measurement from an authorized objective through a reproducible reported finding”, addressing this associated condition: Define the measurand, reference plane, event population and decision criterion. Define the measurand, reference plane, event population and decision criterion Source: §7.27 I/Q-derived modulation identity: distinguish discriminating features from unique source attribution (p. 3801)

Copyright 2026, James M. Atkinson

- Alternative explanations and failure modes: Construct two plausible technical explanations for “a receiver measurement from an authorized objective through a reproducible reported finding”. Using “Define sensitivity as a reproducible decision”, specify a discriminator and the result expected under each explanation Source: §2.5 Define sensitivity as a reproducible decision (p. 653)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to a receiver measurement from an authorized objective through a reproducible reported finding, including the effect of missing measurements and inconsistent operating conditions Source: §5.27 Calibration and negative-survey validity for dynamic IF paths (p. 2559)
- Scholarly synthesis and implications: Explain what the result about a receiver measurement from an authorized objective through a reproducible reported finding authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)
- Closing: Conclude by answering “Design a receiver measurement from an authorized objective through a reproducible reported finding” using only the demonstrated evidence; state the remaining decisive verification step Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

V011-VOL-ESSAY-026. Construct a domain-aware uncertainty treatment for a logarithm of an added-noise estimate.

- Opening: Present a thesis that answers this precise question: Construct a domain-aware uncertainty treatment for a logarithm of an added-noise estimate. Identify which evidence would falsify the proposed conclusion Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)
- Core terminology and scope: Define Construct, domain-aware, uncertainty in the question's particular technical setting; explain how treatment, logarithm, estimate differ if that distinction would change the analysis of "Construct a domain-aware uncertainty treatment for a logarithm of an added-noise estimate" Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Start from matched on/off transfer and additive powers, retain covariance and the complete possible domain, then distinguish exact linear difference variance from local log dispersion Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a domain-aware uncertainty treatment for a logarithm of an added-noise estimate to the claimed result, following "From a calculated temperature to a defended result"; name the intermediate states and measurable outputs Source: §2.28 From a calculated temperature to a defended result (p. 689)

V011-VOL-ESSAY-050. Develop an end-to-end case in which the reported conclusion is narrowed after a justified technical correction.

- Opening: Present a thesis that answers this precise question: Develop an end-to-end case in which the reported conclusion is narrowed after a justified technical correction. Identify which evidence would falsify the proposed conclusion Source: §16.15 Close the receiver method through configuration-specific regression (p. 9287)
- Core terminology and scope: Define case, reported, conclusion in the question's particular technical setting; explain how justified, technical, correction differ if that distinction would change the analysis of "Develop an end-to-end case in which the reported conclusion is narrowed after a justified technical correction" Source: §16.15 Close the receiver method through configuration-specific regression (p. 9287)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define the original measurement and source records, identify a concrete state/normalization/coverage error, recompute with valid models and preserve both versions Source: §16.15 Close the receiver method through configuration-specific regression (p. 9287)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting an end-to-end case in which the reported conclusion is narrowed after a justified technical correction to the claimed result, following "Reproducible Analysis and Derived Products"; name the intermediate states and measurable outputs Source: §15.18 Reproducible Analysis and Derived Products (p. 8706)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for an end-to-end case in which the reported conclusion is narrowed after a justified technical correction. Explain which observation remains, which inference changes and what regression prevents recurrence Source: §15.18 Reproducible Analysis and Derived Products (p. 8706)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Case study 3.D8. Temperature-dependent drift and the risk of overcorrection” that resolves the question about an end-to-end case in which the reported conclusion is narrowed after a justified technical correction; derive the relevant result with units and stated validity conditions Source: §3.33.8 Case study 3.D8. Temperature-dependent drift and the risk of overcorrection (p. 1342)
- Evidence and method: Specify the native observations, control records and calculations that would resolve an end-to-end case in which the reported conclusion is narrowed after a justified technical correction. Explain which observation remains, which inference changes and what regression prevents recurrence Source: §16.15 Close the receiver method through configuration-specific regression (p. 9287)
- Worked application or illustrative case: Build a worked example of “an end-to-end case in which the reported conclusion is narrowed after a justified technical correction”, addressing this associated condition: Define the original measurement and source records, identify a concrete state/normalization/coverage error,.... Define the original measurement and source records, identify a concrete

Discussion Questions

[Discussion instructions: For each discussion question, prepare approximately 500 spoken words for delivery over 2.5–3 minutes (approximately 167–200 words per minute). Address the ten subject prompts below in their stated order. Use the opening to frame the issue and the closing to synthesise the principal findings, conclusions and unresolved questions.]

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-001. A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. How would you redirect the work?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. How would you redirect the work?” Put this particular dispute to the panel: A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. How would you redirect the work. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 02. Student A, terminology and scope: Agree the operational meanings of chooses, needs, terminal and strength, attribution, work in “A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. How would you redirect the work”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and

Copyright 2026, James M. Atkinson

request a specific example from the stated receiver scenario. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Attach calibration to a stated measurement result”. Explain that one receiver output cannot silently serve all three claims and preserve the authorization and observation scope Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §13.18.10 Example 13.X10. Why field strength cannot be inferred from connector power alone (p. 7575)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Attach calibration to a stated measurement result”. Explain that one receiver output cannot silently serve all three claims and preserve the authorization and observation scope Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Define the intended quantity and evidential category first, then select reference planes, configuration, calibration and tests Put two specific questions to

Copyright 2026, James M. Atkinson

Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is

missing. Source: §13.18.10 Example 13.X10. Why field strength cannot be inferred from connector power alone (p. 7575)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Copyright 2026, James M. Atkinson

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. Explain that one receiver output cannot silently serve all three claims and preserve the authorization and observation scope Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §13.18.10 Example 13.X10. Why field strength cannot be inferred from connector power alone (p. 7575)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A team chooses a receiver mode before

Copyright 2026, James M. Atkinson

deciding whether the report needs terminal power, field strength or device attribution, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. Explain that one receiver output cannot silently serve all three claims and preserve the authorization and observation scope Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §13.18.10 Example 13.X10. Why field strength cannot be inferred from connector power alone (p. 7575)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or

Copyright 2026, James M. Atkinson

device attribution and How would you redirect the work; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution”, addressing “How would you redirect the work”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A team chooses a receiver mode before deciding whether the report needs terminal power, field strength or device attribution. How would you redirect the work”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the

V011-VOL-DISCUSSION-002. Two layouts have identical total gain, and the procurement comparison calls them equally sensitive. What should be evaluated?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Two layouts have identical total gain, and the procurement comparison calls them equally sensitive. What should be evaluated?” Put this particular dispute to the panel: Two layouts have identical total gain, and the procurement comparison calls them equally sensitive. What should be evaluated. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §2.20 Application 2B.3: distinguish loss from temperature (p. 680)

- 02. Student A, terminology and scope: Agree the operational meanings of identical, total, calls and equally, sensitive, evaluated in “Two layouts have identical total gain, and the procurement comparison calls them equally sensitive. What should be evaluated”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §2.20 Application 2B.3: distinguish loss from temperature (p. 680)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of Two layouts have identical total gain, and the procurement comparison calls them equally sensitive; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Derive passive loss from thermal equilibrium”. Include remote gain and passive-loss temperature where relevant; equal desired gain is insufficient for equal detection capability Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two layouts have identical

V011-VOL-DISCUSSION-011. Only the hot noise state approaches converter clipping. How should the calibration be interpreted?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Only the hot noise state approaches converter clipping. How should the calibration be interpreted?” Put this particular dispute to the panel: Only the hot noise state approaches converter clipping. How should the calibration be interpreted. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

- 02. Student A, terminology and scope: Agree the operational meanings of noise, approaches, converter and clipping, calibration, interpreted in “Only the hot noise state approaches converter clipping. How should the calibration be interpreted”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of Only the hot noise state approaches converter clipping; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “From a calculated temperature to a defended result”. Cold-state linearity and averaging cannot justify an inversion using distorted hot power Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Only the hot noise state approaches converter clipping; explain what each record can establish State what the existing record establishes, what it does not

trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A narrow source-generated spur and receiver spur share frequency; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §12.23 Application 12B.6: Distinguish a common random phase from lost coherent power (p. 6983)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Falsification-led survey closure and the evidential status of negative observations”. Use phasor bounds or independent source/combiner characterization with a stage-specific challenge Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §16.16 Falsification-led survey closure and the evidential status of negative observations (p. 9288)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Unknown relative phase permits reinforcement or cancellation, so the measured total is not necessarily a sum of independent powers Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would

Copyright 2026, James M. Atkinson

discriminate between them without changing the measurand. Source: §11.19 Application 11A.10 Bound a coherent contaminating product (p. 6388)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A narrow source-generated spur and receiver spur share frequency: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §11.19 Application 11A.10 Bound a coherent contaminating product (p. 6388)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A narrow source-generated spur and receiver spur share frequency; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §12.23 Application 12B.6: Distinguish a common random phase from lost coherent power (p. 6983)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A narrow source-generated spur and receiver spur share frequency: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §11.19 Application 11A.10 Bound a coherent contaminating product (p. 6388)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A narrow source-generated spur and receiver spur share frequency, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §16.16 Falsification-led survey closure and the evidential status of negative observations (p. 9288)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A narrow source-generated spur and receiver spur share frequency:

V011-VOL-DISCUSSION-057. A decoder passes its training waveform but fails a separately captured reference. What should be released?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A decoder passes its training waveform but fails a separately captured reference. What should be released?” Put this particular dispute to the panel: A decoder passes its training waveform but fails a separately captured reference. What should be released. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

- 02. Student A, terminology and scope: Agree the operational meanings of decoder, passes, training and fails, captured, released in “A decoder passes its training waveform but fails a separately captured reference. What should be released”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A decoder passes its training waveform but fails a separately captured reference; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Application 7A.1: Show which error a fitted gain removes”. Investigate alignment and applicability, and avoid representing fitted success as general receiver performance Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A decoder passes its training waveform but fails a separately captured reference; explain what

opinion. Source: §7.22.5 Application 7B.5. Weight changing modes by their actual durations (p. 3783)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Noise density uses a different denominator”. The same bits can support different rates only with explicit denominators Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. State active and full wall intervals separately, use actual delivered counts and duration weighting, and retain gaps/exclusions Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval (p. 3782)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A burst receiver reports its active rate as a whole-survey rate: specify the altered receiver state or source

Copyright 2026, James M. Atkinson

condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval (p. 3782)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A burst receiver reports its active rate as a whole-survey rate; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §7.22.5 Application 7B.5. Weight changing modes by their actual durations (p. 3783)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A burst receiver reports its active rate as a whole-survey rate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive

Copyright 2026, James M. Atkinson

the proposed test. Source: §7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval (p. 3782)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A burst receiver reports its active rate as a whole-survey rate, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A burst receiver reports its active rate as a whole-survey rate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval (p. 3782)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A burst receiver reports its active rate as a

Volume Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-VOL-ESSAY-001 — Define the measurand, reference plane, event population and decision criterion; map the complete analog/digital/recording chain; identify irreversible losses; and link calibration, uncertainty, coverage and challenge evidence. Distinguish detection from functional attribution and state the accepted scope.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 14 — Attach calibration to a stated measurement result; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-ESSAY-002 — Derive their matched noise weighting, track desired and blocker levels at each stage, and assess installed bias/stability and field geometry. Specify reference tests for actual transfer, loading and capability; explain why a common corrected mean level does not establish equal sensitivity.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval; Chapter 13 — Remote amplification requires electrical and installed checks.

V011-VOL-ESSAY-003 — State the lower gain condition from later-stage noise and upper condition from admitted blockers or converter range. Include preselector loss/rejection, empty-interval handling and state validity. Explain why digital scaling cannot repair analog SNR or clipping.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Choose gain from a feasible interval; Chapter 10 — Range and error are separate obligations; Chapter 11 — Compression and Gain Change.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-004 — Separate protection leakage, survival and observable-specific recovery; retain a weak reference through a bounded strong event. Track AGC/filter/trigger persistence, establish valid intervals and calculate coverage only from those intervals. Do not equate a survival rating with restored measurement quality.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-ESSAY-005 — Subtract compatible linear powers before logarithms, use applicable transfer at named planes and distinguish unknown-state sets from statistical uncertainty. Propagate supported dependencies, check log-domain positivity and independently close the forward calculation.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Build a correction chain with signs that can be checked; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-006 — Record source temperatures at the receiver plane, passive loss and physical temperature, hot/cold linear powers, bandwidth, matching and common gain. Check hot-state compression, source-state settling and covariance, then distinguish the noise result from waveform-specific detection verification.

Review: Chapter 2 — Invert the same model with two source temperatures; Chapter 13 — Treat connections and unused branches as part of the network; Chapter 14 — Calibrate noise without confusing it with detection; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-ESSAY-007 — Retain signed frequency, LO branches, image intervals, sampling equivalence and NCO convention. Predict movement under a controlled change and preserve desired transfer; explain why one moving line cannot uniquely establish an image or external source.

Review: Chapter 4 — Model 4A: a declared conversion map; Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-ESSAY-008 — Use complex-envelope representation and declared average/peak conventions, measure amplitude and phase response over occupied bandwidth, and assess stage loading. Explain envelope reversal or filtering ambiguities and limit source-modulation claims when the path is incompletely characterized.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 3 — Use preselection as a measured transfer function; Chapter 11 — Compression and Gain Change.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-009 — Define nonzero/valid signal intervals, branch handling, finite-difference meaning and resets. Retain absolute sample indices and deterministic clock mapping; distinguish carrier offset from modulation and avoid treating discontinuous records as one coherent trajectory.

Review: Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-VOL-ESSAY-010 — Define symbol populations, reference energies and fit degrees of freedom; retain the fitted coefficient and unfitted phase result. Use held-out data and demonstrate which physical error the fit can conceal. Separate lower residual from improved clock or receiver calibration.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-ESSAY-011 — Specify training/evaluation symbols, weights, normalization and excluded startup data; verify actual receiver state and event boundaries. Report settled-payload quality separately from whole-burst capture and avoid using a clean selected constellation as evidence for omitted intervals.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Verify the trigger at its actual signal-path location.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-012 — Define finite symbol/bit/frame populations, overhead ownership, active and wall intervals, unique payload positions and retransmissions. Separately compute stored I/Q bytes with container width and channels, and retain chronology and continuity so neither storage rate nor coded count is mislabeled as information delivery.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

V011-VOL-ESSAY-013 — Relate each to the intended tone, density, integrated-power or transient estimate; describe window normalization and sweep/filter settling. Show why finer plotted frequency spacing or a lower displayed floor does not add measured history or establish event detectability.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory; Chapter 9 — Define the record before interpreting the display; Chapter 9 — Noise density uses a different denominator; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-ESSAY-014 — Define the actual estimator and source law, distinguish gamma/log-bias conditions from intermittent mixtures, and subtract compatible additive powers before logs. Retain covariance and positivity domains; explain why display smoothness or repeated averaging does not validate an inapplicable statistical correction.

Review: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace; Chapter 8 — A stated statistical model; Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-015 — Specify paired ensembles, conjugation/channel order, window normalization and phase branch; retain actual sample indices and clock relationships. Analyze shared contributions and coherence limits, and distinguish a one-pair unity estimate from evidence of a physical coupling.

Review: Chapter 9 — Define the ensemble before normalizing; Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis; Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-VOL-ESSAY-016 — Include native format and scale, absolute indices, oscillator phase, filter history, decimation phase, valid supports and software identity. Bind calibration and selected interval, test with known references and retain gaps; explain why byte hashes or a similar plot alone are insufficient.

Review: Chapter 10 — Signed formats and explicit conversion points; Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 10 — Separate signed artifacts from operating configurations; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-ESSAY-017 — Compare zero filling with silent deletion, map nonzero filter support to affected outputs and retain absolute phase/time. Restrict uniform-sampling estimators to valid segments or state a different model. Distinguish a preserved grid from reconstructed missing waveform.

Review: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 9 — Define the record before interpreting the display; Chapter 15 — Bind sample continuity, storage accounting and derived results.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-018 — Define signed formats and conversion points, bound intermediate ranges and rounding, check clipping/overflow with known stimuli, and retain scale metadata. Explain why digital gain can improve representation use without recovering an already lost analog SNR or waveform.

Review: Chapter 10 — Range and error are separate obligations; Chapter 10 — Quantization margin and channel bandwidth; Chapter 2 — Turn the cascade into bounded design requirements; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

V011-VOL-ESSAY-019 — Specify parent powers, frequencies, loading and stage reference plane; use the local cubic law only within its domain, retain per-tone convention and intercept asymptote. Characterize sources/combiners and coherent contamination, then vary a control before the proposed stage while preserving desired capability.

Review: Chapter 11 — Fix the voltage convention and operating domain; Chapter 11 — Construct the intercept from the linear asymptote; Chapter 11 — Ten worked applications of Model 11A; Chapter 16 — Localize an artifact by changing the stage that could create it.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-020 — Use paired desired-reference and blocker observations, identify gain/band/state changes, characterize source spectrum and channel weighting, and test oscillator phase-noise relevance. State which models survive each outcome instead of assigning one universal dynamic-range score.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions; Chapter 11 — Integrate the channel that actually produces the reported value; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-VOL-ESSAY-021 — Define deterministic clock error, finite integration band and carrier conversion, then discuss covariance and Gaussian premises for phase differences. Include common random rotation and independent/correlated cases, and show why equal scalar RMS does not fix every receiver consequence.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 9 — Define the ensemble before normalizing; Chapter 11 — Integrate the channel that actually produces the reported value.

V011-VOL-ESSAY-022 — Account for cable/filter/conversion phase, reference distribution, epoch, trigger and index mapping. Test retune/reset repeatability, preserve branch and uncertainty, and explain what a shared clock or one calibration tone does not establish.

Review: Chapter 12 — Accept coherence at the required boundary and state; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 14 — Frequency, phase, and delay require their own observables; Chapter 15 — Verify the trigger at its actual signal-path location.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-023 — Separate antenna-terminal power from field conversion, state loading/polarization/geometry/field-region conditions, and include remote paths and common mode. Assign corrections once, verify the installed arrangement and distinguish traceability from complete applicability.

Review: Chapter 13 — Keep field conversion separate from terminal power; Chapter 13 — Define a complete path at named planes; Chapter 14 — Attach calibration to a stated measurement result.

V011-VOL-ESSAY-024 — Characterize new gain, noise, bandwidth, timing and power-state behavior; carry a relevant weak reference; preserve geometry and raw comparisons. State alternative effects of the intervention and the bounded inference when capability cannot be matched.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 12 — Accept coherence at the required boundary and state; Chapter 16 — Preserve comparable observation capability.

V011-VOL-ESSAY-025 — Write signed equations for a phase difference and an averaged corrected level, show cancellation versus persistence, and avoid double counting. Check matrix admissibility and units; explain why shared labels or separate budget rows do not establish the required dependence.

Review: Chapter 12 — Application 12B.5: Include covariance when combining timing contributions; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 14 — Application 14B.5: cancel a shared phase reference correctly; Chapter 14 — Application 14B.8: identify the uncertainty that averaging cannot remove.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-026 — Start from matched on/off transfer and additive powers, retain covariance and the complete possible domain, then distinguish exact linear difference variance from local log dispersion. Explain what changes if zero is admitted and why neither a positive center nor factor-two interval proves positivity.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-VOL-ESSAY-027 — Compare a signed affine correction with hot/cold inversion, phase-slope delay and squared-voltage power. Identify finite-moment requirements, curvature/singularity boundaries and input distributions; show why numerical simulation cannot validate unsupported physical assumptions.

Review: Chapter 2 — Invert the same model with two source temperatures; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-028 — State the measurand and applicable correction, propagate supported dependencies, justify the coverage factor and predeclare accept/reject/indeterminate conditions. Explain how follow-up should target dominant terms while preserving the original rule and result.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 14 — Declare the decision rule before seeing the result; Chapter 14 — Application 14B.8: identify the uncertainty that averaging cannot remove; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

V011-VOL-ESSAY-029 — Derive eligible starts for a declared positive contiguous criterion, preserve actual record continuity, merge periodic unions and justify the event-phase law. Keep detector validity separate and show why disconnected pieces or nominal command spans cannot be counted as one record.

Review: Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-VOL-ESSAY-030 — Define the relative event/schedule phase, derive complement multiplication only where justified, retain unequal probabilities or joint dependence and analyze endpoint trial counts. Explain how actual schedule changes differ from saving more copies of the same observation.

Review: Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 15 — Application 15A.7: Keep a deterministic repeated miss deterministic; Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-031 — Map trigger and recording path locations, test relevant stimulus shapes and event pairs, establish pretrigger validity and recovery, and relate trigger timestamps to sample apertures. Retain complete boundaries, gap evidence and limits of a CW-only check.

Review: Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 10 — Source indices, stored offsets, and time anchors.

V011-VOL-ESSAY-032 — Calculate payload using actual representation, include overhead and reserve, test full-duration writing and rollover, and monitor counters/clock/overruns. Hash closed files and bind metadata, but distinguish byte consistency from acquisition continuity and valid coverage.

Review: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-ESSAY-033 — Retain source hashes, intervals, channels, scales, calibration, windows, alignment, exclusions and manual decisions. Use a second implementation and reference/noise-only records where relevant, disclose parameter sensitivity and avoid treating multiple outputs from one source as independent evidence.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 9 — Estimator Validation and Reporting; Chapter 15 — Reproducible Analysis and Derived Products; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-034 — Define actual physical state bundles, all meaningful combinations, response plane and criterion, capable references, fresh replications and run-order/blocking plan. Retain missing states, transitions and alternatives; explain why interaction alone does not name the responsible circuit.

Review: Chapter 16 — Receiver challenges with interacting controls; Chapter 16 — Arrange the comparisons before examining their outcomes; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 15 — Verify the trigger at its actual signal-path location.

V011-VOL-ESSAY-035 — Map shared antenna, clock, power, software and correction paths; verify the relevant weak or burst reference in each state. Distinguish agreement, disagreement and nondetection at tested limits, then identify an intervention that changes the relevant error structure.

Review: Chapter 13 — A constructed acceptance case for the assembled chain; Chapter 12 — Accept coherence at the required boundary and state; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-ESSAY-036 — Define each direct observable and clock/state relationship, identify shared causes and processing, and distinguish correlation from physical linkage. Require appropriate localization and information-path evidence before advancing the finding category.

Review: Chapter 15 — Metadata, Time, and Site Context; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence; Chapter 16 — Findings, Reports, and Decision Ladders.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-037 — Use corrected same-plane differences with uncertainty for compatibility, predeclared challenges for mechanisms and additional physical/operational evidence for function. Explain why a favorable test count, decoded identifier or low EVM cannot supply unspecified likelihoods or authorization.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 16 — Reconcile evidence without assigning unsupported probabilities; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-ESSAY-038 — Preserve old/new executable and configuration identities, reuse accepted references across levels and states, rerun retained samples and compare both derivations. Check scale, correction, alignment and timing separately; keep native observations and explain revised outputs.

Review: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 14 — Close the calibration record across the working interval; Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-ESSAY-039 — Identify the affected function, last demonstrated valid state and change time; preserve native data and both reference results. Investigate whether a bounded retrospective correction is supported, qualify unknown intervals and avoid silently extending the latest calibration backward.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 13 — Integrated Path Acceptance; Chapter 14 — Close the calibration record across the working interval; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-040 — State separate domains, identify additional geometry, trigger, recovery and coverage evidence needed, and retain usable narrow claims. Explain why a valid certificate or repeated successful use does not automatically extend acceptance.

Review: Chapter 13 — A constructed acceptance case for the assembled chain; Chapter 14 — Attach calibration to a stated measurement result; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-ESSAY-041 — Use examples of wrong cable, duplicated correction, binary-point error and incorrect covariance. Explain which require correcting the model or data identity rather than enlarging a budget, and specify independent physical and arithmetic checks.

Review: Chapter 13 — Define a complete path at named planes; Chapter 10 — Signed formats and explicit conversion points; Chapter 14 — Attach calibration to a stated measurement result.

V011-VOL-ESSAY-042 — Track desired spectral transfer, ENBW, time response and trigger-path location; keep normalization and state corrections explicit. Use a known waveform and blocker challenge to distinguish a useful rejection improvement from discarded information or sensitivity change.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 9 — Noise density uses a different denominator; Chapter 15 — Verify the trigger at its actual signal-path location.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-043 — Follow analog/digital frequency maps, validate synchronization and symbol mapping with references, preserve held-out/noise-only tests and state uncertainty. Report the classification actually supported without converting plausible content into device attribution.

Review: Chapter 4 — Model 4A: a declared conversion map; Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation; Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Interpret hypothetical receiver records.

V011-VOL-ESSAY-044 — Use phase-error cancellation in one difference and shared error in two agreeing receivers. State coupling and covariance, retain absolute versus relative scope, and propose an independent reference/path observation when required.

Review: Chapter 12 — Application 12B.5: Include covariance when combining timing contributions; Chapter 14 — Application 14B.5: cancel a shared phase reference correctly; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence.

V011-VOL-ESSAY-045 — Reconcile planned, commanded, valid and preserved intervals, passbands, source states and event classes. Include sensitivity, trigger and schedule assumptions; identify gap/guard exclusions and avoid claiming absence beyond the supported acquisition.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-046 — Use complex-envelope or SSB examples to distinguish mean, peak and coherent contributions; show how a correctly normalized FFT can conserve energy while missing relevant peak loading or temporal recovery. Retain waveform and stage-level evidence for nonlinearity/protection claims.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 9 — Energy closure and its limits; Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 11 — Compression and Gain Change.

V011-VOL-ESSAY-047 — Distinguish lines from densities, retain finite bands and carrier conversion, and apply actual channel weighting to admitted blockers. Identify unmeasured bands and avoid using one integrated RMS to certify every coherent or reciprocal-mixing condition.

Review: Chapter 9 — Noise density uses a different denominator; Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin; Chapter 11 — Integrate the channel that actually produces the reported value.

V011-VOL-ESSAY-048 — Derive state-specific admissible corrected results, preserve disjoint unions and missing validity intervals, and avoid assigning probabilities without evidence. Explain which follow-up can identify the state and how release is narrowed if it cannot.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 14 — Declare the decision rule before seeing the result; Chapter 16 — Close the receiver method through configuration-specific regression.

Copyright 2026, James M. Atkinson

V011-VOL-ESSAY-049 — Trace each plot, decode, EVM, trigger log and comparison to native sources and shared clocks/software. Retain complementary observables but avoid unsupported multiplication; identify missing physical contrasts and specify the evidence for any proposed likelihood model.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 15 — Reproducible Analysis and Derived Products; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

V011-VOL-ESSAY-050 — Define the original measurement and source records, identify a concrete state/normalization/coverage error, recompute with valid models and preserve both versions. Explain which observation remains, which inference changes and what regression prevents recurrence.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 9 — Estimator Validation and Reporting; Chapter 14 — Close the calibration record across the working interval; Chapter 16 — Close the receiver method through configuration-specific regression.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-VOL-DISCUSSION-001 — Define the intended quantity and evidential category first, then select reference planes, configuration, calibration and tests. Explain that one receiver output cannot silently serve all three claims and preserve the authorization and observation scope.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 13 — Keep field conversion separate from terminal power; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-DISCUSSION-002 — Compare component order, input-equivalent noise and blocker exposure, then validate actual assembled transfer. Include remote gain and passive-loss temperature where relevant; equal desired gain is insufficient for equal detection capability.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval; Chapter 13 — Define a complete path at named planes.

V011-VOL-DISCUSSION-003 — Show that neither constraint is necessarily met, identify the empty feasible interval and propose changing rejection, stage placement or operating conditions. Keep desired transfer, sensitivity and loading requirements explicit.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Choose gain from a feasible interval; Chapter 11 — Dynamic Range Is a Family of Conditions.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-004 — Consider total mean power and possible instantaneous/coherent loading at each vulnerable stage, with actual frequency-dependent admission. Use the local nonlinear model only where supported and preserve a weak-reference challenge.

Review: Chapter 3 — Find the first stage that can lose validity; Chapter 11 — Fix the voltage convention and operating domain; Chapter 13 — A constructed acceptance case for the assembled chain.

V011-VOL-DISCUSSION-005 — Compare desired amplitude/phase response across the waveform, rejected blockers, noise bandwidth and gain state. Retain the improvement and waveform cost separately; center-tone gain or a quieter display does not establish overall fidelity.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 9 — Noise density uses a different denominator.

V011-VOL-DISCUSSION-006 — Treat the noise bound as one requirement, characterize rejection at actual blocker frequencies and confirm loading before the vulnerable stage. Avoid transferring desired-frequency loss to the blocker path.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 3 — Use preselection as a measured transfer function; Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-007 — Include dissipative noise temperature, referred downstream noise, desired loss and impedance-sensitive receiver behavior. Evaluate target sensitivity and uncertainty rather than declaring a match improvement universally beneficial.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 13 — Treat connections and unused branches as part of the network; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-DISCUSSION-008 — Keep reference noise factor separate from actual source-temperature degradation, use the applicable cascade and bandwidth, and verify the detection procedure separately. Explain the zero-added-noise exception without generalizing it.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 14 — Calibrate noise without confusing it with detection; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-DISCUSSION-009 — Retain hot/cold powers and receiver-plane temperatures, assess delivered noise and impedance-dependent receiver response, and establish common gain, bandwidth and linearity. A scalar ENR entry alone does not close the model.

Review: Chapter 2 — Invert the same model with two source temperatures; Chapter 13 — Treat connections and unused branches as part of the network; Chapter 14 — Calibrate noise without confusing it with detection.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-010 — It establishes repeated behavior of that state-dependent experiment, not the equal-gain inverse. Recover or model gain states, test settling and compression and recompute under valid assumptions.

Review: Chapter 2 — Invert the same model with two source temperatures; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-DISCUSSION-011 — Inspect raw range flags and actual transfer, reduce loading or adopt a validated configuration, and retain the failed condition. Cold-state linearity and averaging cannot justify an inversion using distorted hot power.

Review: Chapter 2 — Invert the same model with two source temperatures; Chapter 10 — Quantization, Clipping, and Converter Performance; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-DISCUSSION-012 — Require event-specific waveform/threshold tests, instantaneous-band coverage and usable schedule with a justified phase law. Distinguish noise calibration from timing opportunity and decision performance.

Review: Chapter 2 — Turn the cascade into bounded design requirements; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 16 — Preserve comparable observation capability.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-013 — Identify the model mismatch, retain actual state history and seek an additional-state or changed-target explanation. Do not force the observed trajectory into a monotone inverse; restrict corrected intervals to validated behavior.

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-DISCUSSION-014 — Carry the actual terminal state into the new interval, use identified attack/release conditions and retain valid sample timing. Do not restart from equilibrium merely because a new file begins.

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-DISCUSSION-015 — Use the observable-specific phase criterion and calibrated timing boundary, while retaining the different amplitude recovery. Hardware survival or amplitude closure cannot establish restored coherent validity.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-DISCUSSION-016 — Map the detector/AGC path, exercise relevant leading edges and prior states, and measure trigger-to-sample timing with paired events. Incorporate demonstrated exclusions into usable coverage.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-017 — Characterize impulse/time response and detector behavior, compare a known pulse through the same path and retain valid context. A ringing output is not automatically a prolonged external transmission.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 15 — Verify the trigger at its actual signal-path location.

V011-VOL-DISCUSSION-018 — Verify the frequency-time trajectory and filter settling using a suitable signal, retain bandwidth/detector state and valid intervals, and distinguish smooth presentation from response validity.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory; Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 14 — Build a correction chain with signs that can be checked.

V011-VOL-DISCUSSION-019 — Identify the detector and averaging operation, quantify noise/statistical change and validate the intended event response. Smoothing can conceal variation or short events without changing upstream noise performance.

Review: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace; Chapter 2 — Turn the cascade into bounded design requirements; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-020 — Reconstruct linear-power averaging versus log-level averaging, source law and normalization, then report the declared estimator. Calibration agreement is not meaningful until both results describe the same quantity.

Review: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace; Chapter 9 — Estimator Validation and Reporting; Chapter 14 — Attach calibration to a stated measurement result.

V011-VOL-DISCUSSION-021 — The conditional/common-mean distributional premises may fail; inspect the mixture and actual operation order. Preserve raw powers and derive or validate an appropriate correction rather than reuse a label-based constant.

Review: Chapter 8 — A stated statistical model; Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-VOL-DISCUSSION-022 — Correct each accepted interval to a common plane, then duration-weight physical powers for the requested mean. Retain unknown/invalid intervals and distinguish the result from an average of logarithmic labels.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-023 — Establish compatible fixed transfer and additive-power conditions, subtract in linear units and retain covariance. Transform only a supported positive difference and explain that the original dB subtraction formed a ratio.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 11 — Convert added power into a conditional noise-rise limit; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-VOL-DISCUSSION-024 — No; retain the linear result and clarify physical/model interpretation. Clipping changes the estimator, while a finite logarithm cannot cover nonpositive values; use a justified domain-aware treatment.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-VOL-DISCUSSION-025 — Unknown relative phase permits reinforcement or cancellation, so the measured total is not necessarily a sum of independent powers. Use phasor bounds or independent source/combiner characterization with a stage-specific challenge.

Review: Chapter 4 — Model 4A: a declared conversion map; Chapter 11 — Ten worked applications of Model 11A; Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-026 — Both admitted RF intervals, signed conversion branch, preselection and potential coherent combination. Verify transfer separately and challenge the image path; one IF label cannot identify a unique original RF source.

Review: Chapter 4 — Model 4A: a declared conversion map; Chapter 3 — Use preselection as a measured transfer function; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-DISCUSSION-027 — Track spectral orientation and digital phase-derivative convention through the configured path. Test a known modulation before asserting a source change, and preserve branch and reference information.

Review: Chapter 4 — Model 4A: a declared conversion map; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 10 — Model 10B for digital mixing filtering and decimation.

V011-VOL-DISCUSSION-028 — Separate predicted alias mapping from changed admission and transfer, preserve a reference and characterize both configurations. Movement alone is not a unique alias proof when several factors change.

Review: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation; Chapter 3 — Use preselection as a measured transfer function; Chapter 16 — Receiver challenges with interacting controls.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-029 — Reproduce the intended absolute-index mixing law across continuous blocks, retain original and revised outputs and show the artifact's dependence on the reset. Do not alter native samples to hide the earlier processing error.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 12 — Accept coherence at the required boundary and state; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-DISCUSSION-030 — Propagate invalid support through the channelizer/filter and retained output phases, inspect actual indices and preserve the gap. Do not assume a new RF source merely because the transient appears in a separate channel.

Review: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 10 — Model 10C for a polyphase analysis channelizer; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-DISCUSSION-031 — State that the grid is preserved but waveform values are not measured, mark affected filter outputs and limit later estimators. Keep the gap map and distinguish representation continuity from physical acquisition completeness.

Review: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-032 — The changed index-to-time relation, artificial join and oscillator/filter state, then compare only justified valid segments. A cleaner plot does not demonstrate restoration of the missing event or original frequency law.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 9 — Define the record before interpreting the display; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-VOL-DISCUSSION-033 — Use a known physical reference with declared format and calibration, independently verify binary-point and units, and retain software identities. Agreement on identical misinterpreted inputs is limited evidence.

Review: Chapter 10 — Signed formats and explicit conversion points; Chapter 14 — Build a correction chain with signs that can be checked; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence.

V011-VOL-DISCUSSION-034 — Separate quantization-error and range obligations, identify affected samples/states and validate scaling at worst-case inputs. A local rounding bound cannot justify overflow or reconstruct lost values.

Review: Chapter 10 — Range and error are separate obligations; Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 16 — Close the receiver method through configuration-specific regression.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-035 — The original amplitude and waveform information lost at clipping. Retain flags and raw representation, establish a valid analog/digital gain state and repeat the reference test instead of treating post-scaling as recovery.

Review: Chapter 10 — Quantization, Clipping, and Converter Performance; Chapter 3 — Choose gain from a feasible interval; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

V011-VOL-DISCUSSION-036 — The preserved file bytes are consistent with the hash, but acquisition continuity failed. Retain both facts, the gap map and bounded valid intervals; neither finding cancels the other.

Review: Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-DISCUSSION-037 — Payload rate and duration capacity using actual components, channels and container width, plus overhead and margin. Recheck sustained writing; converter resolution does not determine stored byte count.

Review: Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Quantitative Model for Triggering, Burst Capture, Recording, Metadata, and Reproducibility.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-038 — Test sustained planned-duration operation, monitor loss and thermal/clock state, provide reserve or a changed capture design and document any resulting coverage limits. Peak speed cannot establish continuous preservation.

Review: Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 10 — Data Transport, Gaps, and Reproducible Recording; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-VOL-DISCUSSION-039 — No; verify conjugation and order conventions, actual channel reference planes and clock mapping. Preserve the original order and interpret the delay only under a consistent signed definition.

Review: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-DISCUSSION-040 — Examine whether each bin uses only one nonzero Fourier pair, define the ensemble and repeated paired averaging, and test shared noise or processing. A normalized finite identity need not estimate population coupling.

Review: Chapter 9 — Define the ensemble before normalizing; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence.

V011-VOL-DISCUSSION-041 — Their shared samples and statistical dependence, plus the separate event-phase assumptions if used for capture probability. Define the estimator and trial experiment explicitly instead of equating segment count with independent evidence.

Review: Chapter 9 — Averaging and Statistical Stability; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 16 — Record repetition and the limits of the design.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-042 — Window sum versus energy normalization, ENBW, sample rate and one/two-sided conventions. Preserve each declared quantity and check integrated power rather than assume a single denominator applies to all displays.

Review: Chapter 9 — Noise density uses a different denominator; Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 14 — Attach calibration to a stated measurement result.

V011-VOL-DISCUSSION-043 — Actual resolving evidence and source discrimination based on the unchanged time record. Compare window/record effects and obtain more valid data where needed; interpolation adds grid points, not independent observation.

Review: Chapter 9 — Define the record before interpreting the display; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-DISCUSSION-044 — Peak-envelope and relative-phase loading at vulnerable stages can differ despite correct mean-energy closure. Retain time-domain waveform and stage-level linearity/protection checks.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 9 — Energy closure and its limits; Chapter 11 — Compression and Gain Change.

V011-VOL-DISCUSSION-045 — Measure carrier/sideband transfer and phase, compare a known waveform and preserve the gain state. Magnitude extrema at the output may not represent the original source, especially with reversal or unequal sideband admission.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 3 — Use preselection as a measured transfer function; Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-046 — Retain the valid declared power statistic while declining to reconstruct lost phase/sign or source waveform uniquely. Use coherent samples and validated bandwidth for claims requiring that information.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 9 — Energy closure and its limits.

V011-VOL-DISCUSSION-047 — Signal validity, phase branch and finite-interval definition, resets and actual sample timing. Do not interpret an undefined or unstable phase derivative as a physical instantaneous frequency without supporting evidence.

Review: Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 10 — Gap representations, phase, and the limits of timing claims.

V011-VOL-DISCUSSION-048 — Average tuning accuracy can be good while coherent integration or blocker susceptibility is limited. Retain separate deterministic time error, phase-noise spectrum and relevant channel/covariance models.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 11 — Integrate the channel that actually produces the reported value.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-049 — State each band, carrier and line/density treatment, identify unmeasured contributions and relate spectral placement to the intended receiver function. Equal numerical RMS is not interchangeable evidence.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin; Chapter 11 — Integrate the channel that actually produces the reported value.

V011-VOL-DISCUSSION-050 — A justified joint distribution and relevant covariance of phase differences, including deterministic components. RMS alone does not select the exact Gaussian finite-coherence law.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power; Chapter 9 — Define the ensemble before normalizing; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-VOL-DISCUSSION-051 — The common factor preserves coherent-sum magnitude, but absolute and inter-record phase can vary. Define the target boundary and retain the shared reference relationship rather than infer universal synchronization.

Review: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power; Chapter 14 — Frequency, phase, and delay require their own observables; Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-052 — Shared nominal frequency is established, while relative timing and phase at the actual measurement boundary remain uncalibrated. Test simultaneous input and retain cable/converter/trigger contributions.

Review: Chapter 12 — Accept coherence at the required boundary and state; Chapter 10 — Source indices, stored offsets, and time anchors; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-DISCUSSION-053 — Only with supported inter-record phase information or a new justified correction. Preserve individual power results and reset history; amplitude agreement does not establish complex continuity.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 12 — Accept coherence at the required boundary and state; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-DISCUSSION-054 — Determine its offset, latency variation and clock relation to sampled apertures and the stimulus. Numerical timestamp precision does not by itself establish event-time accuracy.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 14 — Frequency, phase, and delay require their own observables.

V011-VOL-DISCUSSION-055 — Not necessarily; the fit may remove the phase error the calibration measures. Report coefficient, residual normalization and held-out scope alongside the unremoved phase result.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 12 — Accept coherence at the required boundary and state; Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-056 — Recover numerator, denominator, selected symbol population and fit freedom, then express a common declared metric where supported. A lower percentage may be a normalization change rather than improved physical modulation.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 14 — Attach calibration to a stated measurement result; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-DISCUSSION-057 — The training result and validation failure with their states, fit choices and native records. Investigate alignment and applicability, and avoid representing fitted success as general receiver performance.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Interpret hypothetical receiver records; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-DISCUSSION-058 — The outputs may share a false lock or stale interpretation; use independent valid/noise-only records, separate implementations and physical linkage. A duplicate display is not independent evidence of device function.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence; Chapter 16 — Findings, Reports, and Decision Ladders.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-059 — Finite symbols, code rate, overhead populations, complete frames, repeated payload and wall duration. Distinguish nominal coded rate from actually delivered unique information and retain captured coverage.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-DISCUSSION-060 — State active and full wall intervals separately, use actual delivered counts and duration weighting, and retain gaps/exclusions. The same bits can support different rates only with explicit denominators.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-DISCUSSION-061 — Apply declared integer frame and payload rules, identify padding or incomplete units and avoid fractional extrapolation without a model. Preserve event boundaries and actual retained data.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 15 — Verify the trigger at its actual signal-path location.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-062 — Identify payload positions, deduplicate overlaps and retransmissions, and retain channel-specific evidence separately. Multiple observations can strengthen verification without increasing unique information count.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 16 — Reconcile evidence without assigning unsupported probabilities; Chapter 15 — Bind sample continuity, storage accounting and derived results.

V011-VOL-DISCUSSION-063 — Trace absolute timing, NCO phase and phase-difference intervals, compare against the original native sequence and a known reference. Do not assign the shift to source motion until processing continuity is validated.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-VOL-DISCUSSION-064 — Use actual load/bias/environment states, independent output and desired references, and selective cable or power interventions. Treat instability, pickup and leakage as alternatives rather than declare a unique oscillation from one line.

Review: Chapter 13 — Remote amplification requires electrical and installed checks; Chapter 11 — Distinguish strong-signal mechanisms through paired interventions; Chapter 16 — Localize an artifact by changing the stage that could create it.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-065 — The feature is sensitive to that combined intervention; supply noise and conductive coupling remain alternatives. Preserve reference capability and design a more selective follow-up before naming the cause.

Review: Chapter 13 — Remote amplification requires electrical and installed checks; Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 16 — Receiver challenges with interacting controls.

V011-VOL-DISCUSSION-066 — Verify that the altered path can capture the same event duration and spectrum with adequate sensitivity and timing. If not, retain an inconclusive negative comparison instead of unique coupling attribution.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 16 — Preserve comparable observation capability.

V011-VOL-DISCUSSION-067 — The voltage and impedance convention, available versus delivered quantity and receiver/path correction. Apply only the supported conversion and propagate its uncertainty; a nominal factor-two example is not a universal mismatch repair.

Review: Chapter 13 — Keep field conversion separate from terminal power; Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Attach calibration to a stated measurement result.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-068 — Retain measured terminal quantities and identify the unsupported field model; obtain geometry-appropriate characterization for stronger field claims. Receiver calibration alone does not establish the local electric/magnetic relation.

Review: Chapter 13 — Keep field conversion separate from terminal power; Chapter 14 — Attach calibration to a stated measurement result; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-DISCUSSION-069 — The consequential multiport state and impedance-dependent transfer/noise response, with appropriate characterization. An independent matched two-port sum is insufficient if the branch visibly affects the result.

Review: Chapter 13 — Treat connections and unused branches as part of the network; Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 14 — Calibrate noise without confusing it with detection.

V011-VOL-DISCUSSION-070 — The conducted transfer may remain supported while installed geometry/common-mode conversion is unresolved. Preserve both scopes and selective reference tests rather than blame the receiver or external field uniquely.

Review: Chapter 13 — A constructed acceptance case for the assembled chain; Chapter 13 — Separate the intended coaxial path from installed coupling; Chapter 16 — Localize an artifact by changing the stage that could create it.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-071 — Reconstruct a physically admissible joint dependency model with units and positive semidefiniteness. Simulation or a favorable final total cannot legitimize an inconsistent covariance description.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 12 — Application 12B.5: Include covariance when combining timing contributions.

V011-VOL-DISCUSSION-072 — Identify a common calibration floor or other nonreducible contribution and improve its characterization if relevant. Retain the reading model and predeclared decision rather than assume all terms shrink with count.

Review: Chapter 14 — Application 14B.8: identify the uncertainty that averaging cannot remove; Chapter 9 — Averaging and Statistical Stability; Chapter 14 — Declare the decision rule before seeing the result.

V011-VOL-DISCUSSION-073 — Indeterminate, with the factor, uncertainty model and rule preserved. Explain legitimate follow-up on dominant terms and avoid changing the limit or calling overlap proof of exceedance.

Review: Chapter 14 — Declare the decision rule before seeing the result; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

V011-VOL-DISCUSSION-074 — The central value no longer uses the available correction and may change the decision improperly. Apply the supported offset, retain its uncertainty and verify sign/plane implementation independently.

Review: Chapter 14 — Use covariance and model sensitivity deliberately; Chapter 14 — Build a correction chain with signs that can be checked; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-075 — No; fix the configuration identity and recompute with applicable characterization. An uncertainty budget describes supported inputs, not a license to use the wrong physical path.

Review: Chapter 13 — Define a complete path at named planes; Chapter 14 — Attach calibration to a stated measurement result; Chapter 10 — Separate signed artifacts from operating configurations.

V011-VOL-DISCUSSION-076 — Coverage of a measured quantity, capture/detection performance and attribution/authorization are separate claims. Require their own models and evidence, and use the supported finding category without transferring a percentage.

Review: Chapter 14 — Declare the decision rule before seeing the result; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-DISCUSSION-077 — The interval until the required weak-signal function is demonstrably recovered, with relevant control/filter/trigger behavior. Survival does not establish valid observation opportunity.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-078 — Establish whether acquisition was continuous; preserve the unfolded interval and filter/index history before applying the contiguous criterion. A coordinate or storage boundary need not be a physical gap.

Review: Chapter 15 — Application 15A.8: Preserve one contiguous window across the period origin; Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-VOL-DISCUSSION-079 — Use the union of eligible phases, counting each event start once, while retaining the single-record contiguous criterion. Do not confuse overlapping opportunity sets with summing disconnected waveform pieces.

Review: Chapter 15 — Application 15A.6: Take the union of overlapping capture-start sets; Chapter 9 — Estimator Validation and Reporting.

V011-VOL-DISCUSSION-080 — Only with an actual justified independent phase experiment; otherwise use deterministic or joint timing analysis. Distinguish event count from new opportunity and preserve the true schedule.

Review: Chapter 15 — Application 15A.7: Keep a deterministic repeated miss deterministic; Chapter 8 — Interpret a swept trace through its frequency-time trajectory; Chapter 16 — Record repetition and the limits of the design.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-081 — State the demonstrated rearm/holdoff limitation, test controlled separations and incorporate unusable intervals into coverage. The isolated pass does not establish unrestricted burst performance.

Review: Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 16 — Preserve comparable observation capability.

V011-VOL-DISCUSSION-082 — Only where their state and validity are supported. Retain transition timestamps and flags, distinguish comparable context from invalid samples and avoid applying settled corrections across the change.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 15 — Verify the trigger at its actual signal-path location.

V011-VOL-DISCUSSION-083 — Test both paths with the intended event, map bandwidth and latency and verify actual retained samples. Presence in the recorder representation does not guarantee the trigger will initiate preservation.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 16 — Preserve comparable observation capability.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-084 — Preserve calibrated desired references and separately vary meaningful clock/route states, including reversals. Shared cause is plausible, but changed sensitivity or phase state must be distinguished.

Review: Chapter 12 — Accept coherence at the required boundary and state; Chapter 16 — Arrange the comparisons before examining their outcomes; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-DISCUSSION-085 — A bounded temporal correlation with stated clocks and direct observables. Test shared measurement paths and establish physical/operational RF linkage before claiming a transmitter or surveillance function.

Review: Chapter 15 — Metadata, Time, and Site Context; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence; Chapter 16 — Findings, Reports, and Decision Ladders.

V011-VOL-DISCUSSION-086 — Not without an explicit justified model; retain the missing contrast and its limitation. Obtain a meaningful alternative where feasible and avoid treating an incomplete design as proof of component causation.

Review: Chapter 16 — Arrange the comparisons before examining their outcomes; Chapter 12 — Accept coherence at the required boundary and state.

V011-VOL-DISCUSSION-087 — Record the actual physical/processing bundle and characterize each state, using event-appropriate capability references. The front-panel label does not isolate a single causal mechanism.

Review: Chapter 16 — Receiver challenges with interacting controls; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-088 — Retain run order and source state, block or cross relevant gain comparisons within comparable intervals where possible, and report missing contrasts. Repetition alone cannot separate gain from source-time effects.

Review: Chapter 16 — Record repetition and the limits of the design; Chapter 3 — Choose gain from a feasible interval; Chapter 15 — Metadata, Time, and Site Context.

V011-VOL-DISCUSSION-089 — Label them as derived analyses sharing the same acquisition, then obtain fresh physical-state repetitions for the intervention. Preserve overlapping-sample dependence in any statistical claim.

Review: Chapter 9 — Averaging and Statistical Stability; Chapter 15 — Reproducible Analysis and Derived Products; Chapter 16 — Record repetition and the limits of the design.

V011-VOL-DISCUSSION-090 — Performance beyond those fitted examples. Use independently retained reference and noise-only records, disclose selection and retain the earlier outputs rather than presenting training cleanup as universal validation.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 16 — Interpret hypothetical receiver records; Chapter 15 — Reproducible Analysis and Derived Products.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-091 — Formal asymptote intersection, actual compression/validity range, parent convention and hardware exposure limits. Use appropriate stage and system tests; an extrapolation is not a survivability specification.

Review: Chapter 11 — Construct the intercept from the linear asymptote; Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Choose gain from a feasible interval.

V011-VOL-DISCUSSION-092 — Retain the actual unequal-parent cubic amplitude dependence and stage conditions rather than transfer a simultaneous equal-tone slope. Check source contamination and desired response during the challenge.

Review: Chapter 11 — Derive the retained spectral amplitudes; Chapter 11 — Construct the intercept from the linear asymptote; Chapter 16 — Localize an artifact by changing the stage that could create it.

V011-VOL-DISCUSSION-093 — Source sidebands, direct leakage, baseline drift and gain-control changes can contribute. Preserve fixed channel calibration and desired gain, characterize admitted spectrum and test the weighted reciprocal-mixing prediction.

Review: Chapter 11 — Integrate the channel that actually produces the reported value; Chapter 11 — Distinguish strong-signal mechanisms through paired interventions; Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-094 — The uncontaminated product may approach zero under coherent cancellation, so the inferred upper intercept can be unbounded within that observation model. Retain phasor/domain limits and seek better source characterization.

Review: Chapter 11 — Ten worked applications of Model 11A; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 16 — Write findings that preserve the strength and limit of each test.

V011-VOL-DISCUSSION-095 — Only the bound artifact identity, not correct deployed behavior. Restore the intended state, calibration and parameters, then run relevant reference and regression checks.

Review: Chapter 10 — Separate signed artifacts from operating configurations; Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 16 — Close the receiver method through configuration-specific regression.

V011-VOL-DISCUSSION-096 — Only the tested functions until configuration-specific checks establish the deployed method's needs. Preserve the prior accepted state and explicitly retain the unverified capabilities.

Review: Chapter 10 — A continuity condition for finite filtering and decimation; Chapter 15 — Verify the trigger at its actual signal-path location; Chapter 16 — Close the receiver method through configuration-specific regression.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-097 — Use known change times and last valid checks to identify affected functions and intervals, preserve all records and investigate a supported correction or narrower claim. Do not overwrite the earlier state with the latest correction automatically.

Review: Chapter 13 — Integrated Path Acceptance; Chapter 14 — Close the calibration record across the working interval; Chapter 16 — Reconcile evidence without assigning unsupported probabilities.

V011-VOL-DISCUSSION-098 — Preserve records needed for the authorized purpose and verification with appropriate access controls, minimize unnecessary content under the declared policy and document migration/deletion. Derived images must not silently replace essential native evidence.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 15 — Coverage Review and Storage Governance; Chapter 15 — Reproducible Analysis and Derived Products.

V011-VOL-DISCUSSION-099 — Separate unresolved classification from authorization and functional linkage, preserve the measurement and pursue operational or physical evidence. Technical capability or unfamiliarity does not establish the stronger category.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 16 — Findings, Reports, and Decision Ladders; Chapter 16 — Integration with Direction, Wireline, Optical, and Physical Evidence.

Copyright 2026, James M. Atkinson

V011-VOL-DISCUSSION-100 — The configured quantity and planes, valid native data, signed corrections, normalization, uncertainty, timing/coverage, challenges and supported inference. Preserve failed tests and old/new processing states so a later correction can narrow the conclusion without rewriting observations.

Review: Chapter 1 — Model 1A: configured transfer, correction and recoverability; Chapter 14 — Close the calibration record across the working interval; Chapter 15 — Bind sample continuity, storage accounting and derived results; Chapter 16 — Close the receiver method through configuration-specific regression.

Copyright 2026, James M. Atkinson

Volume Glossary

ABSOLUTE-FREQUENCY CUSP: The change of slope produced when a signed conversion product passes through zero and its displayed frequency is represented by an absolute value. The signed trajectory can remain linear while the nonnegative trajectory has two branches. Endpoint changes must be calculated from the absolute values or the appropriate piecewise map; one local slope cannot be extended across the crossing.

ABSOLUTELY CONTINUOUS PHASE: A phase trajectory whose change over the interval is recovered by integrating its almost-everywhere derivative. This condition supports the equality between finite-interval phase change and average instantaneous frequency. A discrete phase reset must split the analysis; merely choosing an unwrapped display does not establish the required trajectory.

ABSOLUTE SAMPLE INDEX: Integer identity of a sampling event within a declared source segment, distinct from its retained file position.

ACCEPTANCE CASE: A bounded technical argument that a declared configuration satisfies specified applicable requirements using identified evidence and decision rules.

ACCUMULATOR: The arithmetic storage and update operation that combines successive products or terms into a sum. Its required width depends on the signed input and coefficient ranges and the actual accumulation path. A final in-range result does not establish that every intermediate sum avoided saturation or modular overflow.

Copyright 2026, James M. Atkinson

ACQUISITION-CONDITIONED METRIC: A result calculated only on intervals for which the receiver met its declared acquisition or lock criterion. It describes that selected population and must be accompanied by attempted acquisitions, failures and exclusions when the complete event matters. It does not establish uninterrupted reception during omitted intervals.

ACQUISITION INTERVAL: The declared span of physical time during which observations are eligible to contribute to a measurement. Its usable portion may exclude transitions, failed captures, or invalid states; a file's existence alone does not establish continuous valid coverage.

ACTIVE SYMBOL RATE: The rate of transmitted symbol instances during a declared active interval, determined from their spacing or count under the stated clock convention. It can differ from the average number of transmitted data symbols per second over an interval that also includes guards or idle time. A nominal accounting grid must be identified separately.

ACTUAL STATE: The receiver configuration supported by status and observation evidence for a particular record interval. It may differ from the commanded state because of rejection, settling, automatic control, or other changes that affect the measurement.

ADAPTIVE CONTROL: A mechanism that changes a receiver or processing state in response to input or operating conditions. Its effect must be retained in configuration identity when it alters gain, validity, timing, or another part of the measurement law.

Copyright 2026, James M. Atkinson

ADDITIVE-POWER MODEL: A model in which mean powers of specified contributions can be added because their relevant mean cross-power vanishes under the declared observation. The premise concerns their relationship and averaging operation. Merely describing one component as noise, or recording two separate levels, does not establish it.

ADDITIVE WHITE GAUSSIAN NOISE: A noise model combining addition to the signal, Gaussian amplitude statistics and a flat spectral-density assumption over the modeled domain. It is an explicit premise of the chapter's matched-filter optimum. It does not describe every interferer, nonlinear receiver artifact or frequency-selective propagation effect.

ADJACENT-CHANNEL POWER: Power evaluated in a specified neighboring frequency channel under a declared integration bandwidth, reference and detector procedure. It concerns spectral occupancy outside the selected channel rather than the correctness of recovered symbols. Coding margin can improve data recovery without reducing that emitted power.

ADJUSTMENT: An intervention intended to change a measuring system's response to the required relation. It is distinct from calibration, which establishes a relationship and its uncertainty, and verification, which checks a stated requirement. A changed response can require new characterization before previous corrections or uncertainty statements are used.

Copyright 2026, James M. Atkinson

ADMISSIBLE RESULT SET: The set of results permitted by the supplied inputs, discrete alternatives and constraints. Model 7B applies this concept to rates under count, duration and format premises. Discrete alternatives combined with bounded continuous factors can produce separated intervals; an overall minimum-to-maximum enclosure may include values no admitted state realizes. Retain the union when its gaps matter. A midpoint, equal state probabilities or another weighting requires additional evidence.

ADMITTED ANALOG BAND: The set of input frequencies allowed by an explicitly justified front-end and signal-class specification before sampling.

ADMITTED BLOCKER POWER: The power of a specified interfering carrier at the conversion-stage input after preceding gain, loss, and frequency selection, at a declared reference plane.

ADMITTED RF BAND: The physical RF-frequency region that can influence a selected receiver path under its actual filter and switching state. It may extend beyond the displayed span, and weak skirt transmission can matter for a strong input. A nominal bandwidth label does not define a perfect exclusion boundary. Conversion claims therefore combine the frequency map with an applicable measured transfer or stated admission threshold.

AFFINE MEASUREMENT FUNCTION: A measurement relation consisting of a constant plus a fixed linear combination of the input quantities. Its output mean and variance follow exactly from the input mean and covariance when the required second moments exist. Neither independence nor normality is required for that identity; the coefficients retain their signs and units.

Copyright 2026, James M. Atkinson

AFFINE UNCERTAINTY PROPAGATION: Exact evaluation of output variance for a fixed affine measurement function from finite input second moments and their covariance.

AGGREGATE INPUT POWER: The combined power presented by all relevant admitted components at a specified stage input. Mean powers can be summed when the applicable cross-power terms vanish under the defined averaging or ensemble convention. The aggregate mean does not by itself establish peak voltage, crest behavior, or the nonlinear products generated by several strong signals.

ALIASING: Indistinguishable mapping of spectral components caused by sampling without adequate band limitation or by intentional zone translation.

ALIGNMENT TRAINING SET: The disclosed samples or symbols used to estimate the corrections applied before an error-vector evaluation.

AMPLITUDE MODULATION: A representation in which a message changes the amplitude of a carrier-related waveform. Conventional AM in Model 6A uses a positive carrier term and a real normalized message. A magnitude envelope preserves that signed relationship only while the nonnegative-envelope condition and the applicable receiver transfer hold.

AMPLITUDE SPECTRAL DENSITY: The nonnegative square root of a power-like spectral density, expressed in amplitude units per square root of hertz. It is a density representation rather than the amplitude of an isolated spectral line. Integrating it directly as though it were mean-square density would use the wrong operation and units.

Copyright 2026, James M. Atkinson

ANALOG MODULATION: Variation of a carrier or pulse parameter according to a continuously represented message. Amplitude, frequency, phase and pulse behavior provide different observation quantities. Their measured structure can support waveform classification, but does not by itself identify the transmitter, recover its content reliably or establish its purpose.

ANALOG MULTIPLIER: A device or mathematical model whose output is proportional to the product of its input quantities within a stated range. The proportionality and input normalization determine the selected mixing-product amplitude. Model 4A explicitly fixes that scaling; its ideal multiplier is not automatically an energy-validated passive mixer circuit.

ANALOG-TO-DIGITAL CONVERTER: A device that maps an analog input into a finite digital code representation. In the sampled receiver, its code range, sampling behavior, input bandwidth, distortion and clock conditions affect the resulting record. A nominal bit count describes a representation capacity; it does not establish the measured accuracy or dynamic range of the complete receiver.

ANALYSIS CHANNELIZER: A bank that filters one sampled input into several indexed output streams with specified frequency translation and sample retention.

Copyright 2026, James M. Atkinson

ANALYTIC SIGNAL: A complex representation of a real signal that retains its positive-frequency content with the corresponding amplitude convention and removes the redundant negative-frequency conjugate content. In Model 4A the admitted translated envelope must remain at positive physical RF frequency. Its complex magnitude and the real waveform's average loaded power require their declared normalization; they must not be interchanged without that convention.

ANGULAR FREQUENCY: The rate of phase rotation expressed in radians per unit time. It equals ordinary frequency in cycles per unit time multiplied by the angle of one full turn. The conversion factor must be retained when differentiating phase to obtain a frequency in hertz.

ANTENNA FACTOR: Frequency-dependent relationship used to convert antenna-terminal voltage to incident electric-field strength under stated conditions.

ANTENNA PATTERN: The directional variation of an antenna's response at a specified frequency, polarization and installation. A change in received level after rotation can reflect this response rather than changed source power. Comparisons require the relevant orientation and mounting geometry.

ANTENNA TERMINAL PLANE: The declared electrical boundary between an antenna and the receiving path. A conducted reference applied there can test the downstream chain under the stated loading. It does not by itself characterize the antenna's conversion from an incident field, which also depends on direction, polarization, geometry and environment.

Copyright 2026, James M. Atkinson

ANTI-ALIAS FILTER: A filter placed before a sampling or sample-rate-reduction boundary to attenuate components that would otherwise become indistinguishable in the retained band. Its needed rejection follows the admitted unwanted signals and actual folding paths. A later filter cannot separate contributions already combined at the same retained frequency.

APERTURE DELAY: The timing displacement associated with when a converter actually samples its input relative to the declared timing reference. Unequal channel apertures contribute to relative timing alongside analog paths and digital processing. A calibration of a convenient clock connector does not automatically measure this acquisition-boundary contribution.

APERTURE JITTER: Variation of the converter's actual sampling delay from one acquisition event to another. It is distinct from a fixed aperture delay and from a known channel offset. Because the resulting voltage error depends on input slope, its significance changes with waveform and frequency; other clock and timing contributions retain their own covariance.

APPLICABILITY RATIONALE: The technical explanation establishing whether a criterion belongs to a declared acceptance case; an unknown relationship remains unresolved.

ARCHITECTURE MAP: A representation placing plausible mechanisms and accessible controls at their locations in the measurement chain. It supports predictions about how a controlled change should affect a candidate cause. A front-panel setting is not a causal location by itself, especially when the setting changes several paths or states together.

Copyright 2026, James M. Atkinson

ARITHMETIC MEAN: The sum of the selected numerical values divided by their count when equal weighting is intended. Applied to calibrated powers, it preserves a linear-power population interpretation. Taking its logarithm afterward generally differs from averaging the separately transformed logarithmic values.

ARITHMETIC OVERFLOW: A condition in which an exact arithmetic value lies outside the range allocated to its numerical representation. Saturation and modular wrap are different responses to that condition. Later scaling can conceal an earlier overflow in the displayed range without recovering the information lost at the affected intermediate operation.

ARTIFACT: A feature introduced by the measurement apparatus or processing that can resemble a component of the environment. The term identifies an explanatory possibility or supported finding; it does not by itself identify every responsible circuit or coupling path.

ARTIFACT RECORD: A reusable account of a demonstrated measurement artifact, including its affected configurations, stimulus or transition, predicted and observed response, challenge evidence and accepted mitigation. Its scope remains the tested conditions. A single incident should not become a universal rule about other receivers or environments without additional evidence.

ARTIFACT TAXONOMY: An organized inventory of mechanisms that could produce an observed indication through the receiver, installed path or environment. Its purpose is to generate competing explanations and discriminating tests. Membership in a familiar category does not identify the cause of a particular observation without supporting architecture and challenge evidence.

Copyright 2026, James M. Atkinson

ASSEMBLY RECORD: Identification and order of the physical components, connections, and terminations that form a measurement path.

ASSOCIATIVITY: The algebraic property that regrouping an operation does not change its result. Exact addition has this property, but an implementation that rounds or saturates intermediate results need not preserve it. The chapter's three-product example therefore specifies the actual grouping when comparing finite-word and exact arithmetic.

ASYMPTOTIC LIMIT: A value approached as a model parameter tends toward a limiting regime, without necessarily being attained at a finite setting. The two-stage noise model approaches the first stage's temperature as its gain increases. With positive later-stage noise, equality to that limit cannot be obtained by a finite gain.

ATTACK TIME CONSTANT: The positive time constant identified for a specified control response following an input change that calls for gain reduction. In Model 5A it describes one applicable exponential segment, with a calibrated gain polarity and declared target. It does not include an unmodeled detector delay, slew limit or hold rule, and it need not equal the release constant.

ATTENUATOR: A component that reduces signal level by a specified transfer under stated frequency, impedance and operating conditions. Its placement determines which later stages receive protection and which noise penalties enter the input budget. Correcting the reported level for attenuation does not undo the physical loss or restore an overloaded earlier stage.

Copyright 2026, James M. Atkinson

ATTRIBUTION: An evidence-supported connection between an observed component and a physical emitter or system. It requires more than detection or a waveform-family label and must retain the assumptions and alternative explanations relevant to that connection. Distinguish a link to a physical device or its operation from temporal association, localization, authorization status and confirmation of an information path or surveillance function. A plausible identifier alone does not supply these additional conclusions.

AUTOCOVARIANCE: The covariance of one process evaluated at two observation indices or times, with centering and complex-conjugation convention stated. It describes dependence within that process. A colored autocovariance changes expected spectral ordinates even when integrated mean-square closure remains correct.

AUTOMATIC GAIN CONTROL: Feedback or feedforward process that changes receiver gain according to detected level or state.

AUTOSPECTRUM: A spectral estimate formed from weighted squared magnitudes of a channel's Fourier coefficients. Its units follow the measured quantity and density normalization. The chapter's coherence ratio requires both autospectra to be positive and to use the same paired record population and compatible weighting as the cross-spectrum.

AVAILABLE NOISE POWER: Noise power that a source can supply under the specified matching condition. In the chapter's classical thermal model it is kBT_s, where k is the Boltzmann constant in joules per kelvin, B is equivalent noise bandwidth in hertz, and T_s is source noise temperature in kelvins. It is a source quantity at a declared plane and differs from the power actually accepted by a mismatched receiver.

Copyright 2026, James M. Atkinson

AVAILABLE SOURCE POWER: The power a source could supply under its specified matching condition, distinguished from the power actually delivered to a particular connected load. A mixer specification stated using available input power cannot automatically be substituted for the chapter's ratio of loaded sinusoidal powers at positive real resistances. The source, load, matching, and selected output conventions must be reconciled before comparing the quantities. The ideal effective-aperture relation in Chapter 13 also uses available power for its stated receiving-antenna conditions. It does not establish power delivered to an arbitrary installed load or coupling path.

AVERAGE OF LOGARITHMIC POWERS: The arithmetic mean of calibrated power levels after each sample has been converted to logarithmic units. It estimates a different statistic from the logarithm of an arithmetic power mean. Under the chapter's single exponential noise-power model, its decibel expectation has a fixed offset that additional independent averaging does not remove.

BAND-LIMITED PHASE VARIANCE: The phase variance contributed by a stated finite set of offset bands and line measures under an explicit spectral normalization.

BAND-PASS FILTER: A filter that preferentially transmits a bounded frequency band while rejecting frequencies on either side under the stated response specification. It can admit the displayed desired band while suppressing remote parents of an internally generated product. That interpretation requires verified desired transfer and source-path controls.

Copyright 2026, James M. Atkinson

BANDWIDTH: The frequency extent associated with an admitted path or reported measurement. Its precise definition must accompany the result because a nominal setting does not by itself identify the energy, filtering, or estimator represented by the indication.

BASEBAND: The frequency region used to represent a signal after its carrier reference has been removed or translated near zero. A complex baseband record can distinguish positive from negative offsets under its declared convention. A real magnitude-only display can discard that distinction and leave two different RF inputs compatible with the same peak.

BIAS CURRENT: The current associated with establishing or maintaining an active component's operating state. Its value and supply path can affect gain, stability and recovery. A receiver's RF configuration is therefore incomplete when the relevant bias state is unknown or changes between the compared observations.

BIAS DELIVERY: The actual supply path and operating state used to power a remote active component. Cable resistance, protection elements and coupling to other equipment can make the remote condition differ from the source-terminal indication. Record the feed arrangement and available monitoring rather than inferring the amplifier's state from supply voltage alone.

BIAS TEE: Network combining or separating direct-current power and RF on a common conductor.

BINARY POINT SCALING: Representation in which an integer code is multiplied by a stated power of two; the fractional-bit count fixes the code step.

Copyright 2026, James M. Atkinson

BIN-CENTERED TONE: A tone aligned with an integer-frequency component of the declared finite record under the model's sampling convention. Its complex transform at that bin is related to the coherent sum of the window weights. Real-tone amplitude recovery also requires the stated negative-frequency image condition and special treatment at the endpoints.

BIT: A binary digit whose counted role must be stated in a reception result. Coded label bits, information bits, payload instances and unique delivered payload positions belong to different populations. Their numerical counts can differ even when they describe the same transmission interval.

BIT ERROR RATE: The fraction or modeled probability of incorrectly recovered bits under a stated comparison rule and operating condition. A measured fraction requires a known bit reference, denominator and interval. Geometric EVM does not supply it without an additional justified channel, decision and coding model.

BIT RATE: A specified count of bits divided by the time interval to which the count belongs. The population may be coded, information, represented payload or unique delivered payload. A rate without those labels can confuse coding, overhead and duplication with actual changes in the transmission.

BLANKING: A deliberate exclusion or suppression of observations during specified intervals, such as a known disturbance. Its timing and affected path must be retained because excluded data do not establish signal absence. Blanking can aid a controlled comparison but cannot restore an event that never entered the usable observation window.

Copyright 2026, James M. Atkinson

BLINDING: A design measure that limits access to information capable of influencing a comparison or interpretation before the relevant observations or decisions are recorded. It can reduce confirmation bias when feasible. Its role and restrictions must be documented; merely calling a test blinded does not establish independent observations or comparable receiver states.

BLOCKER: An interfering signal whose admission can impair observation of a desired signal. Its effects may involve loading, gain control, intermodulation, reciprocal mixing or direct spectral overlap. The blocker's own frequency-dependent path and incident waveform must be tracked separately from the desired-signal correction.

BLOCKER OFFSET: The signed frequency separation between an admitted interfering carrier and the declared desired-channel center. Model 11B uses it to identify which oscillator phase-noise frequencies enter the weighted channel. An even phase spectrum does not make positive and negative blocker offsets interchangeable when the observation filter is asymmetric.

BLOCKER-SOURCE NOISE: Noise carried by the applied interfering source into the desired observation channel or another relevant admitted region. It can produce a measured noise rise without requiring the proposed receiver mechanism. A reciprocal-mixing interpretation therefore needs this contribution bounded or accounted for under the same source, frequency, and path conditions.

Copyright 2026, James M. Atkinson

BLOCKER-TO-DESIRED TRANSFER RATIO: The ratio of preceding power transfer at the blocker frequency to that at the desired-signal reference frequency. It determines the selective change in an internally generated blocker contribution when referred to the desired external input. Blocker attenuation alone omits desired-path loss, and the ratio alone does not establish the change in total sensitivity.

BLOCKER TRANSFER: Frequency-specific gain or loss connecting an external interfering signal to a vulnerable receiver stage.

BLOCKER-TRANSFER VERIFICATION: Characterization of the interfering-signal levels admitted up to the vulnerable stages under the stated assembly and state. It complements desired-signal transfer because a narrow downstream channel does not protect every earlier component. Retaining the desired reference during a blocker challenge helps distinguish changed gain from a raised noise contribution.

BLOCKING: Loss of sensitivity or accuracy caused by a strong signal outside or beside the desired channel.

BOLTZMANN CONSTANT: The physical constant that converts absolute temperature to the thermal energy scale used in the classical noise model. Its unit is joules per kelvin. Multiplication by noise temperature and bandwidth in inverse seconds gives power in watts; this dimensional relation does not supply the missing matching or bandwidth assumptions.

Copyright 2026, James M. Atkinson

BUFFER OVERFLOW: A data-path condition in which pending data exceed the capacity or service capability of an intermediate receive or recording buffer. Its status can indicate a continuity problem but does not alone identify the exact missing source indices. The complete recording path and workload must be exercised to support a loss-free interval claim.

BUILD ATTESTATION: A verifiable statement associating an output artifact with claims about its build, such as builder, source and parameters. Its subject must match the examined artifact and its claims must satisfy the stated expectations. An authentic statement can describe a build that the receiver's acceptance policy does not permit.

BYTE ORDER: The ordering of the constituent bytes of a multibyte numerical representation. A reader must use the declared order together with the correct signed-code convention. The chapter's asymmetric integer test exposes a byte-order mismatch that zero-only data and a successful software installation would not reveal.

CALIBRATED CONTROL INTERVAL: The voltage range over which a specified control-to-gain relationship is supported by calibration and applicable operating conditions. A model trajectory used for gain prediction must remain inside this interval or be segmented under separately justified mappings. Mathematical monotonicity of voltage does not validate gain extrapolation beyond the measured range.

Copyright 2026, James M. Atkinson

CALIBRATED NOISE SOURCE: A reference source whose relevant noise temperatures or excess-noise-ratio relation have been characterized for stated conditions. Its calibration plane and convention must be retained. Loss between that plane and the receiver alters the effective hot and cold temperatures, so the source certificate alone does not characterize the installed connection.

CALIBRATION: An operation establishing, under specified conditions, the relationship between reference values and indications with their associated uncertainties, enabling a measurement result to be obtained from an indication. It is distinct from changing instrument settings or checking a requirement. Its relevance depends on the particular quantity, state, range and reference plane being reported.

CALIBRATION APPLICABILITY: The conditions under which existing calibration information supports a particular measurement result. A changed path, gain state, detector, software process, or reference plane can require reassessment even when the instrument still carries a valid certificate.

CALIBRATION CERTIFICATE: The record of a calibration's identified instrument or system, conditions, references, results and uncertainties. It provides evidence to be interpreted within its stated scope. Possession of the certificate does not establish that a different accessory assembly, firmware state or measurement quantity was covered, or that the configuration remained unchanged afterward.

Copyright 2026, James M. Atkinson

CALIBRATION CHANGE CONTROL: The identification and evaluation of changes that may invalidate a correction or its uncertainty statement. Firmware, processing, accessories, reference planes, gain states and remote power arrangements can alter applicability. Evidence about the affected quantities determines whether targeted recharacterization suffices; an unchanged certificate or successful self-test is not enough by itself.

CALIBRATION ERROR ENVELOPE: A justified deterministic bound on accumulated time or phase error over a declared interval after calibration.

CALIBRATION HIERARCHY: The ordered sequence of calibrations connecting a reference to a final measuring system, with each stage depending on preceding calibration results. It describes the structure supporting a traceability claim. The uncertainty and applicability of each stage must reach the final result; the receiver's physical signal-chain order need not be the same sequence.

CALIBRATION INTERVAL: The elapsed interval over which a declared error criterion remains satisfied under justified initial-error, frequency-error and drift bounds. Model 12A compares their accumulated envelope with a carrier-dependent phase tolerance. The admissible interval can be zero, finite or unrestricted within the assumed model; a schedule alone does not establish those bounds.

CALIBRATION SCOPE: Quantities, ranges, states, reference planes, and conditions for which calibration results and uncertainties apply. An adapter already included in an antenna calibration must not be corrected a second time. A field cable beyond the calibrated receiver connector remains outside that receiver calibration and needs its own justified treatment.

Copyright 2026, James M. Atkinson

CANDIDATE SPUR LATTICE: A bounded set of integer parent-frequency combinations used to test possible product locations without predicting their amplitudes.

CAPTURE EFFECT: Tendency of an FM receiver to favor the stronger of two signals within its passband.

CAPTURE FEASIBILITY: The existence of an event start that can satisfy the declared capture criterion under the model's domain. For one contiguous window, the positive required overlap cannot exceed the event or window duration. An impossible criterion produces zero probability before any averaging over start phases is considered.

CARRIER: The declared oscillatory reference around which a modulated waveform is represented. Its frequency and amplitude conventions determine the interpretation of sidebands and envelope quantities. A carrier reference can remain part of the signal model even when the corresponding discrete carrier component is suppressed in the transmitted waveform.

CARRIER ACQUISITION: The initial process of bringing carrier estimates into a usable relationship with the received signal. Its success and duration depend on the declared search range, reference structure and receiver settings. Excluding this interval from a settled metric does not remove its consequence for short-burst reception.

CARRIER PHASE: The angular position of a carrier relative to the declared time and phase reference. In the real conversion model, the RF and oscillator phases combine differently for the sum and difference products. High-side representation at positive IF also reverses the difference-phase sign, which matters to later coherent comparisons.

Copyright 2026, James M. Atkinson

CARRIER PHASE AMBIGUITY: An unresolved choice among carrier-phase alignments that can preserve the apparent constellation point set while changing the association between points and intended labels. A tight fitted constellation does not resolve the ambiguity. Known reference structure or another justified check must establish the required mapping.

CARRIER POWER: The average power associated with the specified unmodulated carrier component at a declared reference plane. Under Model 6A's peak-voltage convention it is carrier peak squared divided by twice the positive real load resistance. Sideband powers, total average power and peak envelope power are separate quantities.

CARRIER REINSERTION: The introduction of a local carrier reference for coherent recovery of a suppressed-carrier or single-sideband signal. Its frequency and phase determine the recovered baseband orientation and projection. An adjustment made by ear is a processing choice; it does not independently calibrate the original RF frequency.

CARRIER STORAGE: Retention of excess charge carriers in a semiconductor after they are introduced by a large event or bias condition. In the chapter's PIN-limiter explanation, stored charge changes RF resistance and its removal contributes to recovery. This qualitative mechanism does not supply a universal numerical recovery time for an arbitrary mounted network.

Copyright 2026, James M. Atkinson

CARRIER SYNCHRONIZATION: The estimation and tracking of the frequency and phase relationship needed to compare an observed modulated signal with its declared carrier reference. Its acquisition range, loop behavior, fitted parameters and slips affect the symbol experiment. Successful numerical alignment does not by itself establish source identity or correct symbol labels.

CARRIER TRACKING: Continued adjustment of an acquired carrier estimate as the received frequency or phase changes. Tracking quality depends on loop settings, residuals and slips across the actual interval. A stable-looking selected constellation does not establish successful tracking throughout an unexamined capture.

CARSON BANDWIDTH ESTIMATE: The engineering estimate twice the sum of peak frequency deviation and the highest declared modulating frequency, without an automatic exact-containment or filter-distortion claim.

CARTESIAN PRODUCT DOMAIN: An allowed input set in which every combination of the stated component intervals is admitted. It supports the chapter’s rectangular worst-case searches and corner extrema when the response is suitably monotone or affine. The construction assigns no probability distribution and is not a statement of statistical independence.

CASCADED CONVERSION BRANCH: A particular sequence of selected sum or difference choices and sign regions through a receiver’s conversion stages. The chapter’s first-order real-difference orientation rule applies to a fixed sequence of nonzero branches, multiplying their local signs. A different LO choice can give the same final center IF with a different orientation. State changes therefore require an updated branch record and verification.

Copyright 2026, James M. Atkinson

CASCADE NOISE TEMPERATURE: Equivalent input noise temperature of an ordered chain, found by referring each added stage contribution through the gain preceding it.

CAUCHY–SCHWARZ INEQUALITY: The bound on an inner product's squared magnitude by the product of the two vectors' squared lengths. The chapter applies it to window sums and paired weighted Fourier coefficients. Its coherence bound relies on one consistent nonnegative weighted construction, not arbitrary separately selected spectral summaries.

CAUSAL RELATIONSHIP: A relationship in which a change in one physical process produces a change in another under the relevant conditions. A statistical fit or high coherence does not alone establish that direction or mechanism. Competing paths, shared sources and instrument coupling require separate discriminating observations.

CEILING FRAME COUNT: The smallest integer number of complete frames whose stated payload capacities can contain a positive request. With fixed positive capacity, it is the request size divided by capacity rounded upward. This rule preserves the complete-frame boundary; multiplying that count by full capacity can include final padding that is not original request payload.

CENTRAL MOMENT: The expectation of a stated integer power of a random quantity's deviation from its mean, when that expectation exists. Variance is the second central moment. The squared-Gaussian derivation also uses the third and fourth central moments; second-order information alone would not supply those values for an arbitrary distribution.

Copyright 2026, James M. Atkinson

CHALLENGE TEST: A controlled intervention selected because competing causal explanations predict different observable consequences. The comparison retains enough configuration, desired-signal transfer and observation capability to interpret the change; an unexplained disappearance alone does not identify a mechanism.

CHANNEL CODING: A declared transformation that adds redundancy to information bits for transmission and recovery. The chapter's finite accounting counts the actual input and coded bits of complete blocks, including relevant termination conventions. The count relationship alone does not quantify correction performance or successful delivery.

CHANNEL GRID: The signed center-frequency list and spacing assigned to a channelizer, distinct from each output stream's sampling frequency.

CHANNEL-POWER INTEGRATION: An estimate formed by combining calibrated spectral contributions over a declared channel interval using the appropriate frequency weighting and detector convention. A single narrow marker is generally insufficient when a modulated signal spans several filters. The integration limits, normalization and calibration must distinguish wanted energy from neighboring admitted components.

CHANNEL-SWAP TEST: A controlled interchange of channels or paths used to test whether an observed timing or phase residual follows the electronics, the path or the measurement geometry. Its interpretation requires preserving the other relevant conditions and recording the swap. It supports localization without making one successful comparison a universal calibration.

Copyright 2026, James M. Atkinson

CHARACTERISTIC FUNCTION: The expected complex exponential of a real random quantity at a specified argument. Model 12B evaluates it for a Gaussian phase difference to obtain a mean-phase factor and a variance-dependent attenuation factor. Applying that identity to a non-Gaussian difference requires its actual distribution, not merely a matching variance.

CHECKSUM: A value computed from a defined data structure and compared with a declared check rule to detect inconsistency. A passed check can support the internal validity of a decoded structure. It does not alone authenticate a sender, locate a transmitter or establish unique delivered payload.

CIRCULAR BUFFER: A recording arrangement that continually retains a rolling interval, replacing older data until selected content is preserved. Triggered extraction can provide pre-event context while controlling retained storage. That context remains usable only if its samples are valid and belong to the accepted configuration and continuous timing record.

CIRCULAR COMPLEX GAUSSIAN NOISE: In this chapter, zero-mean complex Gaussian noise with equal quadrature variances and independent real and imaginary components. Its distribution is unchanged by a common complex phase rotation. The calibrated squared magnitude has the stated exponential power law; a tone, clipping or changing-level mixture need not share it.

CLIPPING THRESHOLD: The boundary at which the declared response begins limiting rather than retaining its ordinary gain relation. Uncertainty in gain and limit position affects the input threshold inferred from a flag. An unsaturated reading can support a bounded inverse even when a clipped reading from the same system cannot.

Copyright 2026, James M. Atkinson

CLOCK TIME ERROR: The difference between a clock's reading and ideal reference time, positive for an advanced clock in the adopted convention.

CLOSING GUARD: An excluded interval at the end of a nominal acquisition during which the retained data no longer satisfy the declared validity conditions. It reduces the usable window independently of an initial settling guard. Coverage calculations must use the remaining contiguous interval and state the reasons for the exclusion.

CLOSING VERIFICATION: A check after an important observation that assesses specified functions of the measurement chain at the time of the check. Its assurance is limited to the states and conditions exercised; the check alone does not establish uninterrupted validity throughout the preceding acquisition.

COAXIAL TRANSMISSION MODE: The intended guided propagation in the space between a coaxial cable's inner conductor and the inside of its shield. Its acceptable match does not establish the absence of a separate current on the shield's outer surface. The installed path must distinguish internal transmission from external pickup and radiation.

CODE-CENTER TEST: A chosen input record exactly aligned with representable quantizer levels; its favorable error is not a distribution-wide guarantee.

CODED LABEL BIT: A bit position in the specified binary label mapped to a data symbol. A known power-of-two constellation with its declared labeling determines how many such positions belong to each symbol. This count does not by itself specify input-information bits, entropy, delivered unique payload or stored ADC data.

Copyright 2026, James M. Atkinson

CODE RATE: For the complete-block count convention in Model 7B, the number of input-information bits divided by the corresponding coded label bits. The model scopes this ratio to redundancy-adding coding without compression. It is distinct from framing efficiency and cannot be estimated as a zero-over-zero empirical ratio from an empty record; a configured rate may be known separately.

CODE SIGNING: Use of a digital signature to associate specified code content with a signing source under a verification and trust policy. Appropriate checks support integrity and source authentication. They do not demonstrate correct filtering, scaling or receiver behavior, and signed content can still be unauthorized under the acceptance policy or technically defective.

COEFFICIENT QUANTIZATION: Replacement of intended filter coefficients by values on a declared numerical grid. It changes the implemented filter itself, before any subsequent arithmetic error is considered. Equal coefficient sums can preserve DC gain while changing rejection elsewhere, so a DC check alone does not verify the quantized frequency response.

COHERENCE: Normalized spectral measure of linear relationship between two signals under stated averaging conditions.

COHERENCE RESIDUAL: The minimum weighted spectral residual $P_{yy}(1-C)$ for a single complex-gain fit, conditional on positive autospectra and the declared estimator.

COHERENCE TIME: Interval over which relative phase remains sufficiently stable for a specified coherent operation.

Copyright 2026, James M. Atkinson

COHERENT CONTAMINATION: An unwanted complex amplitude at the same observed frequency whose phase-dependent addition can raise or lower the magnitude attributed to the modeled source.

COHERENT DETECTOR: Detector using a phase- and frequency-related reference to recover a modulated quantity.

COHERENT GAIN: Window-dependent amplitude scaling for a sinusoid centered on a transform bin.

COHERENT IMAGE COLLISION: Combination of desired and image contributions at the same selected IF with a retained phase relationship. Their IF phasors add before power is formed, so the observed power can increase or decrease relative to the desired-only result. The high-side phase transformation must already be applied. One power reading cannot separate the contributions or establish that their powers add independently.

COHERENT PHASOR SUM: A complex sum that preserves the relative phases of its declared contributions. Its squared magnitude contains self and cross terms, so common rotation and relative rotation have different consequences. The chapter's normalized signal-power result does not by itself include additive noise, amplitude variation or uncertainty introduced by estimated phase corrections.

COHERENT PROJECTION: Recovery of the component of a complex envelope aligned with a declared real reference phase.

Copyright 2026, James M. Atkinson

COHERENT WEIGHT SUM: The signed sum of the actual window coefficients. For the chapter's coherent complex tone it is the factor multiplying that tone's complex amplitude in the selected transform coefficient. Coherent-amplitude normalization requires this sum to be nonzero; it must not be confused with the sum of squared weights.

COLD-HOT-COLD SEQUENCE: A noise-measurement order that brackets a hot-source observation with cold-source observations. Differences between the cold records can reveal time-dependent behavior that a single ratio conceals. The sequence does not by itself identify the cause or provide a gain correction at the intervening time.

COLD-SOURCE TEMPERATURE: Effective source noise temperature in the lower-temperature state of a hot/cold measurement at the stated input plane.

COLLECTION BOUNDARY: The authorized limits on what an engagement may acquire and how that information may be retained or disclosed. In receiver work these limits are implemented through frequency, time, mode, channel, recording, and handling choices.

COMBINED STANDARD UNCERTAINTY: The standard uncertainty obtained by propagating the relevant input uncertainties and covariances through the stated measurement model. In the local Y-factor calculation it is the square root of the sensitivity-weighted variance sum, including any applicable cross terms. It is distinct from an expanded uncertainty and does not itself specify a chosen coverage probability. The affine variance relation is exact under its stated finite-moment and covariance premises. Applying its first-order form to a nonlinear function additionally requires a justified local approximation.

Copyright 2026, James M. Atkinson

COMBINER: A network that joins signals from separate source paths into a common test path. Inadequate isolation or nonlinear behavior can make the sources interact and generate products before the receiver. Its applied levels and purity must therefore be bounded before a newly observed product is assigned to the receiver.

COMBINER ISOLATION: The degree to which a combining network prevents energy from one input port from reaching another under specified conditions. In a two-source challenge, inadequate isolation can let generators interact and produce artifacts before the receiver. Isolation must be considered with the combiner's linearity and actual applied levels; it is not the same as insertion loss.

COMMANDED STATE: The configuration requested by an operator, script, or controller. It records intended operation but does not alone prove that the receiver accepted the request, settled, or maintained that state throughout the associated acquisition.

COMMON CALIBRATION CONTRIBUTION: An input uncertainty shared across several observations, whose effect depends on its coupling and the signed coefficients of the reported quantity.

COMMON-FACTOR CANCELLATION: Algebraic removal of the same nonzero multiplicative quantity from a ratio. The Y-factor derivation cancels the common bandwidth, gain and Boltzmann factor. The cancellation is justified by actual common values and states; similarly named quantities or repeated front-panel settings do not establish the premise.

COMMON-MODE CURRENT: Current flowing on conductors together with respect to an external reference or surrounding structure.

Copyright 2026, James M. Atkinson

COMMON PERIOD: An interval after which every component in the stated periodic waveform has completed an integer number of cycles. Averaging over complete common periods supports the orthogonality used in the synthetic power calculations. A record endpoint chosen independently of those periods need not retain the same cancellation.

COMMON PHASE ROTATION: A phase contribution shared by every sample in a record, which can alter ensemble complex phase without causing relative cancellation within that record.

COMPLEMENT EVENT: The set of outcomes in which a specified event does not occur, under the same experiment and sample space. Model 15A computes at-least-one capture by subtracting the all-miss probability from one. That complement identity needs no independence assumption; multiplying individual miss probabilities does.

COMPLETE CODE BLOCK: An included input-and-output population whose coding relationship is fully represented for the declared count ratio. Counting only a partial segment can require explicit treatment of boundaries, termination and other coding structure. The chapter's fixed code-rate products assume complete stipulated populations rather than inferring them from a constellation display.

COMPLETE-FRAME PAYLOAD CAPACITY: The number of useful payload positions available in one fully specified frame after the separately declared coding and header conventions. Repeating full frames can achieve a capacity rate different from the actual rate for a finite request whose last frame contains padding. Capacity is not evidence that every position was filled with requested data or delivered successfully.

Copyright 2026, James M. Atkinson

COMPLEX CROSS-PRODUCT AVERAGING: Averaging the complex paired-channel products before taking the magnitude used in a coherence calculation. Opposing phases can cancel in this operation. Averaging the individual normalized magnitude ratios instead loses that information and gives unity for every nonzero single pair, regardless of a repeatable relationship.

COMPLEX ENVELOPE: The complex amplitude-and-phase function that describes a signal relative to a chosen carrier in an analytic representation. Multiplying that envelope by the carrier exponential locates its spectrum around the carrier. Carrier choice, envelope bandwidth, and admitted physical RF band must be consistent. The envelope is a representation of the waveform, not proof that an image or an alias has been rejected by the receiver.

COMPLEX EXPONENTIAL: A complex sinusoidal representation that retains phase rotation and a signed frequency coordinate. Model 4A uses it to translate a complex envelope by the oscillator frequency without the absolute-frequency folding of a real difference display. Its sign convention must agree with the recorded I/Q ordering.

COMPLEX LOCAL OSCILLATOR: A rotating complex multiplier used to translate an analytic band without the absolute-frequency folding of a real difference display. The chapter uses a negative complex-exponential frequency convention for downconversion and retains the LO phase. The sign of that convention must agree with I/Q ordering and subsequent frequency-axis labeling. A mathematical unit-magnitude rotation does not state a physical mixer’s conversion loss.

Copyright 2026, James M. Atkinson

COMPLEX MODULUS: The nonnegative magnitude of a complex quantity. Squaring it removes phase information from that quantity, making the order of complex averaging and magnitude formation consequential. Averaging separately normalized single-record magnitudes cannot substitute for the paired cross-spectrum estimator.

COMPLEX RMS PHASOR: A complex sinusoidal representation whose magnitude uses the stated root-mean-square voltage convention and whose angle uses the declared phase convention. Power conversion requires the corresponding load model. A gain magnitude and phase rotation act on this representation before magnitude detection, which can remove the phase information.

COMPRESSION: Reduction of incremental gain as a stage approaches nonlinear or limiting operation.

CONDITIONAL CAPTURE PROBABILITY: The probability of meeting a defined acquisition geometry under a stated event-phase distribution and separately established signal and detector conditions.

CONDITIONAL EFFECT: The observed consequence of changing one factor at a specified setting of the other relevant factors. It may differ at another setting, indicating an interaction in the response. The result narrows the tested relationship without automatically identifying a faulty component or the unique physical cause.

CONDUCTED REFERENCE: Known signal applied at a specified electrical port to verify the transfer or response of the downstream path.

Copyright 2026, James M. Atkinson

CONFIGURATION BINDING: The specified association among device, executable artifacts, loaded images, calibration data, and actual settings used by an examination.

CONFIGURATION COMPARABILITY: Established compatibility of reference planes, corrections, observation limits, timing, and relevant instrument states sufficient to support a specified comparison.

CONFIGURATION IDENTITY: Complete hardware, firmware, software, option, accessory, and setting state required to reproduce a receiver observation.

CONFIGURATION TRANSITION: A change between receiver states that can include transient, relocking, or settling behavior. Records affected by the transition must be distinguished from intervals governed by an established valid configuration.

CONFIGURED OPERATOR: The complete declared transformation from an identified input to the retained output in Model 1A. It can include changes of units, representation, timing and sample indexing, as well as physical transfer. Writing an operator symbol does not imply linearity, a dimensionless gain, stationary noise or a unique inverse.

CONFOUNDING: An inability of the available design to separate the consequences of factors that vary together. Reference state and session are confounded when each state is observed in only one distinct session. More observations within the same incomplete arrangement do not establish the missing distinction.

Copyright 2026, James M. Atkinson

CONJUGATE-BAND REJECTION: Selection that removes the unwanted conjugate spectral band when constructing or processing the intended analytic complex signal from a real input. It is part of the representation and filtering required by the stated conversion convention. The associated factor-of-two amplitude normalization must be tracked. Merely naming an output I/Q does not demonstrate adequate rejection, correct channel ordering, or freedom from sampling aliases.

CONJUGATE SYMMETRY: The paired relationship between positive- and negative-frequency components of a real waveform: the coefficients at opposite frequencies are complex conjugates. This redundancy explains why a real magnitude observation cannot by itself distinguish the two sides of a conversion LO. An analytic representation removes the redundant band under an explicit normalization; a correctly retained complex record can then preserve signed-frequency information. For a real windowed record, the opposite-frequency squared magnitudes are equal and support the stated one-sided power folding. A general complex record need not have this symmetry, so its spectrum cannot automatically use the same doubling rule.

CONNECTOR REPEATABILITY: The consistency of a connection's electrical response when it is assembled again under controlled conditions. Reconnection, torque, contamination or mechanical strain can alter loss or reflection. A previous calibration remains relevant only to the extent that the resulting installed connection satisfies the required transfer and uncertainty conditions.

Copyright 2026, James M. Atkinson

CONSERVATIVE ENCLOSURE: A range guaranteed to contain the results permitted by the stated premises, even if some values inside it are unattainable. It can summarize several separate intervals but should retain that qualification. An enclosure is different from a probability distribution or a standard uncertainty.

CONSTANT COMPLEX-GAIN FIT: A weighted least-squares estimate of one complex coefficient that scales and rotates a disclosed ideal-reference sequence. Positive training reference energy makes the minimizer unique. The fit minimizes training residual energy, not every normalized EVM or held-out error, and its coefficient remains part of the result when the correction is permitted.

CONSTANT-ENVELOPE SIGNAL: A signal whose magnitude remains fixed over the stated interval and representation, even if its phase changes. Its power statistics differ from the chapter's Gaussian-noise example. A correction derived for exponentially distributed noise powers must not be applied solely because this signal is displayed on a decibel axis.

CONSTELLATION: The set or plotted arrangement of complex symbol locations under a declared reference and receiver processing. Its geometry describes amplitude and phase relationships, while labeling assigns information to locations. An apparently compact received cluster can depend strongly on synchronization, equalization and selected samples.

Copyright 2026, James M. Atkinson

CONSTELLATION MAPPING: The declared correspondence between symbol labels and complex reference values. A geometric point set alone does not establish this correspondence. Rotation or relabeling can preserve a constellation's appearance while changing the represented labels, so mapping validation is separate from a visually tight or numerically well-aligned display.

CONTENT RECOVERY: Reconstruction of information carried by a signal rather than mere detection or classification of its waveform.

CONTIGUOUS-OVERLAP CRITERION: A capture requirement met by one uninterrupted event-window intersection of at least a specified positive duration.

CONTINUITY VALIDITY MASK: Binary dependency indicator identifying outputs whose nonzero filter terms all use resolved available samples or justified known prehistory.

CONTINUOUS-WAVE STIMULUS: A sustained, unmodulated RF test signal over the observation interval. It is useful for transfer and level measurements, but a continuous-wave sweep does not expose every transient or post-pulse recovery condition. The stimulus must represent the capability that the acceptance claim is intended to cover.

CONTROL CLAMP: A limit that restricts a control quantity to an allowed range. Its action can make the observed large-change response differ from an unconstrained local model. Predictions of useful recovery must retain the clamp condition and gain mapping rather than extending the exponential law through an unverified limit.

Copyright 2026, James M. Atkinson

CONTROL INTERACTION: Dependence of the observed effect of changing one control on the setting of another, evaluated for a declared response and measurement context.

CONTROL POLARITY: The direction in which a control-voltage change affects receiver gain in the active calibrated range. A negative local slope means increasing voltage reduces gain; a positive slope gives the opposite relationship. Polarity belongs to the gain map and must not be confused with the positive time constant or the sign of a residual.

CONTROL RESIDUAL: The signed difference between actual control voltage and the target used for the current segment. Under the stipulated positive-time-constant one-pole law, a nonzero residual decays without changing sign. Its magnitude can be converted into gain-error magnitude only through an applicable gain slope. A target error or detector offset can create an apparent residual floor.

CONTROL STATE: The internal quantity used by a control model to represent the system’s present condition. Model 5A uses a voltage whose actual value carries into the next target interval. A new trigger or setting command does not establish that this state has already reached its target.

CONTROL TARGET: The equilibrium control voltage toward which a particular Model 5A segment relaxes. It is constant within that segment and is distinct from the voltage already reached. A new input, range or mode can change the target. Uncertainty in the target remains a separate contribution even after uncertainty in the initial state has decayed.

CONVERSION LOSS: Ratio of available input power at one mixer port to desired output power at the selected product port.

Copyright 2026, James M. Atkinson

CONVERSION ORIENTATION: The sign with which a local RF-frequency change maps into the selected real or complex output-frequency coordinate.

CONVERSION SCHEDULE: Ordered locations and rules at which a numerical pipeline changes format, rounds, saturates, or wraps.

CONVERSION-STATE BOUNDARY: A transition between receiver configurations that may change an LO plan, selected IF, injection side, preselector, or correction path. Both amplitude transfer and frequency orientation can change across it. Retaining state identity and timing allows observations to be interpreted with the applicable map. Verification should exercise relevant frequencies on each side and distinguish settled states from uncharacterized transition intervals.

CONVOLUTION: The operation that forms a linear filter output by summing appropriately delayed input values multiplied by the corresponding impulse-response coefficients. The chapter's finite causal sum fixes which source samples contribute to each output. Compressing a gap or resetting history changes those dependencies even when the coefficient list is unchanged.

CORRECTION CHAIN: The ordered, documented transformations that convert an original indication into a result at a declared reference plane. Retaining each term, sign, state, and applicability permits reconstruction and exposes omitted or double-counted contributions.

CORRECTION COVARIANCE: Joint uncertainty between correction inputs, retained with the signs of their measurement sensitivity coefficients.

Copyright 2026, James M. Atkinson

CORRECTION INTERPOLATION: Estimation of a correction between characterized points using a stated model and position. Endpoint uncertainty and covariance are distinct from the residual between the physical response and that interpolation model. An uncertain position, extrapolation or unresolved response structure changes the measurement equation and cannot be omitted merely because the file provides a smooth curve.

CORRECTION OWNERSHIP: The assignment of each gain, loss or conversion to the calibration or processing step responsible for it. Explicit boundaries prevent omission and double correction when antenna, accessory and receiver records overlap. The correct assignment follows the actual measured assembly and quantity, not merely the presence of a certificate or file.

CORRECTION RECORD: The record identifying a correction's measured transfer, reference planes, frequency grid, interpolation, uncertainty and serialized applicability. It establishes which measured path and state the correction describes. It must distinguish corrections already applied from those still required and retain raw observations where needed to reconstruct the result.

CORRELATION COEFFICIENT: A dimensionless normalized measure of covariance between quantities with nonzero standard deviations. Its contribution to output variance also depends on the signs of the measurement sensitivities. A favorable coefficient must be supported by the joint calibration model or evidence; it cannot be chosen to obtain a desired uncertainty or decision.

Copyright 2026, James M. Atkinson

COSINE PRODUCT IDENTITY: The trigonometric relation that expresses the product of two cosines as one half of the cosine of their angle difference plus one half of the cosine of their angle sum. It underlies the two real products in Model 4A and makes the multiplier normalization explicit.

COVARIANCE: The expected product of two quantities' departures from their respective means, when defined. Its units are the product of their units. Covariance contributes cross terms when observations are combined; omitting it can misstate averaging uncertainty, and zero covariance does not generally establish independence.

COVARIANCE MATRIX: The matrix of pairwise covariances of a specified input vector, with each entry carrying the product of the corresponding input units. A physically admissible matrix is symmetric and positive semidefinite. Separate plausible pairwise correlations need not form a valid complete matrix, so the joint model must be checked. Model 12B uses a specified valid geometric lag structure before evaluating its coherent-power sum; the admissibility check applies to the complete joint matrix.

COVERAGE FACTOR: Multiplier applied to combined standard uncertainty to obtain an expanded uncertainty under a stated convention.

COVERAGE FAILURE: Failure to observe an event because the relevant channel or interval was not validly acquired, such as a burst occurring while a scanning receiver was tuned elsewhere. It is distinct from a failure to detect an event during a valid dwell. Actual observation and settling records are needed to assign the failure category.

Copyright 2026, James M. Atkinson

COVERAGE INTERVAL: An interval assigned a stated probability of containing the measurand's value or values on the available information. It need not be symmetric about the reported estimate. Its endpoints and probability require an adequate uncertainty model; multiplying a local standard uncertainty by two does not establish that interpretation without further justification.

COVERAGE PROBABILITY: The probability assigned to an interval under a justified output-distribution and uncertainty interpretation. Multiplying standard uncertainty by two does not independently establish a universal probability. Such interval coverage is also distinct from the false-alarm or detection probabilities of a receiver search procedure.

CRITICAL SAMPLING: Filter-bank rate condition in which the aggregate output sample rate equals the input rate; it does not by itself establish reconstruction.

CROSS-CORRELATION: A lag-dependent comparison formed from paired signal values, with the complex-conjugation, averaging and normalization conventions stated. It can support timing or coherence analysis, but a feature in the result must be interpreted with the actual signal bandwidth, phase history and channel calibration. Correlation does not independently establish a propagation mechanism.

CROSS-DOMAIN CORROBORATION: Agreement among observations from different physical or information domains after their timing, state and dependencies have been reconciled. It can support a mechanism or linkage, but the domains may still share a cause. An optical observation establishes optical activity within its scope and does not automatically establish an RF source.

Copyright 2026, James M. Atkinson

CROSSED CONTROL STATES: An experimental arrangement in which every selected setting of one control is observed with every selected setting of another, subject to documented physical feasibility and comparability.

CROSS-POWER TERM: The interference contribution that appears when power is formed from the sum of two selected IF fields. Its value depends on their relative phase and on the averaging operation. Adding the individual mean powers is justified only when the relevant averaged real cross term vanishes. An unknown phase is not sufficient evidence for that condition, and a fixed quadrature relationship is distinct from statistical independence. Model 11B also retains a bound on the cross term between kept and omitted phase contributions. Their powers cannot be added without accounting for that interaction under the adopted averaging model.

CROSS-SPECTRAL CONJUGATION CONVENTION: The declared choice of which channel coefficient is complex-conjugated in each cross-product. Reversing that choice conjugates the resulting cross-spectrum, reverses its phase and leaves magnitude-squared coherence unchanged. A delay inference must retain the selected convention and any remaining phase-branch ambiguity.

CROSS-SPECTRUM: A complex spectral estimate formed from products of corresponding Fourier coefficients from two aligned channels, with a stated conjugation direction, common weights and compatible normalization. Its magnitude and phase describe a second-order relationship under that construction. Neither a nonzero value nor its phase alone identifies a unique physical coupling path.

Copyright 2026, James M. Atkinson

CROSS-SPECTRUM CANCELLATION: Reduction or disappearance of an averaged complex cross-spectrum because admitted shared components contribute opposing signs or phases. Both channels can still contain substantial shared power. The chapter's two-source and changing-state examples show why low coherence does not by itself establish that the channels have no common contribution.

CRYPTOGRAPHIC DIGEST: A fixed-length value computed from declared bytes using a specified cryptographic hash algorithm. Comparing it with an authenticated expected digest supports an artifact-identity check under the algorithm's security assumptions. The value alone does not show which file was loaded or establish the correctness of its executable behavior.

CUBIC INTERMODULATION MODEL: A bounded memoryless voltage relation retaining linear and third-order terms under explicit amplitude, loading, frequency, and fixed-state assumptions.

CUMULATIVE POWER GAIN: The product G_j of the linear power gains from the selected input through stage j. It describes signal power transfer between those planes in the stated fixed-state model. G_0 is defined as one, allowing the first stage noise contribution to be handled by the same recurrence as later stages. For any selected output plane, the overall decibel gain combines gains and losses with their forward-path signs. It is not established by averaging unrelated gain settings or applying one correction across an unverified transition.

Copyright 2026, James M. Atkinson

CURVATURE BIAS: The difference arising when the expected output of a nonlinear transformation differs from the transformation evaluated at the expected input. The squared-voltage example exhibits this mean shift explicitly. It is a model consequence, not evidence of an instrument fault, and its significance depends on the intended accuracy of the reported result.

CYCLIC REDUNDANCY CHECK: A structured binary error-detection check computed from a message using a specified polynomial convention. Its format and verification must match the decoded record. Independent CRC validation can help reject false decoder outputs, but a passed check is not a physical-source or cryptographic-authentication result.

CYCLOSTATIONARITY: Periodic variation in a signal's statistical structure, such as correlations associated with symbol or framing cycles. It can provide a classification observable when the estimator and observation interval are justified. A detected periodic feature is supporting evidence, not a complete modulation, decoder or source-identity validation.

DATA-SLOT FRACTION: The number of data-symbol slots divided by all nominal opportunities on the explicitly declared finite grid. It accounts for pilot or other nondata opportunities in that grid and differs from a payload-bit fraction. Its denominator must be positive, and any combined efficiency that already includes this reduction must not apply it again.

DBC: A logarithmic power ratio referenced to a specified carrier, expressed as ten times the base-ten logarithm of component power divided by carrier power. It describes a relative level rather than watts or dBm. The carrier definition and whether the component is a spectral line or integrated noise must remain explicit.

Copyright 2026, James M. Atkinson

DBC PER HERTZ: A logarithmic carrier-relative density notation with a one-hertz normalization. In Model 11B it labels the explicitly defined single-sideband phase density. Convert the value to linear density before weighted integration; a discrete spur has line power and cannot be treated as a density sample without an appropriate observation definition.

DBM: The logarithmic power-level convention referenced to one milliwatt. Its numerical value converts to a positive physical power through that reference. It must be distinguished from a dimensionless power ratio in decibels, and it cannot represent zero power by a finite value.

DC BIN: The zero-frequency transform coefficient. It represents the retained record's weighted constant component under the stated preprocessing. It is not doubled in the one-sided power sum, and subtracting a mean before transformation can remove it by changing the analyzed record rather than merely changing normalization.

DC OFFSET: A constant additive component in the declared complex sample or symbol coordinates. It can contribute to EVM even when an ordinary gain fit is permitted. Mean removal changes the measurement and may remove an intended nonzero-mean component, so the offset's physical cause requires an independent check.

DEAD TIME: Interval during which an acquisition system cannot accept or record another event.

Copyright 2026, James M. Atkinson

DECIBEL: A logarithmic unit for a ratio under its stated power or amplitude convention. In the scalar power model, gain and loss expressed in decibels correspond to multiplicative power transfer. Their signs in an inverse correction follow the forward path; a decibel difference does not represent subtraction of physical powers.

DECIMATED TRIGGER: A trigger operating on a rate-reduced representation of the signal. The preceding filter and sample-rate change can alter the event information and timing available to it. Its behavior must be checked against the saved waveform and intended event criterion rather than assumed equivalent to a full-rate trigger.

DECIMATION PHASE: Retained input-index residue modulo the decimation factor, specifying output time origin and coherent phase.

DECISION BOUNDARY: A boundary between symbol-decision regions in the receiver's declared observation space. Carrier phase, timing, normalization and the selected mapping determine how observations relate to it. A constellation can look geometrically regular while its decision regions remain associated with the wrong labels.

DECISION CRITERION: The stated condition under which an observation or numerical estimate supports an intended action or conclusion. It includes relevant validity and uncertainty requirements and must not be inferred merely from the appearance of a display. A procedure may specify acceptance, rejection and an indeterminate region relative to a requirement. Select and preserve the rule before examining the result; a later rule change creates a different decision rather than changing the earlier evidence.

Copyright 2026, James M. Atkinson

DECISION INSTANT: The declared time at which an observed, processed waveform sample is paired with a reference symbol for detection or quality assessment. Filtering, delay, symbol-clock configuration and timing recovery determine that pairing. Samples between decision instants are not silently included in a metric whose stated population consists only of symbol points.

DECISION STATISTIC: The quantity computed from an observation and compared with a criterion to decide whether a specified event has been detected. Examples in the chapter include amplitude, correlation, or coherent-integration results. Its distribution, duration, receiver state, and processing affect detection and false-alarm behavior; mean noise power alone does not specify those properties.

DECODER: A processing system that interprets a received representation under a stated format and produces fields or data. Its software version, synchronization assumptions, checks and failure behavior belong to the result. Plausible output can arise from false lock or a wrong-format input and therefore requires independent validation.

DE-EMPHASIS: A frequency-dependent operation in the recovered baseband path, commonly associated with an intended complementary emphasis characteristic. It changes the derived waveform and must be recorded with an audio result. Its presence alone does not establish the transmitter's characteristic or validate an amplitude or deviation measurement.

DELIVERED NOISE POWER: Noise power accepted by the receiving port under the actual source and load conditions. It equals available noise power in the stated matched real-impedance model. A matched-port insertion-loss value alone does not establish delivered power for a reactive antenna and a state-dependent receiver input match.

Copyright 2026, James M. Atkinson

DELIVERED POWER: The power transferred into the specified load under the actual source and load conditions. It can differ from available power when impedances are mismatched. A receiver indication and a calibration factor must refer to compatible loading before a terminal or field conversion is assigned.

DEMODULATED AUDIO: An audio-band product formed by applying a declared tuning, detection and processing chain to an RF or IF record. It retains only the information admitted by that transformation. Reproducibility requires a link to the native interval and configuration; intelligibility alone does not calibrate the output or identify a source.

DEMODULATION: Processing that recovers a baseband representation from the admitted modulated signal under an assumed waveform and reference model. The output depends on tuning, phase, filtering, gain and detector settings. A plausible audio result alone does not establish that the original RF relationship was preserved.

DEMODULATION FIDELITY: The extent to which a recovered representation preserves the particular amplitude, phase, frequency or timing relationship being claimed. It requires a stated reference and measurement criterion. A receiver can produce plausible audio while its filtering, phase alignment, limiting or normalization biases the intended quantitative result.

DEMODULATOR TRANSFER: The relationship between an admitted modulated waveform and a stated recovered output under a particular receiver configuration and state. It includes tuning, filtering, detector operation and relevant gain or conditioning behavior. Verification for one level, bandwidth or waveform does not automatically establish the relationship throughout the instrument’s operating range.

Copyright 2026, James M. Atkinson

DESENSITIZATION: Degradation of receiver sensitivity caused by overload, control action, noise elevation, or other strong-signal effects.

DESIRED INPUT EQUIVALENCE: Referral of an internally generated disturbance to the desired-signal input using the declared desired transfer; a center-frequency scalar requires a narrow signal or a justified constant-transfer approximation.

DESIRED SIGNAL: The signal component whose observation or measurement the current configuration is intended to support. Its retained amplitude, phase, modulation quality and detection opportunity supply the relevant acceptance criteria. Suppressing a blocker is not a successful improvement if the change also removes or invalidates the desired observation.

DESIRED-TRANSFER VERIFICATION: A check of the response to a known desired signal between stated planes in the relevant configuration. It establishes the traversed path at the check time and supports comparisons whose detection capability is retained. An injection at the receiver connector bypasses upstream components and cannot verify their contribution.

DETECTION: A finding that energy or a structured component met a stated decision rule under declared observation conditions. It does not automatically establish waveform class, emitter identity, carried content, or intent.

Copyright 2026, James M. Atkinson

DETECTION PROBABILITY: The probability that a specified rule produces a successful observation for the defined signal and eligible observation conditions. Its population must distinguish valid channel dwells from intervals when the receiver could not observe the event. A mean noise level or stipulated signal-to-noise ratio alone does not determine it.

DETECTION THRESHOLD: The declared boundary applied to a decision statistic for a defined detection event. Its selection should reflect a false-alarm objective and be tested with suitable noise-only and weak-reference observations. Lowering it can increase detected weak events while also increasing unwanted crossings; the threshold is not interchangeable with a receiver noise-floor number.

DETECTION TRIAL: One defined opportunity to evaluate a signal against the declared success rule. In a scanning receiver, a valid dwell and a period spent on another channel belong to different observation conditions. The denominator used to estimate performance must preserve that distinction instead of pooling sensitivity failures with coverage failures.

DETECTOR: The operation that converts the signal presented to it into the quantity used for an indication, such as a selected sample, peak or RMS value. Detector order, interval and subsequent processing are part of the measurand. Equal input waveforms need not give equal outputs under different detector rules.

Copyright 2026, James M. Atkinson

DETECTOR CREST-FACTOR LIMIT: An operating restriction on waveform peak relative to its RMS level for a detector or measurement path. Exceeding the applicable limit can invalidate an RMS or power indication even when average level appears acceptable. The limit depends on the specific detector and conditions; the name RMS does not establish unlimited peak-handling capability.

DETECTOR LAW: The operation that maps the admitted waveform into the detector's output quantity. Peak selection, power averaging and logarithmic averaging produce different statistics. A control voltage or display level cannot be converted into physical power without the applicable law and its bandwidth, range and waveform limits.

DETECTOR RIPPLE: Unwanted variation remaining in a detector output because the detection and smoothing process does not fully separate the desired envelope from faster components. The detector time response can trade ripple against faithful tracking of a changing envelope. The recorded waveform and detector settings determine which effect limits the result.

DETECTOR TAKEOFF: The physical or numerical point from which a detector receives its waveform. Its position relative to filters, gain stages, limiters and converters determines what it observes and which signals can influence control or indication. Audio, spectrum and recorded I/Q outputs can use different takeoffs; common receiver identity does not make their transfer functions equivalent.

Copyright 2026, James M. Atkinson

DETERMINISTIC ERROR BOUND: A justified limit on the magnitude or allowed set of an error under specified conditions. It differs from a standard deviation, which describes dispersion under an uncertainty model. Converting one into the other requires additional information; a multiple of standard uncertainty is not automatically a worst-case enclosure.

DETERMINISTIC PHASE ROTATION: A specified progression of mean phase across the actual sample times, such as that produced by a frequency offset. Model 12B keeps its finite phasor sum separate from independent random phase errors. Special frequencies are evaluated by the finite sum instead of an indeterminate trigonometric quotient.

DETRENDING: Removal of a specified fitted or fixed trend from the retained samples before spectral estimation. Even constant detrending can eliminate the DC component. The chapter's finite-window model assumes no detrending unless explicitly stated, so a software default that removes a mean changes the model input and must be accounted for.

DEVIATION: Peak or instantaneous departure of frequency from its unmodulated reference.

DFT BIN SPACING: The separation between adjacent frequencies at which a discrete Fourier transform is evaluated. It is the sample rate divided by transform length, with the record length used when no padding is applied. This grid spacing does not by itself establish the ability to resolve nearby components through the actual window response.

Copyright 2026, James M. Atkinson

DIFFERENCE PRODUCT: A mixer output component whose signed frequency is formed by subtracting one parent frequency from another under the selected conversion relation. For Model 4A the signed first-order value is RF minus LO; its real positive-frequency representation also depends on the sign of that difference. The component is distinct from the sum product, and selecting it requires a suitable actual signal path.

DIFFERENTIAL EQUATION: A relation involving a quantity and its rate of change that specifies a dynamic model together with appropriate conditions. Model 5A relates the control-voltage rate to its displacement from a constant target. A numerical approximation to that equation can behave incorrectly even when the stated continuous model is stable.

DIGITAL DOWNCONVERTER: Digital mixer, filter, and decimator that translates and selects a sampled frequency band.

DIGITAL MODULATION: Representation of discrete symbol values through specified waveform states, such as amplitude, phase or frequency. The modulation definition includes the mapping and timing needed to interpret those states. A receiver-generated constellation alone does not establish which format was transmitted or validate the decoded information.

DIMENSIONLESS LOGARITHM ARGUMENT: A pure numerical ratio supplied to a logarithm after compatible quantities and units have been reconciled. Model 1A divides physical power by its reference before taking a logarithm. Applying a logarithm directly to an unexplained unit-bearing number conceals the coordinate convention and can change the meaning of the result.

Copyright 2026, James M. Atkinson

DIRECT-CONVERSION RECEIVER: A receiver architecture that translates the intended RF region directly to baseband. Avoiding a conventional nonzero first-IF image does not remove all ambiguity or impairment. The chapter identifies DC offset, even-order distortion, oscillator leakage and I/Q imbalance as separate issues that still require characterization.

DIRECT FEEDTHROUGH: Transmission from an input port to an output path without the intended selected frequency conversion. It is one possible practical mixer response alongside leakage and generated products. Its observed significance depends on the actual routing, isolation and filtering, so it must be distinguished from the desired converted signal.

DIRECTIONAL COUPLER: A network that couples a controlled portion of a traveling RF signal into a measurement or auxiliary path with a specified directional response. It can support exposure and level measurements before a receiver is connected. Its applicable transfer, isolation and power conditions must be included in the complete path assessment.

DISCIPLINED OSCILLATOR: An oscillator whose output is steered using an external reference. Its correction behavior, lock state and loss-of-reference response form part of the timing system. The chapter treats holdover and reacquisition as consequential states; successful discipline on average does not establish negligible short-term phase noise or aligned multichannel samples.

DISCRETE FOURIER TRANSFORM: A finite linear transform that expresses a sample vector through complex coefficients on a discrete frequency grid. Its exponent sign, length and normalization are part of the definition. The coefficients describe the supplied finite record; they do not establish a unique underlying continuous signal or a stationary source.

Copyright 2026, James M. Atkinson

DISCRETE-TIME MODEL: A model that relates states or observations at indexed times through a recurrence. It can be an exact sampled form of a continuous model, an approximation, or the actual law of a discrete controller. Those origins are different and must be identified before simulated behavior is assigned to the physical receiver.

DISPLAY BUCKET: The group of processed observations assigned to one displayed trace location before the selected detector reduces them to an ordinate. Bucket formation and detector operation are implementation details that affect the statistic. A display pixel count cannot be treated automatically as a count of independent calibrated power samples.

DISPLAYED AVERAGE NOISE LEVEL: An analyzer noise indication defined using its stated bandwidth normalization, detector and averaging conventions. It must be interpreted through those conventions before comparison with another instrument or a communications sensitivity specification. The displayed value does not automatically include the complete installed antenna-to-output chain.

DISPLAY INDICATION: The value or feature presented by an instrument or software interface before its physical meaning is fully established. Interpretation requires the relevant plane, state, estimator, scale, and applicable corrections. Identify the supplied quantity, units, detector and processing state before additional external correction. An indication can already contain a correction; applying that correction again can make a plausible value inconsistent with the intended plane.

Copyright 2026, James M. Atkinson

DISPLAY RANGE: The span of levels that an instrument can represent on its selected display scale. It is a presentation limit, distinct from the range over which the receiver can measure a weak signal accurately in the presence of strong inputs. A visible trace therefore does not establish an uncompressed, calibrated measurement.

DISSIPATIVE ATTENUATION: Signal power reduction caused by a passive element that dissipates energy under the stated matched conditions. Its physical temperature determines its thermal emission. For loss L at temperature T_p, Model 2B assigns gain $\frac{1}{L}$ and equivalent input temperature $(L-1)T_p$; arbitrary reflected power is not automatically covered by this relation.

DOUBLE CORRECTION: Repeated application of the same correction to one result when that effect was already accounted for. It changes the central value and may also lead to duplicate uncertainty contributions. The correction's appearances in an export and a calculation record can refer to one shared input rather than two independent calibrations.

DOUBLE-SIDEBAND SUPPRESSED CARRIER: An amplitude-modulated form retaining two message-related sidebands while suppressing the intended carrier component. Coherent reception needs a declared carrier reference. In the chapter's real product-detector example, a residual frequency error creates a rotating projection and can split a recovered sinusoidal message into two tones.

Copyright 2026, James M. Atkinson

DOWNSAMPLING: Retention of selected positions from a sample sequence at a lower output rate, with a stated integer factor and retained phase. Bare sample deletion introduces no automatic reduction of a retained tone's amplitude or independent sample variance. Required filtering precedes deletion when unwanted bands would otherwise alias into the retained output.

DOWNSTREAM LOADING: The signal, noise, and interference presented to a later stage after the gains and losses preceding it. It is evaluated at that stage's own plane and frequencies, not inferred from the final corrected display. Additional early gain can reduce a later noise contribution while simultaneously increasing this loading and reducing the later stage's valid margin.

DUAL CONVERSION: A frequency plan containing two sequential selected conversions. Each real difference stage can preserve or reverse local frequency orientation. Two plans can yield the same final center frequency while mapping a small RF-frequency change in opposite directions, so both oscillator choices and branch states must be retained.

DUPLICATE SAMPLE INDEX: Repeated declaration of one source index in stored data; payload agreement and resolution remain separate questions.

DURATION-WEIGHTED AGGREGATION: A rate calculation that adds each interval's represented count and divides the total by the sum of compatible elapsed durations. It preserves the joint modulation, coding and efficiency factors realized within each interval. Separately averaging factors, or assigning equal weight to unequal-duration modes, generally gives a different result.

Copyright 2026, James M. Atkinson

DURATION-WEIGHTED MEAN POWER: The mean formed by combining compatible interval mean powers with weights proportional to their valid durations. Each interval receives its own applicable correction before aggregation. The result covers the represented intervals; overlapping records or omitted intervals require additional treatment, and averaging logarithmic labels produces a different statistic.

DUTY-CYCLE DISTORTION: A systematic departure of a clock's high and low intervals from their intended proportion. It concerns the relative timing of opposite edges, so a correct repetition frequency does not establish the intended edge pattern. Its measurement convention must identify the edges and reference duty cycle relevant to the sampling or timing path.

DYNAMIC RANGE: The range of signal levels that supports a specified detection or measurement task under declared lower and upper limits. Noise, compression, intermodulation and blocking define different versions. Bandwidth, signal spacing, detector, gain state and permitted error must accompany the number before it describes useful receiver capability.

DYNAMIC-RANGE ACCEPTANCE MATRIX: A structured set of receiver tests spanning the weak references, blockers, tone spacings, modulation, gain states, external paths and recovery conditions relevant to the declared use. Its results establish a bounded operating region and known exclusions. One favorable catalog number cannot replace this configuration-dependent evidence.

Copyright 2026, James M. Atkinson

EDGE TRIGGER: A trigger based on a declared rising or falling crossing in the observed trigger signal. The selected signal-path location, threshold, slope and timing behavior determine which event it identifies. A crossing in that path does not establish complete capture of the corresponding RF event.

EFFECTIVE APERTURE: Equivalent receiving area relating incident power density to available antenna power.

EFFECTIVE CHANNEL GAIN: The ratio of total output signal power to total input signal power for a specified spectral distribution under the applicable combination conditions. It can change when that distribution changes even if the physical path is unchanged. The chapter's two-tone example therefore does not supply a universal correction for every signal in the channel.

EFFECTIVE HEIGHT: A receiving-antenna conversion quantity relating incident electric field to a specified terminal-voltage response under declared direction, polarization and loading conventions. It answers a voltage question, unlike effective aperture's power-density relationship. Its use requires the applicable antenna convention and field conditions rather than treating all antenna conversion factors as interchangeable.

EFFECTIVE NUMBER OF BITS: Converter-performance metric derived from measured noise and distortion relative to an ideal quantizer.

EFFECTIVE PHASE NOISE: The phase-fluctuation spectrum experienced by a blocker in the actual conversion path, including relevant oscillator and driver contributions under a specified operating state.

Copyright 2026, James M. Atkinson

EFFECTIVE SAMPLE INDEPENDENCE: Degree to which samples supply distinct information after filtering, overlap and processing, rather than their nominal count.

ELECTRICAL BONDING: The deliberate conductive connection of equipment or structural parts to establish an intended electrical relationship and current path. Its RF effectiveness depends on the actual connection and frequency. A bonding intervention can change external coupling, so its effect should be assessed alongside the preserved desired-signal transfer and installation geometry.

ELECTROSTATIC DISCHARGE: A rapid release of accumulated electric charge that can expose an input network to a damaging transient. It is one of the events considered in receiver protection. Successful survival does not establish unchanged gain, phase, leakage or sensitivity afterward; the relevant measurement functions still need verification.

ELIGIBLE-START UNION: The union, over usable windows and schedule periods, of event start times that satisfy the declared capture criterion.

EMPTY PRODUCT: A product containing no factors, assigned the value one. In the cascade derivation this convention gives unity gain before the first stage, so that stage’s equivalent input noise enters the total without division by an imagined preceding gain.

Copyright 2026, James M. Atkinson

ENDPOINT ATTAINABILITY: Whether a stated bound can actually occur under the permitted joint inputs and dependencies. Combining individual extremes can give a conservative enclosure whose corner is excluded by those dependencies. The bound remains useful as an enclosure, but its endpoint must not be described as a demonstrated possible outcome without that check.

ENDPOINT TIME COMPARISON: An estimate of average fractional-frequency error obtained from two time-error observations divided by their reference-time separation. Deterministic endpoint-error limits propagate as a bound on that average. They do not become standard deviations without an additional statistical model, and the interval must not conceal an unmodeled reset.

ENERGY ACCOUNTING: The accumulation of power over the durations to which it applies, with represented and missing intervals treated separately. Model 1A uses valid-interval means to obtain retained energy and separately bounds possible gap energy. A plausible observed mean does not determine the total energy of an unobserved interval.

ENSEMBLE: The declared collection of realizations or paired records over which a statistical or finite weighted average is formed. Its selection, alignment and weights determine the estimator’s meaning. Membership in one collection does not establish independence, stationarity or consistency across changing receiver states.

Copyright 2026, James M. Atkinson

ENVELOPE DETECTOR: A detector that estimates a waveform's envelope magnitude through an applicable rectifying, magnitude or equivalent operation. Its bandwidth, time constants and nonlinear behavior affect the result. It loses the sign of an overmodulated real envelope and cannot generally substitute for coherent recovery of suppressed-carrier or single-sideband information.

ENVELOPE REVERSAL: A sign change of a real modulation envelope that magnitude detection cannot preserve.

ENVIRONMENTAL BASELINE: A set of observations describing the site contribution under stated spatial, temporal, polarization, and operating conditions. It helps identify variation relevant to operational sensitivity and possible external noise mechanisms. A baseline is bounded by its coverage and receiver validity; it does not make a quiet laboratory noise figure a guarantee for every occupied-site state.

EPOCH OFFSET: The time-reading error at a declared reference instant. It is the initial condition in Model 12A and is distinct from subsequent fractional-frequency error or drift. Correct average frequency does not remove an existing epoch offset, while a correct initial epoch does not prevent later accumulated error.

EQUALIZER: Adaptive or fixed filter used to compensate channel distortion and intersymbol interference.

Copyright 2026, James M. Atkinson

EQUIVALENT NOISE BANDWIDTH: Bandwidth of an ideal rectangular filter passing the same noise power as the actual filter or processing window. The equivalence assumes white noise and a stated gain normalization; it can differ from a nominal resolution-bandwidth label. A nonuniform spectrum requires the actual power weighting or a justified approximation rather than automatic multiplication by one bandwidth value.

ERROR VECTOR: The complex difference between an observed symbol value and its paired reference under the declared amplitude, timing and mapping conventions. Its real and imaginary components retain directional information. Squared magnitude contributes to residual energy, while the scalar EVM aggregate discards information about direction, symbol dependence and temporal ordering.

ERROR VECTOR MAGNITUDE: Normalized distance between measured and reference modulation symbols after stated processing.

ESTIMATOR: The specified mathematical operation that converts retained observations into a reported quantity. A detector bucket, integrated channel, fitted tone, or timing estimate can answer different questions despite similar display labels.

EVENT DURATION: The elapsed length assigned to an event in the stated capture model. It is distinct from the duration of signal that the intended measurement requires. Detecting a fragment, measuring a steady portion and preserving startup or the whole event can impose different criteria on the same event duration.

Copyright 2026, James M. Atkinson

EVENT REPEATABILITY: Consistency of the particular waveform properties that a repeated-event measurement needs to combine. Similar nominal repetition periods alone do not establish stable amplitude, phase, modulation or startup behavior. A spectrum assembled from repeated bursts requires evidence for the relevant consistency; otherwise it remains an aggregate of different observations.

EVENT START PHASE: The event's start-time position relative to a repeating observation schedule, considered modulo the schedule period. A particular event can have a fixed phase, while a probabilistic model assigns a distribution to possible phases. These are different statements, and ignorance of the encountered phase does not itself justify uniformity.

EVIDENCE APPLICABILITY: The demonstrated relationship between an observation or record and the subject, configuration, conditions, and proposition it is used to support.

EVIDENCE CONTINUITY: The documented connection from the acquired observations through their configurations, processing and supporting records to the reported inference. It allows later review of what was observed and what was derived. Preserving this connection is distinct from asserting that every sample was acquired continuously; both may be relevant to a particular claim.

EVIDENCE RECORD: The retained observations and contextual information needed to review a measurement and its interpretation. It includes consequential settings, native data, timing, corrections, challenges, unsuccessful tests, and limits on what was examined.

Copyright 2026, James M. Atkinson

EXACT SAMPLED RECURRENCE: The discrete update obtained by evaluating a stipulated continuous model at successive sample times without numerical integration approximation. For Model 5A with fixed target over the interval, the residual multiplier is the exponential of the negative interval-to-time-constant ratio. Exactness belongs to that model; it does not establish that a physically discrete controller implements the same rule.

EXCESS-NOISE RATIO: Calibrated noise-source quantity whose temperature and reference convention must be read explicitly; Model 2B uses the on-minus-off temperature divided by 290 K.

EXPANDED UNCERTAINTY: Combined standard uncertainty multiplied by a stated coverage factor, with the basis of the associated coverage interpretation identified.

EXPECTED VALUE: The mean assigned to a random quantity by its specified probability model. It describes the distribution rather than one observed record. The chapter distinguishes the expected logarithmic indication from the logarithm of mean power; neither automatically equals the result of a finite realized capture.

EXPERIMENTAL BLOCKING: Grouping observations under a declared nuisance condition while retaining the relevant comparisons within groups where practicable. It makes the condition explicit rather than removing it. If each reference setting occurs only in a different session, repetition within those sessions cannot recover the missing crossed comparison.

Copyright 2026, James M. Atkinson

EXPONENTIAL AVERAGING: A sequential averaging rule that assigns progressively less weight to older records according to a stated decay convention. It emphasizes recent behavior but can smooth changes and short events. Its apparent average count does not establish the independence or stationarity of the contributing measurements.

EXPONENTIAL DECAY: A decrease in a residual by the same multiplicative factor over equal time intervals under a fixed positive decay constant. In Model 5A it preserves the residual's sign and tends toward zero without reaching exact zero at a finite time from a nonzero initial value.

EXPONENTIAL POWER DISTRIBUTION: The positive power distribution generated by the squared magnitude of the chapter's zero-mean circular complex Gaussian sample at a calibrated plane. Its mean fixes its scale, and its variance is the square of that mean. A tone, clipping or a mixture of changing noise levels does not automatically have this distribution.

EXPOSURE ASSESSMENT: The examination of expected signal levels and waveforms at the receiver path before connection or a controlled challenge. It considers continuous and peak power, duty factor, coupling and transients, together with the applicable component limits. Protection hardware supplements this assessment rather than making the incident conditions irrelevant.

EXTERNAL GAIN: Signal gain contributed by a component outside the receiver indication's reference boundary. In the stated scalar backward level correction it is subtracted, provided its value and operating state apply to the observed path.

Copyright 2026, James M. Atkinson

EXTERNAL TRIGGER: A trigger derived from a separate input or control event rather than solely from the receiver's measured RF signal. It can establish a useful acquisition reference, but the delay and relation to the stored samples require characterization. A command event does not prove that the commanded physical state was reached.

FACTOR LEVEL: A specified physical setting or condition of a factor used in an experimental comparison. Its implementation can change several electrical or processing properties at once. Document the actual connections, terminations, routes and states rather than treating a convenient menu label as a uniquely isolated mechanism.

FALSE-ALARM PROBABILITY: The probability that the adopted decision rule is satisfied under the specified absence or noise-only condition. It depends on the decision statistic, threshold and set of opportunities being evaluated. A value established for one preselected channel cannot be transferred unchanged to an unrestricted frequency-and-time search.

FALSE LOCK: Apparent synchronization to noise or an incorrect structure.

FALSE POSITIVE: Result incorrectly satisfying a detection or classification rule in the absence of the claimed phenomenon.

FAR FIELD: The region where the radiation field admits the relevant far-distance approximations, including a stable angular pattern and approximately planar illumination across the receiving aperture. Applicability depends on wavelength, source dimensions and geometry. A fixed separation does not establish it universally.

Copyright 2026, James M. Atkinson

FAST FOURIER TRANSFORM: An efficient computational method for evaluating a discrete Fourier transform. Its speed does not change the finite-record interpretation, window response or normalization requirements. An FFT-based display remains conditioned by the actual samples and preprocessing, rather than becoming a direct measurement of an unrestricted continuous spectrum.

FEEDBACK LOOP: A control arrangement in which an observed response influences an action on the system. In gain control, detected level can change receiver gain and therefore later detected level. A fitted local control-voltage trajectory does not by itself reconstruct the detector, loop topology or every overload mechanism.

FIELD-TO-TERMINAL CONVERSION: The relationship between an incident field and the electrical quantity at an antenna's terminals under stated conditions. Pattern, polarization, field region, loading and installation affect its applicability. A sound terminal-power measurement therefore does not automatically support an equally sound field-strength estimate in an uncharacterized environment.

FILE ROLLOVER: The controlled transition from one recording file to the next during a longer acquisition. It keeps files manageable while requiring preserved chronology and explicit continuity evidence across the boundary. Successful closure and hashing of individual files do not by themselves show that no samples were lost or repeated between them.

Copyright 2026, James M. Atkinson

FILTER BANK: A set of selectable filters covering declared frequency bands. Changing the selected member can alter insertion loss, noise, phase and calibration even when tuning appears continuous. The record therefore needs the actual band identity and checks near the boundaries where the active path changes.

FILTER-BANK BOUNDARY: A tuning region where a receiver changes between discrete preselector or filter paths. The transition can change gain, phase, noise, or correction applicability even if the displayed frequency changes smoothly. Reference observations on both sides, together with actual band identifiers, are needed to assess continuity and the validity of comparisons across the boundary.

FILTER RINGING: A transient oscillatory response following a change or short excitation, determined by the filter's full dynamics. Ringing can extend an apparent event or alter a detected peak even when a continuous-tone amplitude is correct. Its relevance depends on the waveform and measurand; loaded Q or a single bandwidth label does not completely specify it.

FILTER SETTLING: The approach of an IF path's output to the response required by a stated stimulus and error criterion after a change. It depends on the full filter and observation chain, not merely the gain-control time constant. A burst shorter than the relevant settling interval can be measured before its steady response develops, changing peak or timing interpretation. A tuned or switched dwell can contain an unusable settling portion. Filter shape, architecture and the accepted error criterion matter; bandwidth alone does not supply a universal wait time.

Copyright 2026, James M. Atkinson

FILTER SKIRT: The part of a filter response that changes between its transmitted and rejected frequency regions. A blocker across this region can experience a very different transfer from a nearby desired tone. A wide waveform reaching into the skirt can suffer amplitude and phase distortion not represented by a center-frequency correction.

FILTER SPAN: The finite time or symbol-interval extent retained when implementing a pulse-shaping or receive filter. State its units, coefficient convention and relation to sample rate. Truncation, delay and initial history can affect the residual around transitions even when the nominal filter family and roll-off agree.

FILTER TUNING REPEATABILITY: The consistency of a tunable or switched filter's realized response when commanded to return to a specified state. It includes the response relevant to the intended amplitude, phase, or rejection measurement, not merely agreement of the displayed tuning value. Boundary crossings, temperature, and switching history can require explicit comparison.

FINDING CATEGORY: The explicitly stated evidential status assigned to a reportable observation, such as normal occupancy, artifact, installation defect or unexplained signal. Categories allow a conclusion to remain proportionate to the completed work. Moving to a stronger category requires its additional evidence rather than a more confident adjective.

FINITE DIFFERENCE: A change between sampled quantity values divided, where required, by their stated separation. Applied to correctly unwrapped phase, it gives an interval-average frequency under the chapter's continuity premises. Treating that result as an instantaneous derivative requires a further local approximation and an explicit interval convention.

Copyright 2026, James M. Atkinson

FINITE IMPULSE RESPONSE FILTER: A linear filter whose impulse response has finite support. In the chapter's causal construction, each output is a weighted sum of finitely many current and earlier samples. Its coefficients, source-index alignment and available history determine both frequency response and the duration of dependence on a missing input.

FINITE-RECORD ENERGY CLOSURE: The exact agreement between the correctly normalized discrete spectral integral and the corresponding window-weighted time-domain mean square. It checks transform scaling, side conventions and frequency spacing. It does not establish white noise, adequate sampling, physical calibration, source identity or valid observation of every transient.

FINITE-RECORD LOGARITHMIC BIAS: The difference between the expected logarithm of a finite arithmetic power average and the logarithm of its underlying mean power. For the chapter's independent exponential samples this depends on sample count and approaches zero as that count increases. It differs from the fixed offset of averaging the individual logarithms.

FINITE-SAMPLE SELF TERM: The diagonal contribution obtained when the squared magnitude of a finite coherent phasor sum is expanded. Each unit-magnitude phasor contributes its own power before cross terms are considered. This produces the finite-count contribution in Model 12B and prevents replacing expected coherent power by the squared ensemble-mean phasor.

Copyright 2026, James M. Atkinson

FIR STATE: Stored input history or equivalent realization state required to continue a finite impulse response filter across a processing boundary without changing the declared filter operation. The realization's delay-state coordinates need not be a raw list of prior input samples; transfer the compatible state or reconstruct the equivalent history.

FIRST-ORDER RESPONSE: A dynamic response represented here by one control-state equation and one positive time constant on a fixed-target segment. That local description predicts a monotone exponential approach. It does not prove that a physical receiver has only one internal state or that attack, release, hang and overload behavior share the same parameters.

FITTED-REFERENCE EVM: The normalized residual magnitude when the permitted fitted complex gain multiplies the ideal symbols in both the comparison reference and its energy denominator. The fitted coefficient must be nonzero and evaluation reference energy positive. Reducing the residual numerator does not guarantee a smaller ratio if the fitted denominator also falls.

FIXED-POINT FORMAT: A numerical representation with a specified total word width and a fixed binary scaling position. Together these determine its representable grid and range. Conversion into the format also requires a rounding and overflow policy; the format name alone does not specify where those conversions occur within a processing chain.

Copyright 2026, James M. Atkinson

FIXED-REFERENCE EVM: The normalized residual magnitude relative to a declared reference that is not adjusted by fitting the evaluated observation record. It can retain an amplitude or phase discrepancy that an allowed fit would remove. The reference, population, weights and compatible amplitude convention must still be specified; fixed does not mean independently validated.

FLAT LEAKAGE: The leakage level during the comparatively settled limiting portion of a specified large-signal event, as distinguished from an initial leading transient. The term does not imply identical behavior for every pulse width, frequency, source impedance, or load. It must be tied to the applicable test definition and does not alone establish survival or recovery.

FLAT-SPECTRUM APPROXIMATION: Replacement of a varying linear spectral density by one constant over the frequency region carrying significant filter weight. It is exact for the stated constant-density case and requires justification otherwise. A center-frequency phase-noise value alone does not establish the integrated noise when other admitted offsets have different densities.

FOLDED FREQUENCY: A representative nonnegative frequency in the first Nyquist interval for real-sample magnitude interpretation, without an implied analog-source identity.

FORWARD-EULER APPROXIMATION: A first-order numerical update that advances a state using the derivative at the beginning of the interval. Applied to Model 5A, its residual coefficient is one minus the interval-to-time-constant ratio. This differs from the exact exponential coefficient and can introduce sign alternation or instability when the step is too large.

Copyright 2026, James M. Atkinson

FOURTH MOMENT: The expectation of the fourth power of a stated real random quantity, when finite. Model 11B uses the phase fourth moment to bound omitted nonlinear power. A zero-mean Gaussian marginal supplies a particular moment relation, but that marginal condition alone establishes neither strict stationarity nor a specific phase spectrum.

FRACTIONAL FREQUENCY ERROR: Frequency difference normalized to a reference frequency.

FRACTIONAL SETTLING CRITERION: A requirement expressed as the permitted residual fraction of a specified nonzero initial step. For the chapter's one-pole law, a fixed fraction gives a fixed number of time constants, independent of step magnitude. A common absolute gain tolerance can instead require different waits for different initial errors. The chosen fraction must be tied to the measurement decision.

FRAME HEADER: A defined information field accompanying a frame's payload and counted according to the framing rule. It can consume coded transmission capacity without belonging to the requested payload. The finite-frame example separates header bits from final padding and from redundancy introduced by the channel code.

FRAME PADDING: Unused positions filled under the declared complete-frame rule when a finite request does not occupy all available payload capacity. These positions consume transmitted frame resources but do not add original request bits. Padding must be distinguished from headers, coding redundancy and retransmitted payload to avoid double counting their effects.

Copyright 2026, James M. Atkinson

FREQUENCY-AGILE SIGNAL: A signal whose operating frequency changes during the observation under a stated trajectory or switching behavior. A swept analyzer and the signal can traverse frequency at different times, leaving only fragments in the trace. Validation must reproduce the relevant timing and frequency behavior of the target event.

FREQUENCY-AXIS CALIBRATION: Establishing the relationship between known frequency values and a receiver or processing system's frequency indications under specified conditions. The relationship includes scale, offset, and orientation where relevant, together with applicable uncertainty. A center-tone agreement does not establish the direction of a frequency increment, and a reference or software-scale change can move labels without proving that a physical external tone moved.

FREQUENCY BIN: One discrete frequency coordinate and its associated transform or spectral estimate. A bin is an evaluation location, not an isolated physical band that necessarily contains one independent signal. Adjacent window responses can represent the same tone, and padding can add bin locations without adding observations.

FREQUENCY CONVERSION: The transformation of an admitted signal into another frequency coordinate through a declared mixing or digital operation. A complete description retains amplitude, phase, orientation and path selection as well as the output frequency. The absolute difference alone describes only a limited real first-order conversion case.

Copyright 2026, James M. Atkinson

FREQUENCY-DEPENDENT GAIN: A transfer that differs across the frequencies contributing to the measured quantity. Correct resolved components with their applicable gains before forming a channel total. A single aggregate correction depends on how input power is distributed across that response and cannot generally be obtained by averaging gain labels.

FREQUENCY DISCRIMINATOR: A receiver operation that converts frequency variation into a baseband output according to its applicable transfer characteristic. Deviation scale, bandwidth, linear range and input conditions require verification. The term does not guarantee that amplitude nulls, multiple components or threshold behavior leave the recovered frequency unambiguous.

FREQUENCY DIVIDER: A stage that derives a lower repetition or oscillation frequency from an input according to its division relationship. Divider-related clocks and harmonics can belong in a receiver spur search. The actual relationship and admitted path are needed before a numerical combination can support an interpretation.

FREQUENCY DRIFT: A change of fractional frequency with elapsed time under a declared local model. A constant drift coefficient gives a quadratic contribution to accumulated time error. Its fitted value and validity interval must remain explicit; the same law need not survive warmup, reference loss, restart or environmental change.

FREQUENCY INTERVAL: The declared frequency scope over which components can contribute to an observation or reported estimate. Excluded or unobserved portions remain outside a negative finding unless separate evidence establishes their coverage.

Copyright 2026, James M. Atkinson

FREQUENCY-MASK TRIGGER: A trigger that compares an estimated spectrum with a specified amplitude-versus-frequency boundary and applies the declared entry or exit condition. Its decision depends on the transform, window and processing interval. It therefore has different selectivity and timing from a direct sample-level threshold.

FREQUENCY MODULATION: A signal relation in which a specified message controls frequency deviation from a declared carrier reference. Phase follows by integration. For sinusoidal deviation, the peak phase index is peak deviation divided by positive modulation frequency; a constant offset instead produces a linear phase ramp.

FREQUENCY PLAN: The declared arrangement of oscillator frequencies, intermediate frequencies, injection sides and selected paths that maps an external input into the measured output. Its live state includes band switching and relevant references. Different plans can produce the same output center while retaining different images, orientation and calibration.

FREQUENCY RESOLUTION: The ability of a measurement procedure to distinguish nearby frequency components under stated signal and response conditions. Resolution bandwidth influences it, but filter shape, relative levels, observation time and processing also matter. A narrower display grid does not alone demonstrate improved separation.

FREQUENCY RESPONSE: The amplitude and phase transfer of a path as a function of frequency under its stated operating conditions. It explains which parts of a waveform are transmitted and how their phases change. A center-frequency gain or one bandwidth number does not determine the full response.

Copyright 2026, James M. Atkinson

FREQUENCY-SHIFT KEYING: A modulation family that conveys discrete values through selected frequency states. Classification must consider timing and the actual demodulation convention as well as visible spectral peaks. The choice of frequency states does not, by itself, establish the frame format, coding or source identity.

FREQUENCY SPAN: The frequency interval covered by a stated analyzer acquisition or display. In a swept mode, covering that span takes time and does not establish simultaneous observation of all included frequencies. Span must be interpreted with the actual sweep trajectory, selected filters, segment boundaries and usable observation intervals.

FREQUENCY STABILITY: The behavior of a source's frequency fluctuations over a specified time interval and under stated conditions. It is distinct from closeness to the desired nominal frequency: a stable source can retain a constant offset. The relevant averaging interval and treatment of drift or discontinuities belong with the stability statement.

FREQUENCY STANDARD: A reference that supplies or realizes a frequency used in comparison or calibration, with its applicable uncertainty and operating conditions established. A receiver's internal or external standard must be related to the point actually being tested. Its designation alone does not certify the present tuning, sample clock or distributed channel phase.

FREQUENCY SYNCHRONIZATION: Agreement of specified frequency rates or their controlled relationship over a declared interval. It can coexist with unknown epoch, trigger or channel-phase offsets. Sharing a reference oscillator therefore does not establish the sample alignment or deterministic phase relationship required for every multichannel inference.

Copyright 2026, James M. Atkinson

FREQUENCY SYNTHESIZER: A source that produces controlled oscillator frequencies using a reference and a synthesis architecture. Its references, divider relationships and lock state can contribute to the receiver's conversion map and spur hypotheses. The active configuration must be recorded rather than inferred from a generic block diagram.

FREQUENCY-TIME TRAJECTORY: The sequence of frequency regions observed as a swept or stepped instrument progresses through its acquisition.

FREQUENCY TUNING RESOLUTION: The spacing between adjacent frequencies selectable by the declared oscillator tuning-word model. It is a setting-grid property, distinct from spectral discrimination and actual frequency accuracy. The chapter separates the accumulator grid from phase truncation, clock error and other mechanisms that can affect waveform fidelity.

FULL-RATE TRIGGER: A trigger operating on the undecreased sample stream at its stated processing location. Its relation to saved samples still depends on filtering, comparator behavior and latency. The contrast with a decimated trigger identifies a path distinction; it does not establish universal timing or sensitivity performance.

FULL-SCALE RANGE: The declared amplitude range or reference span against which converter inputs and code spacing are specified. Its endpoint convention must be stated because a nominal positive reference peak need not be an exactly representable code. Signal headroom and crest factor affect the useful mean-square margin within that range.

Copyright 2026, James M. Atkinson

FUNCTIONAL ATTRIBUTION: An inference establishing the relevant operation or information function of a linked system. In the chapter's finding ladder, confirmation requires physical or operational linkage, an information path, authorization context, reproducible behavior and evidence continuity. A dramatic trace or recognizable modulation does not independently establish that complete claim.

FUNDAMENTAL COMPONENT: The output spectral component at one of the declared driving-tone frequencies. Its coefficient can contain both the linear response and nonlinear contributions at that same frequency. An intercept extraction that requires the linear asymptote must not silently substitute the full finite-level fundamental.

FUNDAMENTAL CORRECTION: The contribution of retained nonlinear terms to the amplitude at a parent frequency, distinct from a newly generated intermodulation component.

GAIN ALLOCATION: Choice and placement of gain that satisfies a noise requirement while preserving the valid signal range of later stages.

GAIN BUDGET: The accounting of component gains and losses connecting two declared signal planes. Linear power gains multiply, while their logarithmic gain differences add. Equal total signal gain does not imply equal noise performance, because moving loss or amplification changes how the individual noise contributions refer to the input.

Copyright 2026, James M. Atkinson

GAIN-ERROR MAGNITUDE: The nonnegative difference from the target gain attributable to the control residual under the chapter's calibrated local affine gain map. It equals the residual magnitude multiplied by the absolute gain slope and is expressed in decibels. It is distinct from signed gain change and does not include every calibration or signal-path error automatically.

GAIN EXPANSION: An increase in the selected response gain as the input rises away from the small-signal reference. In the stipulated cubic model, a positive cubic coefficient increases the fundamental amplitude within its declared range. Equal intermodulation powers can occur with the opposite coefficient sign, so those powers alone do not distinguish expansion from compression.

GAIN-FEASIBILITY INTERVAL: The overlap between a lower gain bound required by a noise objective and an upper gain bound permitted by downstream loading, under declared models and conditions. An empty overlap means no gain choice satisfies both requirements. A nonempty interval identifies candidate settings but does not independently establish stability, mismatch behavior, or transient validity.

GAIN-RANGE TRANSITION: A change between receiver gain ranges whose reference gain, control slope, limits or dynamics may differ. A continuous telemetry voltage does not prove continuous RF gain through the transition. Retain the active range and switch timing, use the applicable calibration for each segment, and verify any interval in which the transfer changes or becomes undefined for the intended correction.

Copyright 2026, James M. Atkinson

GAIN STABILITY: Constancy of the applicable signal power gain over the observations being compared. A hot-to-cold power ratio cancels gain only if the gain is common to both states. Repeatable switching-dependent gain changes can bias the inferred noise temperature even when repeated ratios have little random variation.

GAIN-STATE TELEMETRY: A retained record of actual receiver gain settings or gain-control behavior associated with acquisition time. Its temporal resolution must be sufficient for the amplitude interpretation being made. A final setting or average gain does not describe brief transitions, and telemetry cannot restore information lost by clipping or samples that were never acquired.

GAMMA POWER-SUM MODEL: The probability model for the normalized sum of the chapter's independent, identically distributed exponential power samples. It supplies the logarithmic moment used to derive the finite-record correction. Repeated copies, overlapping observations or other dependence do not acquire this model merely because the file contains the same nominal number of samples.

GAP MAP: An explicit record of missing or otherwise unusable sample intervals and their positions in the acquisition chronology. It prevents simple concatenation from erasing the true elapsed interval or creating a false signal discontinuity. Analyses requiring uninterrupted uniform sampling must respect the mapped boundaries.

GATED SWEEP: Measurement restricted to a selected time interval relative to a trigger.

Copyright 2026, James M. Atkinson

GATE WIDTH: The duration of the selected time interval admitted by a gated measurement. It determines which part of the event contributes, together with trigger delay, timing uncertainty and receiver response. A narrow gate does not by itself establish settled operation or capture of all the signal energy required by the intended measurand.

GAUSSIAN DISTRIBUTION: The real normal probability law specified by a mean and variance, including a limiting constant case when the variance is zero. Model 12B uses its characteristic function for a phase difference under an explicit joint-Gaussian premise. A measured RMS value alone neither establishes this law nor makes separate samples independent.

GRADIENT: The set of first partial derivatives of a scalar measurement function at a declared input point. These signed, dimensioned sensitivities define its local linear approximation. They can propagate input covariance locally, but a small or zero derivative does not show that curvature or a nearby domain boundary is negligible.

GROUP DELAY: Negative derivative of phase with angular frequency, used to describe delay of spectral components through a network.

GUARD BAND: Decision margin used to account for uncertainty near an acceptance or compliance limit.

GUARD BIT: Additional representation width retained to accommodate a proved intermediate range; its need depends on the actual operations and input bounds.

Copyright 2026, James M. Atkinson

GUARD INTERVAL: A declared time interval separating active signaling portions or frames. It belongs in elapsed-time rate accounting even when it contains no transmitted symbols. It may be represented as nominal slots only if that grid is explicitly defined through the interval; otherwise its duration is added separately.

HALF-POWER BANDWIDTH: The frequency separation between the two declared points where a response's transmitted power is one half of its reference level, conventionally associated with a three-decibel width. The reference response and crossing convention must be specified. It differs from noise-equivalent bandwidth and other labeled filter widths.

HANG STATE: A declared control mode that delays or modifies release after a specified event. A simple held-state example retains the attained control value for a defined duration before exponential release begins. The trigger, retrigger behavior and held quantity must be identified; replacing a hold with a larger release time constant changes the predicted trajectory.

HANN WINDOW: A cosine-based taper whose actual coefficient vector must be specified as periodic or endpoint-symmetric. Those forms have different finite weight sums, especially for short records. The chapter derives coherent gain and noise bandwidth from the selected vector rather than treating the name as a complete normalization rule.

HARMONIC: A spectral component at an integer multiple of a stated fundamental frequency. Mixer and oscillator harmonics can enter candidate product searches or contaminate a test stimulus. A harmonic's possible location does not establish that it exists at an appreciable level, so source purity and measured response remain separate evidence.

Copyright 2026, James M. Atkinson

HARMONIC GENERATION: Production of components at integer multiples of an input component's frequency by nonlinear behavior. A protection or active stage can create such energy while apparently preserving another part of the useful band. Characterization must distinguish the generated components from energy already present in the source.

HARMONIC PRODUCT ORDER: The declared integer-search measure equal to the sum of the absolute parent coefficients in the chapter's bounded product lattice. It limits which candidate combinations are enumerated. This bookkeeping order does not itself identify the physical nonlinearity, establish that every candidate is generated, or predict amplitude. A search report should retain the bound and any later expansion that increases the number of possible matches.

HEADROOM: Difference between operating level and a specified compression, overload, clipping, or damage limit.

HELD-OUT DETECTION TEST: Evaluation of a fixed detection rule on challenge records distinct from those used to select its threshold or processing. The chapter calls for both noise-only intervals and weak reference events under declared conditions. The separation helps reveal optimistic tuning results, while the tested event population and uncertainty still limit the conclusion.

HELD-OUT SYMBOL EVALUATION: Error-vector assessment on symbols excluded from fitting the stated alignment parameters.

Copyright 2026, James M. Atkinson

HELD-OUT VALIDATION: Evaluation on records not used to select the fitted model, processing rule or decision setting. It supports a claim about behavior beyond the examples used for that choice. Reprocessing the same selected field events under a stricter rule does not by itself provide this independent validation. For timing, phase and delay corrections, preserve the original records and correction method so that overfitting or retained instability can be examined. Alignment on the fitting record alone is insufficient evidence of behavior on excluded observations.

HIGH-PASS FILTER: A frequency-selective network that preferentially transmits frequencies above its transition region and suppresses lower frequencies within its specified response. In a front end, its useful protection depends on the actual blocker and desired-signal transfers, component placement, and power conditions, not just the filter-type label.

HILBERT TRANSFORM: The quadrature transform used with a real message to form an analytic representation. Under the chapter's complex-frequency convention it shifts positive-frequency components by minus a quarter cycle and negative-frequency components by plus a quarter cycle. Pairing the message with this transform supports the stated single-sideband construction; implementation errors still require measurement.

HOLDOVER: Operation of a disciplined clock after loss of its external reference using its internal oscillator and stored model.

HOT-COLD GAIN RATIO: Power gain in the hot source state divided by power gain in the cold state; a value other than unity invalidates the equal-gain Y-factor inversion.

Copyright 2026, James M. Atkinson

HOT-SOURCE TEMPERATURE: The calibrated or otherwise justified effective noise temperature T_h of the higher-noise source state in a hot-cold measurement. It must exceed T_c for the chapter inversion. Its applicability is tied to the reference plane, connection corrections, and source convention; it is not inferred solely from the receiver output being larger.

HOT-STATE COMPRESSION: Nonlinear response caused when the higher-noise source state drives part of the receiver beyond the applicable proportional gain range. It breaks the common linear law used to cancel gain in the hot-cold ratio. A stable output reading does not exclude this effect; both source states require an appropriate linearity check.

IDENTICALLY DISTRIBUTED SAMPLES: Samples having the same individual probability distribution. They can still be dependent. The expected average of their logarithmic powers uses the shared one-sample law, while the stated variance reduction and gamma sum model require additional independence assumptions.

IDENTIFIED CONTROL RESPONSE: A dynamic control-state law fitted or established within a declared operating interval and configuration.

IMAGE FREQUENCY: Unwanted input frequency that produces the same selected intermediate frequency as the desired input.

Copyright 2026, James M. Atkinson

IMAGE REJECTION: Suppression of the response to an unwanted RF input that reaches the same selected IF as the desired input, evaluated under declared frequency, level, and receiver-state conditions. A differential path measurement refers outputs to the actual calibrated input levels and controls source contamination. Rejection can vary with tuning, alignment, temperature, quadrature balance, and overload; a single tested pair does not establish a universal receiver value.

IMAGE-REJECT MIXER: A conversion structure intended to suppress the response from the alternate RF band that would otherwise share the selected output. Its rejection depends on the implemented paths, balance and operating state. Image rejection must be verified with controlled injections rather than inferred from the architecture's name.

IMAGINARY UNIT: The number whose square is minus one, denoted by j in the receiver models. It permits amplitude and phase to be represented together in complex envelopes and exponentials. Its use is mathematical; the physical real RF waveform is recovered through the explicitly stated real-part operation.

IMPEDANCE MATCHING: The interface condition that permits the stated source-to-load power-transfer convention. Model 2B assumes matching to one common real reference impedance, so available and delivered source power coincide. Reactive or state-dependent mismatch can invalidate a scalar correction measured between matched ports and may require a more complete network model.

Copyright 2026, James M. Atkinson

IMPULSE RESPONSE: The time-domain response of a linear path to an ideal impulsive input under the stated initial conditions. It describes the history through which that path acts on a waveform. Retaining the applicable response or a justified model is necessary when a short event cannot be interpreted from bandwidth alone.

INCIDENT POWER DENSITY: The incident electromagnetic power crossing unit area, specified with its direction and averaging convention and expressed in watts per square meter. The chapter's ideal receiving relation multiplies this quantity by effective aperture under the stated far-field, polarization and matching assumptions. It is distinct from terminal power and from power spectral density.

INCREMENTAL GAIN: The local change in an output quantity produced by a small change in the corresponding input quantity at a fixed operating condition. It can differ from the ratio of the total output and input. A compression curve interpreted through this gain must retain the input definition, reference planes and receiver state.

INDEPENDENT CAPTURE TRIALS: Trials whose relevant event phases and capture outcomes satisfy the independence needed by the stated probability model. Counting separate files or repeated commands does not establish this property. Under the additional common-probability premise, the complement of all misses gives the probability of at least one capture.

Copyright 2026, James M. Atkinson

INDEPENDENT COMPARISON: A comparison that changes relevant sources of measurement error while retaining the capability required to observe the component of interest. Separate instruments do not establish independence when shared clocks, input paths, or processing can produce a common result. The required distinction concerns the error mechanisms relevant to the intended inference. A useful added observation changes a coupling, timing or processing path that could otherwise explain the agreement.

INDETERMINATE RESULT: An outcome in which the supplied evidence does not meet the stated conditions for either acceptance or rejection. In the chapter's constructed rule, an uncertainty interval overlapping the upper limit has this status. It neither proves compliance nor proves that the actual quantity exceeds the limit.

INFLUENCE QUANTITY: Under the VIM convention for a direct measurement, a quantity that changes the relation between indication and result without changing the quantity actually measured. Receiver temperature can have this role in a fixed-input amplitude test. The GUM uses a broader convention, so the adopted measurement model must state which effects its inputs represent.

INFORMATION-BIT COUNT: The number of input bits belonging to the complete coding populations included in Model 7B. This count can include payload, headers and padding under the stated framing convention. It is therefore different from both coded label-bit count and useful request-payload count; its interpretation must accompany any code-rate or payload-fraction calculation.

Copyright 2026, James M. Atkinson

INITIAL CONDITION: The state assigned at the beginning of the interval over which a dynamic model is solved. It helps determine the subsequent trajectory together with the model and target. For successive receiver events, the applicable initial condition is the prior terminal state, unless a separately established reset or equilibration supplies another value.

INITIAL-STATE BOUND: A declared interval containing the control voltage at the start of a model segment without necessarily assigning a probability distribution. With fixed target and time constant, Model 5A maps both endpoints through an increasing affine transformation, contracting the interval width. The resulting bound covers initial-state uncertainty only, unless other parameter contributions are treated explicitly.

INJECTION SIDE: Whether the local oscillator lies above or below the desired RF frequency for a selected conversion.

INJECTIVITY: The property that distinct admissible inputs produce distinct complete outputs of a specified mapping. Critical sampling alone does not establish it. The chapter demonstrates a bank with a nonzero invisible input residue and a modified bank whose positive energy lower bound excludes such an input within the stated finite-energy domain.

INNER PRODUCT: A specified sum pairing the components of two vectors, including the required conjugation for complex values. It defines the geometry used in the chapter’s coherence and projection arguments. The reference, weights and ordering must be preserved because changing them changes the fitted relationship.

Copyright 2026, James M. Atkinson

INPUT INTERCEPT POINT: Extrapolated input level at which selected nonlinear products would equal the fundamental output under a defined test. The reference fundamental in Model 11A is its linear asymptote. The input intercept is defined per tone at the loaded input plane, within the declared model and measured interval. It is neither an attainable operating level nor the total power of a multi-tone input.

INPUT PATH: The physical route by which energy reaches the selected receiver input, including consequential antennas, cables, adapters, filters, switches, and other components. Changing the route can change both desired transfer and artifact mechanisms.

INPUT REFERRAL: A reporting transformation that expresses an output quantity at a declared input plane using the applicable transfer law. For noise power in the valid scalar model, divide by the state-specific signal power gain. The operation does not move noise generators physically or restore information lost through an invalid nonlinear state.

INPUT-REFERRED CONVERTER NOISE: The converter-added noise contribution expressed at an earlier selected input plane through the applicable analog signal power gain. Increasing valid analog gain can reduce this referred contribution while leaving the analog signal-to-noise ratio already present unchanged. The conversion requires the actual state and does not justify exceeding converter or upstream-stage range.

INPUT SUPPORT: The complete set of values permitted by the stipulated joint input model. It can determine whether a nonlinear operation is defined throughout the problem. The paired-power example proves a positive difference over its full support before applying a logarithm; a positive central estimate alone would not establish that property.

Copyright 2026, James M. Atkinson

INSERTION LOSS: The reduction in transferred signal associated with inserting a specified path under declared calibration planes, source and load conditions, frequency and level. Its measured value is conditional on those arrangements. Reconnection, strain, mismatch or a different selected branch can change the installed transfer.

INSTALLED PATH: The measurement path in its actual operating geometry and connections. Cable routing, antenna position, polarization, accessories, and coupling conditions can distinguish it from an isolated component characterization.

INSTALLED RESPONSE: Behavior of the receiving assembly in its actual mounting, cable, grounding, and environmental arrangement.

INSTANTANEOUS ACQUISITION BANDWIDTH: The frequency extent admitted for simultaneous acquisition in the stated receiver configuration. It limits which components can be preserved together in one usable interval. A wider displayed or swept span may combine observations made at different times and does not establish simultaneous coverage of that whole span.

INSTANTANEOUS FREQUENCY: In Model 6B, the carrier reference plus the derivative of the stipulated unwrapped phase divided by two pi, wherever that derivative exists. The model requires a meaningful nonzero complex signal and an applicable continuous phase branch. A finite phase difference instead gives an interval average, and a phase reset requires separate treatment.

Copyright 2026, James M. Atkinson

INTEGRATING CONTROLLER: A controller that accumulates a control error over time when determining its action. The cited gain-control example treats integrating behavior separately from its local small-change response. Limits and overdrive can alter the accumulated state, so a one-pole voltage fit alone does not establish the full controller behavior.

INTEGRATOR WINDUP: Accumulation or displacement of an integrating controller's internal state when the requested output cannot be achieved within an actuator or gain limit. Return to ordinary operation can then require recovery of that state. This is a possible large-change control mechanism, not a universal explanation for every slow receiver response; its presence and limits require circuit or input/output evidence.

INTERCEPT EXTRAPOLATION: The procedure of extending specified low-level fundamental and nonlinear-product laws to their algebraic intersection. In Model 11A it equates the linear fundamental asymptote to a selected cubic-product magnitude, retaining per-tone powers and reference planes. A measured fundamental with finite nonlinear correction requires a fitted asymptote or an explicitly bounded correction.

INTERCEPT POINT: The extrapolated input or output level at which a specified nonlinear product and reference fundamental asymptote have equal power under the declared test convention. It is a parameter of those response laws, not an attainable operating level or a compression threshold. The input and output values differ by the declared power gain expressed in decibels.

INTERMEDIATE CHECK: Reference observation between calibrations used to test continued validity for a stated quantity and configuration.

Copyright 2026, James M. Atkinson

INTERMEDIATE FREQUENCY: A frequency coordinate at an internal selected conversion output used for subsequent filtering, amplification, detection, or sampling. A receiver can contain several IFs, and the same final IF can arise through different conversion plans. Its magnitude alone does not identify the external RF input, the injection side, the phase orientation, or which unwanted response may have reached the selected path.

INTERMEDIATE-FREQUENCY CHAIN: The selected path of gain, filtering, detection and possibly digitization operating around an intermediate frequency. It is a measurement subsystem with its own transfer and state. Audio, spectrum display and stored samples may use different branches, so their results require the applicable path and detector information.

INTERMODULATION: Generation of spectral components from interactions among multiple input components in a nonlinear path. Their frequencies and levels depend on the admitted parents and the governing nonlinearity. A matching product signature supports a mechanism test but does not locate the generator without source, combiner and path controls.

INTERNAL CONTRIBUTION: Noise or artifacts generated within the declared measurement system rather than simply arriving at its chosen external input. Equation 1 retains this contribution so that observed output is not automatically equated with an environmental source. The retained output contribution has a quantity type and units compatible with that output. Calling it a residual does not establish independence from the input, a stationary distribution or an additive-power law.

INTERPOLATION RESIDUAL: Difference between a physical response and the adopted interpolation model, characterized separately from uncertainty in the endpoint values.

Copyright 2026, James M. Atkinson

INTERSYMBOL INTERFERENCE: Contribution from other symbol pulses to the observation used to decide a selected symbol. Pulse shape, sampling time, channel response and filter history determine that contribution. A filter name alone does not establish its absence in an imported or incompletely initialized recording.

INTERVAL-AVERAGE FREQUENCY: The unwrapped phase change divided by two pi and the elapsed interval, with any included phase discontinuity explicitly identified.

INTERVAL CONTRACTION: Reduction of an admitted state interval's width by a specified map. With fixed target and time constant, Model 5A multiplies the initial-state width by its positive exponential factor. This deterministic contraction does not include uncertainty in the target, time constant, gain slope or time alignment.

INTRAPULSE MODULATION: Variation of amplitude, phase, frequency or another defined property within the duration of a pulse. It is distinct from the timing or rate at which complete pulses repeat. Averaged spectra or insufficient instantaneous bandwidth can conceal which part of a pulse carried the observed structure.

INVERSE DISCRETE FOURIER TRANSFORM: The inverse finite Fourier mapping under a declared sign and normalization convention. Model 10C defines it with a positive exponential and division by the transform length. Its required unscaled channel sum is therefore the length times that inverse; substituting a differently normalized transform changes the voltage gain.

Copyright 2026, James M. Atkinson

INVERSE PROBLEM: The task of determining which input quantities are supported by a retained output and a declared forward model. A formula can be numerically reversible while the acquisition has discarded information or its state is unknown. Model 1A therefore checks domain, applicability and uniqueness before reporting an inferred input.

INVERSION CONDITIONING: The sensitivity of an inferred quantity to changes in the measured inputs of an inverse relation. The Y-factor temperature inversion is poorly conditioned near $Y = 1$ because its denominator approaches zero. Small ratio or calibration uncertainties can then produce large, asymmetric changes that a local linear uncertainty approximation may not adequately describe.

I/Q IMBALANCE: A departure from the intended relationship between in-phase and quadrature paths, such as unequal gain or an incorrect quadrature phase. It can produce image-like residual structure. A conjugate-component model can test that structure, but an EVM value or successful correction alone does not establish its physical origin.

I/Q ORDERING: The assignment and sign convention by which the in-phase and quadrature channels form a complex sample sequence. Reversing the sign of the quadrature channel conjugates that sequence and reverses its signed-frequency interpretation. A magnitude display may conceal the change. Known tones on both sides of the LO provide an end-to-end check of the saved data and frequency-axis convention.

I/Q SAMPLES: Paired in-phase and quadrature values representing a complex analytic or translated signal.

Copyright 2026, James M. Atkinson

JOINT DISTRIBUTION: The probability law describing a complete set of random quantities together, including their dependencies. Means and covariances alone do not determine an arbitrary joint law. The chapter adds joint Gaussianity when it needs exact nonlinear expectations of phase exponentials, separately from the second-order spectral description.

JOINT GAUSSIAN PHASE MODEL: An explicit distributional model in which every linear combination of the finite phase vector is normally distributed, allowing degenerate cases. The declared mean and covariance then determine the characteristic function used in Model 12B. Stationarity, marginal RMS values or a measured power spectrum alone do not establish this additional assumption.

LATENT SOURCE: An unobserved contributor capable of influencing more than one measured channel. A shared source can produce the same measured second-order spectra as a different linear representation. Coherence alone therefore cannot choose between a common-source explanation and a claimed direct physical path.

LEADING-EDGE LEAKAGE: The early portion of a strong event that reaches the protected downstream path before the later limiting response is established. Its peak and duration can differ from the subsequent leakage. A measurement of only the settled limited level may therefore underdescribe the actual exposure of the protected component.

LEAST-SQUARES CRITERION: A fitting objective that minimizes a stated sum of squared residual magnitudes. Its reference, weights, permitted parameters and fitting indices are part of the definition. Minimizing that objective establishes the best fit within those choices, not the physical correctness of the reference or the adequacy of the model.

Copyright 2026, James M. Atkinson

LIKELIHOOD RATIO: The ratio of the probability or probability density assigned to the same data by two specified hypotheses, with a positive denominator for a finite result. It requires defensible models of the data and selection procedure. This chapter uses the definition to state that requirement and assigns no numerical odds to its artifact or attribution categories.

LIMITER: A protection element whose transfer changes under a sufficiently large input to restrict the signal reaching later circuitry. It also remains part of the small-signal path. Leakage during the event, hardware survival and restoration of valid weak-signal measurement are separate properties requiring their own conditions and checks.

LIMITER CURRENT-RETURN PATH: The external circuit path through which current associated with a limiter's large-signal operation can flow. Its implementation influences the mounted protection response alongside the device itself. Characterizing only the isolated component can omit this circuit dependence, particularly when interpreting leakage, stored charge, and return to small-signal transfer.

LIMITER LEAKAGE: Signal power or transient energy that reaches the downstream path while a protection limiter is responding to a strong input.

LINEAR CHIRP: A waveform whose frequency changes linearly with time over a specified segment. Its accumulated phase is obtained by integrating that frequency trajectory. The chapter's ramp example returns to its initial phase at the end while making a substantial intervening excursion, so matching endpoint phases does not establish an unchanged history.

Copyright 2026, James M. Atkinson

LINEARITY CHALLENGE: A controlled change of input attenuation or another justified operating condition whose predicted response is tested while reference-plane corrections are retained. Departure from the prediction can expose overload or internally generated structure. It does not alone identify the cause, so the comparison must preserve or explicitly model other changed states.

LINEAR-POWER SUBTRACTION: Removal of an identified additive power contribution after converting compatible estimates to linear power units at the same reference plane and bandwidth. It requires justified power additivity. Subtracting decibel levels gives a ratio, and near-cancellation of total and background can make the recovered difference highly sensitive to measurement errors.

LINEAR TIME-INVARIANT SYSTEM: A system whose input-output relation is linear and unchanged by a shift of the time origin within its stated operating state. Model 2B assumes this behavior in selected equivalent-channel coordinates. A frequency converter is not thereby declared time invariant at the original RF waveform level.

LOAD-DEPENDENT STABILITY: The dependence of an active assembly's stable behavior on the impedance and network connected to it. An amplifier may respond differently to an antenna, matched termination, switch branch or cable. Stability evidence therefore covers the configurations actually tested and does not follow solely from one favorable bench arrangement.

Copyright 2026, James M. Atkinson

LOADED CONVERSION POWER GAIN: The ratio of selected IF power to RF power at the two declared loaded planes in Model 4A. For positive real loaded resistances, it equals the squared voltage scale multiplied by RF resistance divided by IF resistance. It therefore differs from the squared voltage ratio when the loads differ. This defined ratio is not automatically an available-power data-sheet gain.

LOADED QUALITY FACTOR: A response descriptor formed, in the chapter's stated resonant approximation, from center frequency divided by the half-power bandwidth. It describes the loaded response under that convention. Equal values do not imply equal skirts, phase delay, ringing or transient behavior, and the descriptor is not a complete filter model.

LOADED VOLTAGE: The terminal voltage under a declared connected load. Antenna factors and voltage-to-power conversions must use the compatible impedance and calibration convention. A nominal impedance label does not remove the need to state whether the calibration describes loaded voltage, open-circuit voltage, available power or delivered power.

LOADED VOLTAGE GAIN: The ratio of output voltage across its declared load to input voltage at its declared loaded plane; power gain additionally depends on both resistances.

LOCAL CONVERSION SLOPE: The derivative describing a small change in selected output-frequency coordinate with respect to a specified parent frequency on a fixed conversion branch. In the integer lattice its magnitude and sign depend on the relevant coefficient and, for a real absolute-frequency output, the sign of the current product. It is conditional on unchanged path selection and does not apply across an unmodeled switch or cusp.

Copyright 2026, James M. Atkinson

LOCAL GAIN MAP: A calibrated relationship between control state and receiver gain over a specified range.

LOCALIZATION: An inference about where a source or coupling region is situated from spatially informative observations. Receiver evidence may contribute through direction or gradients, subject to propagation, geometry and calibration. Localization is a different evidential step from classifying a waveform or linking it to a particular device and function.

LOCAL OSCILLATOR: The receiver's internal or supplied oscillatory reference used for frequency conversion. Its frequency and phase enter the selected conversion relation, while its noise, harmonics and leakage can affect the measurement. The actual oscillator state is part of the configuration that maps displayed coordinates to possible external inputs.

LOCAL-OSCILLATOR LEAKAGE: Unintended appearance of oscillator energy at mixer ports, cables, enclosure, or antenna.

LOCAL PROPAGATION ADEQUACY: Suitability of a first-order uncertainty approximation for the stated input domain and intended output, including the effect of neglected curvature and boundaries.

LO DRIVE: The actual local-oscillator excitation applied to a mixer under a stated waveform, level, frequency, and port condition. It influences physical conversion behavior and cannot be replaced by the dimensionless normalization of an ideal multiplier. A conversion measurement must retain the applicable drive and any disturbance caused by strong input signals. The correct LO frequency alone does not establish the intended conversion gain.

Copyright 2026, James M. Atkinson

LOGARITHM CONCAVITY: The mathematical property that makes the average of positive-power logarithms no greater than the logarithm of their arithmetic average. Equality holds when all included powers are equal. This establishes the direction of the difference for each record; it does not prescribe a universal numerical correction or prove a Gaussian noise model.

LOGARITHMIC AMPLIFIER: Amplifier producing an output approximately proportional to the logarithm of input amplitude over a defined range.

LOGARITHMIC MOMENT: An expected power of the logarithm of a positive random variable under a specified distribution. The first and second logarithmic moments support the chapter's mean and variance calculations for noise-level statistics. They are different from taking logarithms of ordinary power moments.

LOGARITHMIC UNCERTAINTY PROPAGATION: Propagation through a logarithmic transformation of a strictly positive quantity using the appropriate model and sensitivity. The chapter separates exact variance of a linear power difference from the local variance of its logarithm. Exact transformed limits can be asymmetric, and a domain admitting zero or negative power differences requires a different treatment.

LOGARITHM OF AVERAGED POWER: A level obtained by first averaging calibrated powers in linear units and then taking the logarithm of that average relative to the reference power. The linear average is unbiased under the stated stationary model, while its logarithmic conversion can retain a finite-record bias. The number and dependence of the contributing samples matter.

Copyright 2026, James M. Atkinson

LOG-AVERAGE BIAS: Difference between the expectation of an averaged logarithmic noise statistic and the logarithm of mean power under a specified probability model.

LOG-DETECTOR INTERCEPT: The reference offset in a specified calibrated relationship between a logarithmic detector's output and its input level. It is meaningful only with the stated slope, units, waveform conditions and operating range. An incorrect intercept creates a systematic level error, and a printed formula must be checked for consistency with its definitions before being used as a device-specific correction.

LOOP BANDWIDTH: The frequency range over which a synchronization or control loop substantially follows changes, under its stated response convention. Increasing or reducing it changes the tradeoff between following dynamics and admitting noise. Record the setting with acquisition behavior and residual errors rather than treating it as a universal quality score.

LOWER SIDEBAND: The message-related spectral component or band below a declared carrier. In Model 6A's single-tone complex convention its envelope rotates at negative message frequency, and translation retains that sign before any conversion to real-audio magnitude. The label depends on the reference and conversion orientation.

LOW-NOISE AMPLIFIER: An amplifier selected to provide useful gain with a suitably small added-noise contribution. Its benefit depends on placement, admitted blockers, matching and linearity. An amplifier before a lossy path can suppress later noise contributions, while the same placement can expose it to strong signals that a downstream filter would have rejected.

Copyright 2026, James M. Atkinson

LOW-PASS FILTER: A frequency-selective network that preferentially transmits frequencies below its transition region and suppresses higher frequencies within its specified response. It can reduce admission of high-frequency blockers, but its passband loss, phase response and location still determine the effect on the desired observation.

MAGNITUDE-ONLY RECORD: A representation retaining magnitude while discarding the corresponding phase. Several complex inputs can then produce the same stored result. Known complex transfer and bounded amplitude can support a power statement within the model, but cannot reconstruct phase that was never retained.

MANY-TO-ONE TRANSFORMATION: A transformation that maps distinct permitted inputs to the same retained output. Clipping and magnitude detection provide concrete examples in Model 1A. The shared output cannot select one original input without additional information, even when the transformation itself is known exactly.

MARGINAL DISTRIBUTION: The probability law of one component considered without conditioning on the other components of a joint record. Equal phase marginals can coexist with different dependencies between samples. The common-phase and independent-phase cases therefore have the same individual RMS but different coherent signal powers.

MATCHED FILTER: Filter designed to maximize output signal-to-noise ratio for a known waveform under specified noise assumptions.

MAX HOLD: Trace process retaining the highest detected value at each display point over repeated acquisitions.

Copyright 2026, James M. Atkinson

MAXIMUM-REFERENCE NORMALIZATION: Normalization of residual mean square by a declared maximum ideal-symbol energy rather than the record's average reference energy.

MEAN COHERENT SIGNAL POWER: The expectation of the squared magnitude of a declared coherent signal sum, distinct from the squared ensemble-mean phasor and from a complete SNR calculation.

MEAN SQUARE: An average of squared magnitudes under a declared sample population and weighting. It has squared-amplitude units and can be converted to power only through the applicable physical relationship. The window-weighted value recovered by spectral integration need not equal the unweighted mean square of a transient record.

MEASURAND: Quantity intended to be measured, stated with its reference plane, state, bandwidth, and conditions. Receiver-terminal power, field strength, relative phase and detection probability require different measurement models. Defining the intended result before selecting corrections and calibrations prevents the available display from silently choosing the measurement question.

MEASUREMENT CHAIN: The connected physical and computational transformations that carry an input to a reported result. Its relevant boundaries include gain, loss, filtering, conversion, detection, sampling, timing, and analysis.

Copyright 2026, James M. Atkinson

MEASUREMENT CORRECTION: A compensation applied for an identified effect in the measurement model. Its sign follows the physical relationship and its uncertainty remains in the result. A known significant offset should not be concealed merely by widening an uncertainty interval, and a correction already applied by the instrument must not be counted twice.

MEASUREMENT DEFINITION: The stated quantity or proposition together with its reference plane, frequency and time intervals, receiver state, estimator, and intended decision.

MEASUREMENT ERROR: The signed difference between a measured value and the applicable reference value. It is distinct from uncertainty, which describes the dispersion attributed on available information, and from an implementation mistake. A calibration can estimate an error relative to its reference; an unknown error is not made known by reporting a small uncertainty.

MEASUREMENT MODEL: Equation or functional relationship connecting the measurand to input quantities.

MEASUREMENT UNCERTAINTY: A nonnegative measure of the dispersion of values attributed to a measurand using the available information. It can incorporate both repeated-observation evidence and uncertainty in corrections or reference values. Standard and expanded uncertainty are specified forms of expression; uncertainty itself is neither a signed error nor a guaranteed maximum deviation.

Copyright 2026, James M. Atkinson

MEASURE-ZERO EVENT: An event assigned zero probability by the stated continuous probability law even though it need not be logically impossible. A single exact boundary phase has this property under the chapter's uniform phase model. Deterministic boundary tests still require their own endpoint convention, and a discrete or concentrated phase law can change the probability.

MECHANISM PREDICTION: A stated consequence expected from a proposed physical or processing explanation under a specified intervention. Writing competing predictions before changing the setup gives the challenge a discriminating purpose. An observed match supports only the consequences tested and does not exclude alternatives that predict the same behavior.

MEDIAN: A central order statistic or distribution quantile that divides the ordered population under a stated convention. It is not generally interchangeable with an arithmetic mean in algebraic estimator identities. Separate medians of cross-products and autospectral products need not form the single paired construction required by the coherence bound.

MEMORYLESS NONLINEARITY: A relation in which the output at an instant depends on the input at that instant without an internal stored state. The fixed cubic law can produce new frequency components even though it has no memory. Thermal history, control-loop dynamics and frequency-selective storage require a different or extended description.

Copyright 2026, James M. Atkinson

MESSAGE MEAN SQUARE: The declared time average of the squared normalized message. For a zero-mean AM message it determines the additional average power through the squared modulation scale. A unit cosine has mean square one half, but a general bounded message need not; its peak bound alone does not establish this statistic.

MESSAGE NORMALIZATION: The stated scaling that relates a physical or mathematical message to the dimensionless waveform used in a modulation model. In Model 6A the message magnitude is bounded by one and the separate modulation scale sets its contribution to the envelope. Changing that normalization without changing the scale alters the modeled waveform and power.

MINIMIZATION: Technical and procedural limitation of collection, retention, and disclosure to information necessary for an authorized purpose.

MINIMUM DETECTABLE SIGNAL: Input signal level meeting a stated detection criterion under specified conditions.

MINIMUM PRECEDING GAIN: The least first-stage power gain that meets a specified two-stage equivalent-temperature target under the stated positive downstream-noise assumptions. Equation 4J gives $\frac{T_{e,2}}{T_{target} - T_{e,1}}$ when T_{target} exceeds $T_{e,1}$. This is a noise constraint; it does not establish that the required gain is available, stable, or valid under the blocker environment.

MINIMUM TRIAL COUNT: The smallest positive integer number of qualifying trials that meets a specified conditional capture target under the stated probability assumptions. Model 15A rounds the interior logarithmic result upward and checks the preceding integer. Zero-probability, certain-capture and exactly-one target cases require their separate endpoint rules.

Copyright 2026, James M. Atkinson

MISMATCH UNCERTAINTY: Uncertainty caused by unknown or varying phase relationships among reflected waves at imperfectly matched interfaces.

MIXER: A frequency-converting device that combines an input with a local-oscillator signal. A useful output is selected from sum, difference and other possible products. Actual conversion gain, leakage, noise and distortion depend on the architecture and operating conditions; a correct candidate frequency does not establish the amplitude of a real product.

MIXER DE-EMBEDDING: Removal or accounting of surrounding filter, amplifier, cable, and interface effects so that an inferred result refers to the mixer itself at declared planes. Scalar gain subtraction requires compatible power conventions and applicable linear installed-path values; mismatch and interaction can require a more complete treatment. De-embedding changes the measurand and must not be confused with directly measuring the complete receiver transfer.

MIXER LEVEL: The signal level presented at the mixer's specified input plane after preceding gain, loss and filtering. It matters to amplitude accuracy and nonlinear behavior. An input indication or reference-level setting does not establish the actual mixer level without the intervening configuration and transfer information.

MODULAR WRAPAROUND: An overflow rule that discards multiples of a format's code range and returns the corresponding representable signed code. An over-range positive result can therefore become negative. It differs from saturation and from ordinary rounding; restoring a later scale cannot recover the discarded range information or validate an earlier overflowed operation.

Copyright 2026, James M. Atkinson

MODULATING MESSAGE: The waveform used to vary the specified carrier or phase parameter in a modulation model. Its scale, spectrum, mean square and phase relationships affect the result. Equal maximum excursions do not guarantee equal average modulated powers, so the message definition must accompany the reported modulation parameter.

MODULATION FREQUENCY: The rate of a sinusoidal modulating component, expressed in hertz, or an explicitly identified frequency within a more general message. It differs from peak frequency deviation and peak phase excursion. A multicomponent waveform requires the component frequencies and, for a Carson estimate, the highest significant modulating frequency under a stated criterion.

MODULATION INDEX: Dimensionless ratio describing modulation excursion relative to a modulating frequency or carrier parameter.

MONOTONE RESPONSE: A response that moves in only one direction over the specified interval. The fixed-target one-pole solution moves between its initial state and target without overshoot or a reversal of residual sign. An observed violation is evidence against that uninterrupted segment model, not a reason to discard the observation.

MONTE CARLO PROPAGATION: Numerical propagation of an assigned joint input distribution by repeatedly evaluating the measurement model on sampled inputs. Retaining dependencies is essential when references or corrections are shared. The method can represent nonlinear output distributions, but numerical convergence does not verify the physical model or justify unsupported input laws.

Copyright 2026, James M. Atkinson

MULTIPATH: Reception through multiple propagation paths whose delays and phases combine at the observation point. Its frequency-dependent effect can unbalance sidebands or alter demodulated behavior. A changed receiver output therefore needs path and reference checks before it is interpreted as a change in the transmitted modulation.

MULTIPLIER NORMALIZATION: The declared numerical scale of an ideal mixing operation that determines selected-product voltage and power.

MULTISINE: A waveform formed by adding several sinusoidal components with specified frequencies, amplitudes and relative phases. In the cited receiver calibration, it supplies known spectral content across a band for complex-response characterization. Its peak behavior depends on the component choices, and its successful calibration use does not by itself establish response to every waveform or nonlinear operating state.

MUTUAL COUPLING: Electromagnetic interaction through which nearby antennas or conducting structures affect one another’s currents and response. A calibration performed in one arrangement can therefore contain interactions absent from another. Component identity alone does not establish that the installed field conversion is unchanged.

NATIVE RECORD: Data retained in the acquisition system's original useful representation, together with sufficient configuration information to interpret them. The term does not guarantee correctness; it identifies inputs that can support reconstruction before later transformations discard information.

NEAREST EVEN ROUNDING: Selection of the nearest representable code, with an exact halfway case assigned to the even integer code.

Copyright 2026, James M. Atkinson

NEAR FIELD: The region in which the required far-field approximations are inadequate for the stated measurement. Precise local observations remain possible, but extrapolating them through a plane-wave antenna conversion or a simple distance law requires additional justification appropriate to the source and geometry.

NEGATIVE CONTROL: A comparison selected to test a specific alternative explanation under defined conditions. Examples include a terminated input or a noise-only record, each with its own scope. A successful control does not cover every field state, and failures must remain in the record alongside passes.

NEGATIVE FINDING: A bounded statement that no event meeting a defined criterion was observed under demonstrated valid coverage and capability. Its meaning must preserve the tested event class, sensitivity, intervals, and exclusions.

NEGATIVE FREQUENCY: The opposite direction of phase rotation in a signed complex-frequency representation. In a real waveform it is paired with a conjugate positive-frequency component; in a general complex record the two sides need not be redundant. Rewriting a negative-frequency cosine at positive frequency changes the associated phase sign.

NEGATIVE-PEAK DETECTOR: A detector that retains the lowest indication within its specified observation or display bucket. Its meaning depends on the quantity entering the detector and the instrument’s bucket convention. It does not estimate the same statistic as a positive-peak, sample or power detector simply because all results share a decibel display axis.

Copyright 2026, James M. Atkinson

NOISE BUDGET: An accounting of source noise and stage-added contributions referred to one declared plane under a common bandwidth and operating model. Listing each contribution reveals which component controls the total and which improvement can matter. A valid budget also records the assumptions whose failure would make its calculated result inapplicable.

NOISE FACTOR: Ratio of input signal-to-noise ratio to output signal-to-noise ratio under the declared source temperature and matching convention, expressed in linear units. Model 2B uses a 290 K reference source; degradation for a different actual source temperature is a separate quantity.

NOISE FIGURE: The logarithmic expression of noise factor, $NF_0 = 10 \log_{10}(F_0)$, in decibels at the declared reference temperature and conditions. Its numerical convenience does not remove the need to identify the included network and state. It differs from actual SNR degradation when the source temperature differs from the reference temperature, except in the zero-added-noise case.

NOISE FLOOR: The noise level associated with a stated measurement path, bandwidth, detector and observation procedure. It is a scale for interpreting weak observations, not a universal detection boundary. Filtering or coherent processing can change usable sensitivity, while overload can invalidate a component that appears above the displayed floor.

Copyright 2026, James M. Atkinson

NOISE-LIMITED SENSITIVITY: A bounded input-signal requirement derived when the admitted source and receiver noise are the relevant limiting contributions and the detector requirement is separately justified. Equation 4L uses $\gamma k B(T_s+T_e)$ with full desired-signal retention. Compression, structured interference, coverage failures, or another detector law can require a different operational analysis.

NOISE MARKER: An analyzer output intended to report a noise quantity using a specified local measurement and normalization procedure. It may already incorporate statistical or bandwidth corrections. The reported units and processing history must be checked before applying another correction or comparing it with an uncorrected trace.

NOISE-MARKER CORRECTION: A declared processing adjustment used by an instrument or analysis method to convert its measured noise statistic into a specified reported convention. Detector-statistic and noise-bandwidth adjustments have different causes. Establish which adjustments are already present before applying additional corrections, and do not infer the sequence from a marker name alone.

NOISE-ONLY VALIDATION: Evaluation of the chosen detection rule on records intended to represent the stated no-target condition. It supports assessment of false-alarm behavior for the tested state and population. The record must still account for receiver artifacts, environmental structure, processing, and search opportunities; a quiet mean level alone is not a complete validation.

Copyright 2026, James M. Atkinson

NOISE PARAMETERS: A set of quantities used to describe how a device's noise behavior varies with source impedance under a specified model and reference plane. The cited vector-corrected method uses such characterization with measured reflections. Their role marks a boundary of the matched scalar cascade, whose simpler assumptions cannot silently supply them.

NOISE POWER SPECTRAL DENSITY: Mean noise power per unit frequency at a declared reference plane, with the side convention and units stated. A flat density gives integrated mean power proportional to equivalent noise bandwidth. A logarithmic noise display also depends on detector and averaging conventions, so its ordinate is not automatically the density times a front-panel bandwidth label.

NOISE RISE ALLOWANCE: The additional uncorrelated noise power permitted by a stated rise relative to a fixed baseline measured through the same gain, weighting, and reference plane.

NOISE TEMPERATURE: Equivalent temperature used to represent available noise power or device-added noise.

NOMINAL SLOT GRID: An explicitly defined sequence of equal-duration opportunities used for finite rate accounting. It can be continued through a guard interval when that convention is stated, without asserting that physical symbols were transmitted in every opportunity. Its count divided by the common elapsed duration defines the slot rate used by the model.

Copyright 2026, James M. Atkinson

NONALTERNATING RESIDUAL: A residual sequence that does not repeatedly change sign about the specified target. The exact sampled one-pole solution has this property for positive time constant and interval. Forward Euler preserves it only for a positive normalized interval no greater than one, a stricter condition than its asymptotic-stability limit.

NONDISPERSIVE DELAY: A delay that is constant over the frequency region used in the model, producing a linear unwrapped transfer-phase dependence on frequency. A slope estimate can identify it within the selected branch. Phase curvature from filters or other path behavior means that one constant delay may be inadequate for broadband correction.

NONLINEAR MEMORY: Dependence of a nonlinear response on earlier inputs or internal state, rather than solely on the current input value. Filtering, thermal history or control dynamics can make a single fixed memoryless coefficient inadequate. The chapter's local cubic law deliberately excludes those effects; its agreement over one interval does not establish their absence elsewhere.

NONLINEAR ORDER: The degree of an amplitude term in a stated nonlinear expansion. The cubic voltage term generates particular fundamental corrections, harmonics and intermodulation products under the chapter's assumptions. This physical model order is distinct from the integer-search order used to enumerate possible conversion frequencies, and a frequency coincidence alone identifies neither.

Copyright 2026, James M. Atkinson

NONLINEAR REMAINDER: The part of a nonlinear measurement response omitted by its local linear approximation. The suitability of first-order propagation depends on whether that omitted behavior matters over the actual input domain. Near a singularity, boundary or zero derivative, it can change the output dispersion or shape even when the central calculation is finite.

NONZERO COEFFICIENT SUPPORT: The set of declared filter lags whose implemented coefficients are nonzero. It determines which input samples can affect an output in Model 10E. An exactly zero tap creates no dependency, while a small nonzero tap still does; a justified amplitude bound can limit that dependence without making it absent.

NORMALIZED FILTER POWER RESPONSE: The squared magnitude of the declared observation filter after its reference gain has been specified. It weights the noise admitted at each frequency. Model 11B additionally requires this weighting to remain between zero and one for its remainder bound; center normalization alone would not establish that peak constraint.

NORMALIZED RESPONSE ERROR: The difference between observations after the stated gain, attenuation and other required corrections have referred them to a comparable quantity and plane. Its uncertainty and receiver states determine the meaning of agreement. A discrepancy can motivate investigation of compression, internal products or state changes without uniquely naming the cause.

Copyright 2026, James M. Atkinson

NOTCH FILTER: A filter designed to reject a selected frequency region while retaining other regions. In a front end it can reduce a dominant interferer before a vulnerable component, but it also removes any desired signal content occupying the notch. Its installed response, placement, and power handling determine whether it improves the intended observation.

NULL SPACE: The set of inputs mapped to zero by a specified linear operator. A nonzero member establishes that the complete output cannot uniquely distinguish that input from zero. The blind-residue channelizer example constructs such a member; conclusions depend on the declared coefficients, output channels and observation of all affected frames.

NUMERICALLY CONTROLLED OSCILLATOR: Digital phase accumulator and waveform generator used for frequency translation or synthesis.

NUMERICAL STABILITY: The behavior of errors or perturbations under a numerical recurrence, distinct from the stability of the physical system being modeled. For the chapter's Euler residual update, asymptotic decay requires a positive interval-to-time-constant ratio below two. A stable approximation can still have substantial error or unphysical alternation, so stability alone does not validate a settling calculation.

NYQUIST BIN: The transform bin at one half of the sample rate when the transform has even length. For a real record it is its own conjugate-frequency partner and is counted once in the chapter's one-sided power sum. An odd-length transform has no bin exactly at that endpoint.

Copyright 2026, James M. Atkinson

NYQUIST INTERVAL: A frequency interval used to represent one sampling-rate-wide period of a discrete-time spectrum without repeating its aliases. The chosen endpoints and one-sided or two-sided convention must be stated. Real-data symmetry permits folding with special endpoint rules; it does not remove ambiguity about the original analog signal.

NYQUIST ZONE: For the chapter's real-sampling frequency map, one of the consecutive nonnegative analog-frequency intervals of width one half of the sampling rate. Folding can reverse frequency order in successive zones. A band that straddles a zone boundary can overlap itself after sampling, even when its occupied width is small.

OBSERVATION: A recorded result of an examination under a particular measurement state. Its interpretation may support additional propositions, but the observed feature and those model-dependent or source-dependent inferences remain distinguishable.

OBSERVATION LIMIT: The demonstrated boundary of what a specified configuration and record could reveal under the declared criterion. Nondetection above a supported limit is different from proof of complete absence. A substitution that changes sensitivity must retain suitable reference evidence before its negative result can support the intended comparison.

OBSERVED-TIME FRACTION: The proportion of a declared total interval represented by valid retained time. It describes temporal coverage under the accepted state and settling evidence. It is not automatically an event-capture probability, and equal corrected means on the observed portions do not establish the signal behavior during the excluded gap.

Copyright 2026, James M. Atkinson

OCCUPIED BANDWIDTH: The frequency interval assigned to contain a specified portion of signal power under a stated measurement convention. Its interpretation requires the power fraction, integration and observation choices. It is distinct from a decoder's symbol rate, a filter's nominal bandwidth and successful information recovery.

OFF-BIN TONE: A tone whose frequency lies between the selected DFT evaluation frequencies. Its nearest-bin amplitude depends on the window response and offset. Additional padded bins can locate an isolated response peak more closely, but do not narrow that response or prove separation from another nearby component.

OFFSET INTEGRATION BAND: The specified set of positive frequency offsets included in a phase-noise variance calculation. Its limits and any separately included lines form part of the result. Noise outside the set is not measured by the resulting RMS value, and extrapolating a displayed floor requires an additional justified assumption or bound.

ONE-DECIBEL COMPRESSION POINT: A specified stimulus level at which the measured response is one decibel below its declared small-signal linear extrapolation under fixed test conditions. It is a benchmark, not a universal threshold for all measurement error. Automatic gain changes, different stimuli and recovery behavior require separate characterization.

ONE-SIDED SPECTRUM: A frequency representation that combines the conjugate positive- and negative-frequency contributions of a real record under a declared folding rule. Interior positive-frequency powers are doubled, while DC and an even-length Nyquist bin are retained once. Complex records generally lack the symmetry required for this construction.

Copyright 2026, James M. Atkinson

OPEN-CIRCUIT VOLTAGE: The terminal voltage defined with no load drawing current in the stated antenna or source model. It is not the same as the voltage across a specified receiver load. Applying a calibration intended for a loaded voltage to an open-circuit estimate can introduce a systematic conversion error.

OPERATING DOMAIN: The stated range of conditions within which a measurement model or approximation is intended to apply. A local linear description, for example, requires a defined state and limits that address relevant overload or adaptive behavior.

OPPOSITE-SIDEBAND LEAKAGE: An unwanted retained component from the sideband that a receiver or conversion process was intended to reject. It can arise from finite filter rejection, I/Q mismatch, product-detector imbalance or other path imperfections. Its observation is a receiver-performance question unless independent evidence establishes that the component belongs to the source.

OPTICAL ISOLATION COMPARISON: A controlled comparison in which an optical link removes a particular conductive path while its own gain, noise, bandwidth, timing and power state are characterized. Disappearance of a weak feature is inconclusive if the replacement lacks adequate sensitivity. A preserved desired reference makes the comparison more informative but does not identify every mechanism uniquely.

Copyright 2026, James M. Atkinson

ORTHOGONAL FREQUENCY-DIVISION MULTIPLEXING: A multicarrier modulation arrangement whose subcarrier waveforms are chosen to be orthogonal over a defined symbol interval. Synchronization and the interval convention are essential to that relationship. Its recognizable spectral or constellation structure does not independently establish coding, validated packets or a physical transmitter identity.

ORTHOGONALITY: A zero inner product between specified components under the declared averaging operation. It supports the separate power accounting used for carrier and modulation terms. The averaging interval and waveform conditions matter; a complete-period calculation cannot be transferred automatically to a short record with different cross terms.

OSCILLATOR AGING: Change in an oscillator's frequency caused by processes internal to the device over time. It is distinguished from the broader measured drift, which can also include environmental influences. A fitted local drift coefficient does not, by itself, isolate aging or establish that the same trend persists in another operating interval.

OUT-OF-BAND SIGNAL: A signal outside the particular band under discussion, which must be named. Energy outside a displayed span can still lie inside the analog admission path and overload the receiver. Its absence from the selected display does not establish that it is absent at a vulnerable input stage.

OUTPUT-ADDED NOISE: Noise attributed to a stage and expressed at that stage output, excluding the incoming noise it transmits. For stage i in Model 2B the value is $k B g_i T_{e,i}$. Referring this contribution to another plane requires the corresponding signal power gain, rather than treating the stage equivalent input temperature as an output temperature directly.

Copyright 2026, James M. Atkinson

OUTPUT INTERCEPT LEVEL: The output-referred extrapolated intersection associated with the declared input intercept and small-signal power gain. The input and output planes and resistance conventions must be compatible. Substituting a compressed measured fundamental for the linear asymptote can bias the extraction, even before ordinary calibration uncertainty is considered.

OVERFITTING: Adjustment that captures peculiarities of the fitting record without establishing transferable performance. Too many coefficients or too little independent training information can make an in-sample residual deceptively small. The chapter's one-symbol gain fit demonstrates why a zero training residual is not a validation result.

OVERLAP-CORRECTED THROUGHPUT: A rate based on unique identified accepted payload positions after repeated instances across compatible streams have been removed. For two sets, add their counts and subtract the known intersection before dividing by their common duration. Equal bit values do not establish duplicate identity, and unknown overlap supports bounds rather than an invented exact unique rate.

OVERLOAD: Operation outside the valid signal range of a stage or path because the admitted waveform is too large for the required behavior. Its consequences can include compression, new products or altered recovery. A later clean display or level correction does not show that the earlier stage remained valid.

OVERSAMPLED CHANNELIZER: An analysis bank whose aggregate output sample rate exceeds its input sample rate under the stated channel count and decimation.

Copyright 2026, James M. Atkinson

OVERSHOOT: An excursion beyond the final target during a transient. It is excluded by the fixed-target, positive-time-constant one-pole response developed in Model 5A. If observed, it can motivate an additional state, changed target or different model; its mere appearance does not identify which physical element caused it.

PACKET ERROR RATE: The fraction or modeled probability of packets failing a declared acceptance rule. The result depends on the attempted-packet population, acquisition failures, checks and counting convention. Reporting only successfully acquired intervals can conceal a different packet-level outcome, even when the selected symbol EVM is low.

PACKET FRAGMENTATION: Division of a transported packet across multiple receive-buffer returns or stored pieces. Such division need not lose samples. Returned lengths, fragment offsets, source indices and error context distinguish legitimate fragmentation from an actual discontinuity; buffer arrival order by itself is not a source-time record.

PAIRED SPECTRAL ESTIMATE: Autospectral and cross-spectral sums formed from the same paired records with compatible weights and normalization.

PAIRWISE POWER CORRELATION: A stated covariance relationship between two power samples after normalization by their standard deviations. In the chapter's equal-variance illustration, positive common correlation slows the reduction in the arithmetic mean's variance. A nominal sample count therefore cannot replace evidence about filtering, overlap or duplication when estimating repeatability.

Copyright 2026, James M. Atkinson

PARENT-FREQUENCY PERTURBATION: A controlled change in one frequency used to test a candidate conversion relationship while other relevant parents and receiver states are held fixed or accounted for. The signed movement follows that parent's integer coefficient in the stated lattice. The absolute movement may change branch at zero. A useful test predeclares the expected response and keeps the candidate within a measurable region.

PARSEVAL IDENTITY: The equality relating the sum of squared transform coefficients to the corresponding time-domain squared values under a stated Fourier normalization. In this chapter it yields exact closure for the window-weighted record. Passing that algebraic check does not establish adequate sampling, correct calibration, stationarity or complete transient coverage.

PASSBAND: The frequency region a filter is intended to transmit within its stated response limits. A center-frequency calibration alone does not describe amplitude and phase across the entire passband. A desired waveform extending into rapidly changing response can be distorted even when its center is passed adequately.

PASSBAND PHASE DISTORTION: A change in the relative phases of a signal's admitted spectral components that alters the intended waveform or modulation representation through the passband. Center-frequency magnitude alone does not reveal it. Its significance depends on the signal spectrum, measurement objective, and applicable phase or group-delay response of the installed filter state.

Copyright 2026, James M. Atkinson

PASSBAND RIPPLE: Variation of transmission magnitude within a filter's declared useful passband, expressed under a specified normalization and frequency interval. A correction measured only at the center cannot establish the amplitude of a wide waveform across the ripple. The relevant tolerance follows the intended level or modulation measurement, rather than a passband label alone.

PASSIVE-LOSS ALLOWANCE: The permitted interval of matched dissipative loss before a characterized chain under a specified total noise-temperature target. Equation 4K combines the requirement $L \geq 1$ with an upper bound determined by target, physical path temperature, and downstream equivalent temperature. An upper bound below one means the stipulated passive design has no feasible solution.

PASSIVE PATH LOSS: The attenuation assigned to the relevant passive part of a measurement path under the stated conditions. The scalar backward correction adds this loss to the downstream indication when estimating the upstream power.

PATH CORRECTION: Measured gain or loss assigned to a specific serialized signal path and state.

PAYLOAD-BIT FRACTION: The useful represented payload-instance count divided by the corresponding input-information count under the declared framing convention. It excludes separately identified nonpayload information positions such as headers or padding. It acts on bits rather than slots, differs from code rate, and requires a positive information-count denominator.

Copyright 2026, James M. Atkinson

PAYLOAD BYTE RATE: The byte rate occupied by the declared uncompressed sample components before additional headers, padding, timing records or file-system effects. It depends on actual stored component width, channel count and sample rate. Sustained recording capability must include the extra traffic and cannot be inferred solely from this ideal payload calculation.

PAYLOAD INSTANCE: One counted occurrence of a payload bit in the specified transmission or accepted-stream population. Retransmissions or parallel streams can contain additional occurrences of the same identified payload position. An instance count is valid for its stated purpose but does not automatically equal the number of unique useful positions delivered.

PEAK AMPLITUDE: The amplitude scale of a sinusoid measured from its zero reference to its extreme value, rather than its RMS value or peak-to-peak excursion. Model 4A uses peak voltages at loaded planes. Converting that amplitude to mean power requires the declared resistance and sinusoidal convention.

PEAK ENVELOPE POWER: The maximum squared envelope magnitude divided by twice the declared real load resistance under the peak-voltage convention.

PEAK-ENVELOPE-TO-AVERAGE-POWER RATIO: The ratio of peak envelope power to average RF power under the same envelope, load and averaging conventions. It depends on relative component phases as well as their separate powers. It is distinct from an instantaneous RF-voltage peak ratio and must match the hardware headroom quantity being assessed.

Copyright 2026, James M. Atkinson

PEAK INPUT POWER: The largest input power under the stated waveform and time-resolution convention at a specified plane. It is distinct from average power and must be related to the applicable pulse or continuous-wave rating. For pulsed exposure, duration, repetition, source and load conditions, and leading transients can matter alongside the peak value.

PEAK-TO-RMS CONVERSION: The relation between the peak amplitude of a nonzero-frequency sinusoid and its root-mean-square amplitude: RMS equals peak divided by the square root of two. It gives average power equal to peak voltage squared divided by twice the positive real load resistance. The rule does not apply unchanged to DC, arbitrary pulsed waveforms, or an analytic-signal magnitude without its own power convention.

PEAK-VOLTAGE ENVELOPE: A complex envelope scaled so that its magnitude is the local peak RF voltage under the stated band-separation convention.

PERCENTILE: A value locating a declared cumulative fraction of a distribution or empirical record population under a specified convention. A high-percentile display emphasizes different behavior from a mean or maximum. Report the population, record selection and interpolation rule when the distinction affects detection or comparison.

PERIODIC REDUCTION: Representation of times by their positions within one declared schedule period. Model 15A first derives eligible event starts on an unfolded axis and then reduces their union modulo the period. This order preserves a genuinely contiguous window crossing the chosen origin and avoids mistaking the displayed split for an acquisition gap.

Copyright 2026, James M. Atkinson

PERIODIC WINDOW CONVENTION: A coefficient-vector convention intended for periodic DFT use; for Hann it uses N in the cosine denominator, unlike the endpoint-symmetric $N-1$ form.

PERIODOGRAM: A spectral estimate formed from the squared magnitude of a finite, possibly windowed Fourier transform with a declared normalization. Density and line-oriented scaling can differ by the window's equivalent noise bandwidth. Preprocessing defaults, including mean removal, must be matched before comparing implementations.

PER-TONE POWER: The power assigned to one specified sinusoidal component, distinct from the sum of the powers in a multi-tone stimulus.

PHASE ACCUMULATOR: A digital state that repeatedly adds a phase-increment word on the oscillator clock and wraps within its defined phase code range. Its carried state determines continuity between processing blocks. Resetting it at an arbitrary buffer boundary can introduce a coherent phase event although the sampled input remains continuous.

PHASE CENTER: An effective reference point used to describe an antenna's phase response over stated frequencies and directions. It need not coincide with a fixed mechanical point. Frequency-dependent displacement can affect the distance and field interpretation assigned to an installed observation.

Copyright 2026, James M. Atkinson

PHASE CONJUGATION: Reversal of a complex phasor's phase sign. In the chapter's real conversion map, rewriting a negative-frequency difference cosine at positive frequency conjugates its associated phasor. Conjugating a saved I/Q record also reverses signed-frequency orientation. The operation must be retained in the interpretation and processing history whenever phase, sideband, timing, or modulation comparisons depend on the original convention. For a complex quantity, conjugation reverses the imaginary part's sign and preserves its magnitude. Conjugating an entire cross-spectrum reverses its phase while preserving its magnitude and the corresponding magnitude-squared coherence; the stated convention therefore matters to the sign of an inferred delay.

PHASE COVARIANCE: The second-order relationship between phase deviations at two specified times or sample positions. Together with the marginal variances, it determines the variance of their difference. Equal marginal RMS values can therefore produce different coherent behavior when the covariance differs; the required relationship cannot be inferred from a scalar jitter number alone.

PHASE EXCURSION: The amount by which a defined unwrapped phase departs from its reference over the stated interval. Its unit is radians or another declared angular unit. Holding phase excursion fixed while changing modulation frequency generally changes peak frequency deviation; the two quantities cannot be treated as interchangeable generator settings.

PHASE-INCREMENT ALIAS CLASS: Frequencies separated by integer sample rates that produce the same principal sampled phase increment.

Copyright 2026, James M. Atkinson

PHASE-INCREMENT VARIANCE: The variance of the difference between two phase samples, determined by their individual variances and covariance.

PHASE-LOCKED LOOP: A feedback arrangement that uses phase comparison to control a local reference relative to an input. It can support carrier recovery or frequency demodulation within its operating conditions. Lock, reference stability and transient behavior remain part of the measurement state; the architecture's name does not guarantee faithful recovery of every waveform.

PHASE MODULATION: A relation in which a specified message directly controls phase relative to a declared carrier. Differentiation gives frequency deviation. For a sinusoidal message with fixed peak phase, peak frequency deviation grows in proportion to message frequency; a received phase history alone does not uniquely identify the circuitry that generated it.

PHASE NOISE: Random phase fluctuation represented as spectral density around a carrier or reference.

PHASE REMAINDER BOUND: An enclosure for terms omitted from a declared small-phase expansion, with moment and stationarity requirements stated separately from the retained linear model.

Copyright 2026, James M. Atkinson

PHASE RESET: An event that changes the selected phase branch discontinuously or restarts its reference. It interrupts an analysis that assumes one absolutely continuous phase history. Preserve the event and segment the record; do not interpret an ideal jump as an ordinary finite instantaneous frequency or silently bridge it with a fitted trend. A finite difference across a reset contains the step even when the continuous frequency behavior is unchanged on either side. Preserve segment boundaries and any independently established cross-event phase relation.

PHASE SENSITIVITY: The coefficient relating a specified message quantity to phase in the adopted phase-modulation law. Its units are radians per message unit, such as radians per volt. Frequency deviation then depends on the message's rate of change as well as this coefficient and the message amplitude.

PHASE-SHIFT KEYING: A modulation family in which discrete carrier-phase states represent symbol values. The receiver needs a phase reference and a justified mapping to interpret the selected state. Removing a common rotation can improve geometric alignment while leaving the original label association unresolved.

PHASE TRUNCATION: Reduction of the phase-word precision used to address or generate an oscillator waveform while retaining a potentially wider phase accumulator. It is distinct from the accumulator's tuning grid. Its resulting waveform errors require their own analysis; fine nominal tuning resolution alone does not establish low spurious response.

Copyright 2026, James M. Atkinson

PHYSICAL TEMPERATURE: The thermodynamic temperature of an actual component, such as a cable or attenuator, expressed on an absolute scale for the noise calculation. It controls the thermal emission of a matched dissipative loss. It is distinct from the equivalent noise temperature used to represent an active stage's input-referred noise.

PILOT REFERENCE: An identifiable signal component used to support a carrier, frequency or timing reference. Its role and calibration must be stated. Estimating a reference from a pilot differs from adjusting recovered audio by ear, and neither operation should be concealed in the processing history.

PIN DIODE: A diode with an intrinsic region between its p-type and n-type regions. In the limiter mechanism discussed here, stored carriers alter the RF resistance during a large signal, and carrier removal affects recovery. Mounted-network capacitance and the external current-return path also influence the usable response.

POINT-OBSERVATION LIMIT: The separate idealization in which an instantaneous event must lie inside a usable observation window. It is not obtained by treating zero overlap as a successful empty intersection. Model 15A relates it to the limit of fully capturing a shrinking event while preserving the intended detection criterion.

POINTWISE BOUND: An inequality that limits a quantity at every allowed point, rather than only its average or a selected probability. Model 6B bounds the complex small-phase remainder at every real phase value. The retained sideband approximation remains approximate even when the stated bound on its omitted remainder is exact.

Copyright 2026, James M. Atkinson

POLARIZATION COUPLING: The dependence of antenna response on the relationship between incident-field polarization and the antenna's receiving orientation. Rotation can change terminal level without a change in source strength. An installed comparison must therefore retain or deliberately vary orientation according to the stated measurement question.

POLYPHASE COMMUTATOR: The sample-routing schedule that assigns input-index residues to coefficient branches; its phase and progression form part of the filter-bank definition.

POLYPHASE COMPONENT: A filter-coefficient subsequence selected by a fixed lag residue modulo an integer rate-change factor.

PORT ISOLATION: Suppression of unwanted transfer between identified mixer or receiver ports under specified frequencies, terminations, and operating states. Finite LO-to-RF isolation can contribute leakage into an input cable or antenna, while other coupling paths may involve the enclosure. Isolation belongs to the installed configuration and relevant direction; it should not be inferred solely from mixer type or the absence of one displayed line.

POSITIVE-PEAK DETECTOR: A detector that retains the largest indication within its specified observation or display bucket. It can aid discovery of brief activity, but its population and timing differ from an average-power estimate. Changing to this detector changes the measurement statistic and must be disclosed when traces are compared.

Copyright 2026, James M. Atkinson

POST-DETECTION FILTERING: Filtering applied after a specified detector operation to alter the displayed or recorded time response. It can suppress visible fluctuations while slowing the indication. Its position in the processing chain matters, so a video-bandwidth setting cannot be assumed to mean the same operation for every detector or analyzer mode.

POWER-AVERAGE ESTIMATOR: Arithmetic mean of calibrated instantaneous powers; subsequent logarithmic conversion has distinct finite-record statistical properties.

POWER-ESTIMATION PLANE: The declared point in a calibrated measurement model at which samples represent a specified power quantity. Resistance, gain calibration, admitted bandwidth and processing connect that quantity to the original signal path. Raw converter counts are not power samples until that relationship is established; comparisons must use compatible planes.

POWER GAIN: The ratio of output power to input power under declared reference-plane, loading and signal conventions. For the chapter's loaded sinusoidal voltages, both the squared voltage ratio and the input/output resistance ratio enter. A voltage-gain number is therefore insufficient when the reference resistances differ.

POWER HANDLING: The incident-power capability of a component or assembly under specified waveform, duration, duty factor, frequency and environmental conditions. It is distinct from an acceptable small-signal transfer and from recovery time. A rating for one tested device or pulse condition does not establish a limit for an arbitrary receiver assembly.

Copyright 2026, James M. Atkinson

POWER-LAW SLOPE: The change in logarithmic output power per change in logarithmic input power under a fixed response model. Equal-tone cubic products and linear fundamentals have different slopes, while varying just one unequal parent gives a different product dependence. A slope mismatch can reject the proposed model without uniquely identifying the alternative mechanism.

POWER LEVEL: A logarithmic representation of positive power relative to a specified reference power. It is a coordinate for a physical power, not a replacement for that quantity's units or reference plane. Subtraction of two power levels represents a power ratio, whereas subtraction of powers must occur in linear units.

POWER SENSOR: A device used to measure RF power under defined input, frequency and waveform conditions. In front-end characterization it can help establish the applied desired and blocker levels. Its result must correspond to the intended receiver plane and to the relevant mean or peak exposure quantity.

POWER SPECTRAL DENSITY: A frequency-density representation whose compatible integration gives a power-like mean-square quantity. Its units and reference plane determine whether that quantity is voltage squared, current squared or watts. One-sided folding, estimator normalization and window weighting must remain consistent with the claimed integral.

PREAMBLE: A specified leading signal or symbol sequence used to support operations such as acquisition, timing or format recognition. Its duration and role affect which part of a burst becomes usable. Excluding it from a settled payload metric must not conceal acquisition time or count it as delivered payload without justification.

Copyright 2026, James M. Atkinson

PREAMPLIFIER: An amplifier placed before a later receiver or measurement stage. The name identifies its role in the chain, not a universal location relative to preselection or a guarantee of low noise and large-signal immunity. The active path and preceding filters must be recorded for the particular configuration.

PRECEDING GAIN: The cumulative power gain before the stage whose added noise is being referred to the cascade input. The contribution $T_{e,i}$ is divided by G_{i-1}, because the input signal has experienced those earlier stages before that noise is added. Preceding loss increases, rather than suppresses, the downstream input-equivalent contribution.

PRESELECTION: Filtering placed before vulnerable gain or conversion stages to limit admitted spectrum.

PRETRIGGER: Recorded interval preceding the condition that initiated an acquisition.

PRINCIPAL ARGUMENT: The angle assigned to a nonzero complex value within one chosen full-turn interval. Model 6B uses a lower-inclusive, upper-exclusive interval centered on zero. This convention removes multiple numerical angle representations but cannot determine which unobserved whole phase turns occurred between samples.

PRINCIPAL PHASE INCREMENT: The argument of the product of one complex sample and the conjugate of its predecessor, restricted here to the interval from minus pi inclusive to plus pi exclusive. It records a rotation modulo a full turn. Frequency interpretation needs a sample interval and justified information to resolve possible whole-turn aliases.

Copyright 2026, James M. Atkinson

PROBABILITY DENSITY: A function whose integral over an interval gives probability for a continuously distributed quantity. Its variable, support and normalization must be stated. A density at one value is not itself that value's probability, and writing a convenient density does not establish that a receiver record follows it.

PROBABILITY OF INTERCEPT: Probability that an observation strategy overlaps and detects an event meeting the stated criterion.

PROCESSING LINEAGE: The documented sequence connecting retained input data with derived outputs. It identifies software, settings, corrections, selections, and transformations so that a result can be reconstructed and its irreversible steps recognized. It also identifies the selected interval, channel and calibration for a spectrum, decode, image, table or other output. Visual resemblance to a screenshot cannot establish equivalent scaling, normalization or sample selection.

PRODUCT COLLISION: Coincidence of two generated or existing spectral components at one frequency, requiring their complex amplitudes to be combined before calculating power.

PROTECTION RECOVERY CRITERION: Declared observable and tolerance used to decide when a valid weak-signal measurement has returned after a strong event.

Copyright 2026, James M. Atkinson

PROTECTION SURVIVABILITY: The ability of specified hardware to remain within the stated survival criterion after a defined exposure. The criterion and waveform conditions must be retained; survival is distinct from accurate transfer during the event and from prompt recovery afterward. Component survivability data do not automatically establish the survivability or measurement capability of a complete receiver assembly.

PROTOTYPE FILTER: The common filter from which the chapter's analysis-bank channel responses are formed by frequency translation and scheduled sample retention. Its coefficients determine channel gain, leakage and overlap. Shared ancestry does not guarantee independent channel noise, invertibility, or equal energy coverage for different input sample positions.

PROVENANCE VERIFICATION: Examination of an artifact and associated origin or build claims against defined integrity, identity, and policy expectations.

PULSE DUTY FACTOR: The fraction of a stated interval during which a defined pulse condition is present. For a periodic rectangular pulse it is pulse width divided by repetition period. Multiplying constant peak power by this fraction gives mean power only when the stipulated waveform and off-state assumptions apply; the peak exposure remains a separate quantity.

PULSE REPETITION FREQUENCY: The repetition rate of a periodic pulse sequence, equal to the reciprocal of its stated repetition interval. Irregular or missed events require a declared counting and timing convention rather than an assumed periodic rate. Modulation within a pulse and repetition of the pulse are separate waveform properties.

Copyright 2026, James M. Atkinson

PULSE REPETITION INTERVAL: The elapsed time between corresponding reference points on successive pulses. Its reference point and treatment of missing or irregular events must be stated. A time record preserves this structure more directly than an averaged spectrum, provided the acquisition and trigger actually captured the relevant events.

PULSE SHAPING: Selection or filtering of the waveform associated with successive symbols to control its spectral distribution and interaction at decision times. The complete convention includes coefficients, rate, delay and initialization. Receive filtering must be consistent with that convention before symbol residuals can be interpreted.

PULSE WIDTH: The duration assigned to a pulse under declared boundary or amplitude-threshold conventions. The receiver's filtering, detector and trigger can change the width inferred from its output. The measurement must retain those conditions and sufficient temporal response, rather than treating a displayed width as an unqualified source property.

QUADRATURE: A relative phase separation of one quarter of a cycle between two same-frequency sinusoidal components. In the coherent collision example, this makes the real cross term vanish. That particular phase relation is not statistical independence, even though it can produce the same measured power as a justified zero-cross-power average.

QUADRATURE AMPLITUDE MODULATION: A modulation family that assigns symbol values to combinations of in-phase and quadrature amplitudes. The resulting complex locations can have different energies, so reference-population and normalization choices matter. Modulation order alone supplies neither code rate nor payload efficiency.

Copyright 2026, James M. Atkinson

QUADRATURE CONVERTER: A conversion arrangement that retains two nominally orthogonal components for complex signal representation. Their relative gain, phase and ordering matter to signed-frequency interpretation and image behavior. A plausible magnitude display does not establish correct quadrature balance or the intended I/Q convention.

QUANTIZATION: Mapping an input amplitude to one of a stated set of representable levels. The code spacing and rounding rule constrain an individual error, while its mean, correlation and spectrum depend on the input and additional assumptions. A bounded rounding error does not by itself constitute independent uniform white noise.

QUANTIZATION ERROR MEAN SQUARE: Average squared difference between a quantizer's output representation and its input; includes squared bias.

QUANTIZATION STEP: The amplitude separation between adjacent levels of the specified quantizer or fixed-point grid. In the ideal uniform converter model it is the nominal input span divided by the number of codes. The half-step rounding bound applies only under the stated rounding rule and away from overload.

QUASI-PEAK DETECTOR: A detector that weights a signal using a specified temporal response, making repeated-pulse behavior relevant to the indication. It differs from taking the instantaneous maximum. Its required bandwidth, timing and measurement duration belong to the applicable method; a label alone does not establish that the prescribed response was implemented.

Copyright 2026, James M. Atkinson

RAISED-COSINE FILTER: A pulse-shaping response with a flat central frequency region and a cosine-shaped transition, parameterized by symbol rate and roll-off. Its ideal overall pulse satisfies the zero-interference sampling condition at the intended symbol times. Finite implementation, timing error and channel distortion require separate checks.

RANDOM MEASUREMENT ERROR: The component of measurement error that changes unpredictably between replicate measurements of the same quantity under the stated conditions. Its dispersion and dependence affect what averaging can achieve. The chapter's inverse-count variance reduction assumes independent reading errors; it cannot be transferred automatically to correlated observations or an unchanged common calibration contribution.

REACTIVE LOADING: The effect of a component's capacitive or inductive behavior on the connected path, including its matching and frequency-dependent transfer. A protection element can impose this loading even when it is not limiting. Treating it as an ideal open or transparent device omits part of the small-signal measurement chain.

REARM INTERVAL: The period required for the acquisition or trigger system to become ready for another qualifying event. A real rearm gap remains an exclusion in the usable-window model. Adjacent-looking timestamps or saved files do not establish continuous availability across that interval.

RECEIVER-ADDED NOISE: The noise contribution produced by the included receiver chain beyond the admitted source contribution. Model 2B represents it at the input by T_e and at the output by $k B G_n T_e$. This representation depends on the selected path, gain state, bandwidth, and model domain; it is not an arbitrary label for every observed interferer.

Copyright 2026, James M. Atkinson

RECIPROCAL MIXING: Noise produced when local-oscillator phase noise mixes a strong nearby signal into the observation band.

RECIPROCAL MIXING OVERLAP: The dimensionless integral of translated linear single-sideband phase density weighted by the observation channel's normalized power response.

RECORD CONTINUITY: Verified absence or documented location of gaps, repeats, lost packets, or clock discontinuities in sampled data.

RECORD LENGTH: The number of acquired samples retained for a stated finite analysis before any zero padding. Together with the sample rate it defines the observation duration. Changing this length can change leakage, nominal bin spacing and the interval over which statistical or signal-state assumptions must hold.

RECOVERABILITY: The extent to which a specified input property can be determined from the retained data and justified model. It is property-specific: magnitude-only data can support a power correction while leaving phase undetermined. A later calibration cannot reconstruct amplitudes or samples that the original acquisition irreversibly discarded.

RECOVERY ATTRIBUTION: The assignment of an observed post-event delay or disturbance to a particular subsystem or mechanism using discriminating evidence. Protection, amplifier bias, gain control, digital filtering, detector averaging, and trigger behavior can all contribute. A delay observed in the final display is a system observation until the relevant path contributions have been separated.

Copyright 2026, James M. Atkinson

RECOVERY BASELINE: The pre-event reference behavior against which post-event return is evaluated, including the desired response and any required noise or variability measure. It must belong to the same relevant state and processing definition. A later quiet trace cannot substitute for an unrecorded baseline when the recovery criterion depends on a quantitative change.

RECOVERY EXCLUSION: An interval after a stimulus or state change during which the receiver has not yet met the declared criterion for valid observation.

RECOVERY TIME: Time required for a protection or gain stage to return to specified behavior after a strong event.

RECTANGULAR WINDOW: A finite window that gives every retained sample the same weight and excludes samples outside the record. It preserves a narrow central response for a bin-centered tone but has substantial sidelobes for off-grid components. Its simple weight sums do not make a finite observation equivalent to an infinite one.

REFERENCE CANCELLATION: Removal of a shared contribution by the signed structure of a reported difference when its coupling is genuinely identical in both observations. The phase example obtains the same result by an explicit common input or a consistent covariance matrix. Unequal paths, changed states or unresolved phase branches invalidate automatic cancellation.

Copyright 2026, James M. Atkinson

REFERENCE CHECK: An observation of a known or controlled input used to test specified functions of a measurement chain. Its conclusion must remain limited to the capability and conditions actually exercised. The reference waveform, level, frequency and timing must exercise the capability being compared. A comfortable continuous tone does not demonstrate detection of a weak burst beside a blocker or general absence after path substitution.

REFERENCE DISTRIBUTION NETWORK: The installed paths carrying a reference to the devices and boundaries that depend on it. Distribution amplifiers, cables, terminations and state changes can add delay or noise after the primary source. Acceptance therefore identifies and tests the actual outputs rather than relying only on the source's nominal accuracy or lock indication.

REFERENCE LEVEL: The declared analyzer level setting used to establish the display and associated operating configuration. It can influence the applicable gain and attenuation arrangement. Record it with detector and path states when evaluating amplitude accuracy; a changed display reference does not itself improve the physical signal-to-noise ratio.

REFERENCE NOISE TEMPERATURE: Temperature used to define a noise-factor convention, equal to 290 K in Model 2B and distinct from actual source or component temperature.

REFERENCE OSCILLATOR: The oscillating source used to establish a receiver's frequency or timing basis. Its state and distribution path influence tuning, sampling and phase comparisons. A shared nominal reference does not eliminate unequal cable, aperture or processing delays, and a lock indication does not establish every required accuracy or short-term-noise property.

Copyright 2026, James M. Atkinson

REFERENCE PLANE: Declared physical or mathematical location to which amplitude, phase, impedance, or timing is referred. It also locates the boundary at which signal transfer and noise contributions are specified. Moving the reporting plane changes which path components belong to a correction; a comparison requires compatible planes and quantities before it can imply improved performance.

REFERENCE POWER: The positive power used to make a logarithmic power argument dimensionless. The chapter's dBm convention uses one milliwatt. Changing the reference changes the numerical level coordinate without changing the physical power, so the reference must remain attached to the reported quantity and conversion.

REFERENCE RESISTANCE: The stated real resistance used for the chapter's voltage-to-power interpretation at a named plane. Equal input and output resistances permit a squared voltage-gain magnitude to represent power gain in the example. With different or non-real loading, the corresponding power relation requires its own consistent treatment.

REFERENCE-RMS NORMALIZATION: Normalization by the root mean square magnitude of the actual selected reference symbols under the declared weights. In a multilevel constellation, that realized energy depends on the included symbol population and need not equal a uniformly used alphabet's mean energy. It is distinct from normalization by a fixed constellation maximum.

Copyright 2026, James M. Atkinson

REFERENCE SPUR: A discrete unwanted component related to a reference oscillator or its associated synthesis and clock paths. A frequency coincidence or clock-dependent movement suggests a candidate relationship but does not establish its origin. Clock calibration can also relabel the displayed frequency of an external tone, requiring an independent physical-frequency comparison.

REFLECTION COEFFICIENT: The complex ratio of reflected to incident wave amplitude at a specified plane, frequency and reference-impedance convention. Its phase as well as its magnitude can matter to an assembled RF path. The vector noise treatment uses measured reflections because mismatch affects both delivered source power and the receiver's response.

REGRESSION COVERAGE: The justified set of requirements reexamined after a change, based on affected subjects and dependencies rather than the change label alone.

REGRESSION TEST: A repeatable comparison with previously accepted results after a repair or a change in equipment, firmware, software, calibration or accessories. Checks are selected for the functions used by the deployed measurement configuration and retain their known references, accepted ranges and relevant states; a startup self-test covers only its own exercised functions.

REGULARIZATION: A declared constraint or penalty used to limit the freedom of a fitted model, such as an equalizer. It can control unstable or overly flexible solutions, but it also changes the fitted result. Preserve its rule and assess performance on data excluded from fitting.

Copyright 2026, James M. Atkinson

RELATIVE CHANNEL PHASE: The phase relationship between specified channels at a stated frequency and observation boundary. Model 12A obtains it from the difference of their time errors. A common contribution can cancel, but unequal analog paths, apertures, resets and processing delays remain unless measured or otherwise accounted for.

RELATIVE STANDARD DEVIATION: Standard deviation divided by the magnitude of a nonzero mean or stated reference value. It is dimensionless and requires the denominator convention to be identified. The independent-power averaging result in this chapter changes when samples share correlation, even if the stored sample count is unchanged.

RELAY CONTACT: The conducting connection made or broken by an electromechanical relay. In a receiver path, contact condition and wear can alter loss, repeatability or isolation. A change that develops gradually can resemble a calibration or environmental shift unless maintenance and reference comparisons retain the relevant state.

RELEASE ENVELOPE: The documented range of configuration, frequency, level, waveform, environmental, and timing conditions for which a receiver path's stated acceptance criteria are supported. It connects the tests to permitted interpretation and records limitations. A blanket pass without this envelope cannot establish applicability to a changed front-end state or exposure.

RELEASE TIME CONSTANT: The positive time constant identified for the applicable gain-return segment after the controlling condition changes. The actual state at the start of release is carried forward from prior activity. A release constant does not itself specify a preceding hang duration, a timer trigger or the recovery of other RF stages.

Copyright 2026, James M. Atkinson

RELOCK: Re-establishment of a controlled frequency or phase relationship after it was lost or interrupted. A recovered lock indicator does not establish that the previous phase or sample epoch has returned. Coherent comparisons across the event require a demonstrated relationship or a new calibrated segment.

REMOTE PREAMPLIFIER: An active gain stage installed near the sensing element to reduce the effect of downstream cable loss and receiver noise. Its input is also exposed to signals throughout its admitted band. Gain, noise, blocker transfer, bias, protection and stability must therefore be assessed together in the installed arrangement.

REPEATABILITY CONTRIBUTION: The uncertainty contribution associated with variation among observations made under the declared repeated conditions. Averaging can reduce a suitable independent reading-error contribution, but not an unchanged shared calibration input. A repeatability-only estimate can therefore understate the uncertainty of a corrected system-level result.

REPEATED SAMPLE BLOCK: A portion of acquisition data preserved more than once where the intended sample sequence should advance. It can corrupt timing and spectral interpretation even if the final file is internally readable and unchanged. Sequence and sample-domain records are needed to distinguish it from a legitimately repeating waveform.

REPLICATION: Fresh execution of an intervention and acquisition under the declared conditions to examine variability and reproducibility. Replotting one capture or dividing it into overlapping windows does not replicate the physical intervention. The repeated records must retain state, order and source conditions so their relationship can be assessed.

Copyright 2026, James M. Atkinson

REPRODUCIBILITY: Ability to obtain a consistent result from preserved data and a documented method.

REQUIRED OVERLAP: The positive contiguous duration that an event and one usable acquisition window must share to meet the declared capture criterion. It must not exceed either duration for capture to be feasible. Combining disconnected fragments does not satisfy this one-window criterion unless the measurement question is explicitly changed.

RESIDUAL CARRIER: A carrier-frequency component remaining in a representation or recovered path where its suppression or balance is part of the intended operation. Detector imbalance, quadrature errors or path imperfections can contribute. Its presence must be interpreted with the source waveform and receiver configuration, not automatically assigned to an unusual modulation.

RESIDUAL-ENERGY SUM: The sum of the declared nonnegative weights times squared complex error-vector magnitudes over the selected population. It retains squared-amplitude units before division by reference energy. The same sum can arise from different residual directions and time histories, so it does not uniquely identify an impairment or its physical origin.

RESIDUAL FLOOR: An apparent nonzero limiting value in a residual record. It can arise from a wrong target, detector offset, measurement resolution, a hold state or additional physical dynamics. It should not automatically be fitted as a very slow pole. The residual definition, capability and competing mechanisms must be examined before assigning a physical cause.

Copyright 2026, James M. Atkinson

RESIDUAL FREQUENCY OFFSET: The remaining frequency difference between the signal's declared carrier reference and the local conversion or recovery reference. Under the chapter's convention it is carrier minus LO frequency and adds a linear baseband phase trend. Estimating that trend from modulated data can absorb part of the modulation unless the estimation model and interval are justified.

RESIDUAL RESPONSE: Instrument-generated indication remaining with a terminated or otherwise controlled input.

RESOLUTION BANDWIDTH: Analyzer filter bandwidth determining frequency discrimination and admitted noise.

RESONANCE: A frequency-selective response associated with energy exchange and loss in a system. The chapter uses a specified resonance to motivate a loaded quality-factor approximation. Coupled structures, multiple poles and digital filters can require a fuller descriptor than that one center-frequency-to-bandwidth ratio.

RESPONSE DEFINITION: The quantity or criterion fixed before evaluating experimental configurations, including its reference plane, units, bandwidth and processing. Corrected power, logarithmic level and a visibility threshold answer different questions. Keeping the definition consistent prevents an apparent disappearance from being interpreted without accounting for changed sensitivity or scaling.

Copyright 2026, James M. Atkinson

RETAINED-RECORD REPROCESSING: Applying a changed correction or processing method to a preserved acquisition record while retaining the original data, both derived products and their processing identities. This comparison can explain a changed interpretation without treating it as a new physical observation. Independent validation remains necessary when the retained record helped select the new method.

RETRANSMISSION: Another transmission of information already represented in an earlier attempt, under the stated protocol or counting rule. It can increase transmitted-bit and symbol counts without increasing unique accepted payload by the same amount. Delivery records are needed to identify duplication; a constellation or checksum cannot supply that history.

RETURN LOSS: A logarithmic measure of reflection at a stated port and reference impedance, conventionally expressed as a positive decibel value for a passive mismatch. It characterizes port matching rather than through-path insertion loss. Changes in input match can alter delivered power and source interaction, so a matched-port transmission correction may not describe every installed antenna condition. Larger return loss conventionally corresponds to a smaller reflected fraction. An attenuator used to improve matching also reduces the desired signal and adds thermal noise, so the complete measurement consequence must be assessed.

REVERSAL CHECK: A planned return from a modified setup to an earlier configuration to test whether the earlier response returns under comparable observation capability. It checks reversibility and can expose drift or state-history dependence. Reproducing the response does not by itself isolate which changed path caused it.

Copyright 2026, James M. Atkinson

REVERSE ISOLATION: The limitation on signal transfer from a device's output side back toward its input under stated conditions. In a remote receiving assembly, insufficient isolation can allow downstream leakage to propagate toward the antenna. A forward-gain measurement alone does not establish this reverse-path behavior.

REVERSE-TRIANGLE INEQUALITY: The lower magnitude constraint obtained from the absolute difference of two component magnitudes. Together with the ordinary triangle inequality, it bounds a desired coherent phasor when an additive contaminant has unknown phase. If the contaminant can cancel the measured magnitude completely, a positive inferred product need not have a finite upper intercept bound.

REVISIT PERIOD: The elapsed period after which the declared observation schedule repeats. Model 15A places usable windows and event-start phases relative to that period. A nominal revisit specification must retain settling, rearm and transfer gaps; repeated schedules can continue to miss an event whose phase is locked to them.

RF FRONT END: The input-side network that selects, attenuates, amplifies, routes or limits RF energy before later conversion and detection. Its actual component order determines the exposure of vulnerable stages. A narrow displayed span does not prove that the front end admits only that frequency interval.

Copyright 2026, James M. Atkinson

RF INTERVAL MAPPING: The relationship between an admitted IF interval and the RF intervals that can reach it through the stated conversion. A real first-order difference path generally has a lower and an upper interval around the LO, restricted to positive physically admitted RF frequencies. Mapping the complete interval exposes edge and skirt responses that a single image-center calculation omits.

RF SWITCH: A component that selects or routes RF paths. Its state can change transfer, leakage and calibration, while the act of switching can create a transient. The actual route and state belong in the configuration record; a front-panel label alone does not describe every physical consequence.

RISE AND FALL TIME: The durations of the leading and trailing pulse transitions between specified amplitude levels. The chosen levels and measurement path must accompany the result. Limited bandwidth or detector response can alter these durations, so a narrowband trace may not preserve the source transition shape.

RMS AMPLITUDE: The nonnegative square root of a specified mean-square amplitude. State the weighting, record and units before comparing values. An RMS voltage is not automatically an available or delivered power; the load and reference-plane relationship must support any voltage-to-power conversion.

Copyright 2026, James M. Atkinson

RMS DETECTOR: A detector whose intended power-related statistic derives from mean square signal magnitude before square-root or level reporting. Its actual bucket operation, weighting, normalization and subsequent video or trace processing must be established from the instrument implementation. The name alone does not determine every operation that produced the displayed number.

RMS TIMING JITTER: The root-mean-square timing fluctuation associated with a declared phase component and positive carrier frequency. Model 12B obtains it from that component's RMS phase by the stated phase-to-time conversion. The scalar retains neither the detailed offset distribution nor a complete account of deterministic delay, trigger error or sample alignment.

ROBUST SUMMARY: A statistic selected to reduce the influence of particular unusual observations under a declared rule. Its behavior and target must be established for the application. Replacing each part of a spectral ratio with a separate robust summary does not automatically preserve identities proved for a common weighted mean.

ROLL-OFF FACTOR: The parameter controlling the transition and excess bandwidth of a declared cosine pulse-shaping response. It must be recorded with symbol rate and filter span because changing it changes the reference waveform. A value alone does not describe the errors introduced by finite coefficients or imperfect timing.

ROOT-RAISED-COSINE FILTER: A response whose product with its matching counterpart gives the intended raised-cosine response. It permits pulse shaping to be divided between transmit and receive processing. The individual filter and the combined response are different; their names do not establish correct alignment, truncation or scaling.

Copyright 2026, James M. Atkinson

RUN-ORDER RANDOMIZATION: Assignment of feasible experimental configurations to acquisition order by a declared random procedure. It can reduce systematic association between a setting and unrelated temporal changes. It does not remove physical restrictions, relocking requirements or changing source behavior; those constraints and the actual order remain part of the diagnostic record.

SAMPLE ALIGNMENT: The established relationship between sample indices and the corresponding acquisition instants across channels. Trigger paths, aperture times, digital pipelines and missing data can affect it even when the channels share frequency. The required relationship must be verified at the stored-data boundary used by the analysis.

SAMPLE-CLOCK SCALE ERROR: A discrepancy between the actual and nominal sample rates that changes both elapsed-time labels and the frequency scale attached to normalized discrete data. For a fixed interval count, true elapsed time depends inversely on actual rate. Correcting one displayed frequency does not by itself establish correct timestamps or continuity.

SAMPLE COUNTER: A recorded index or count associated with the acquisition sequence. When its semantics, rollover and reset behavior are known, it helps test whether intended samples were retained in order. A plausible file duration or a stable byte hash does not replace this sample-domain continuity evidence.

Copyright 2026, James M. Atkinson

SAMPLE DETECTOR: A detector that selects a sample according to a defined rule for each display bucket instead of retaining the bucket's extremum or a power average. Its sampling rule and relation to the input processing must be documented. A short event between selected samples may not appear in the resulting trace.

SAMPLE EPOCH: Fixed source-index reference establishing the retained output grid or oscillator phase convention within a declared segment.

SAMPLE INDEPENDENCE: The joint statistical condition in which the samples' probability law factors into their individual laws. It is an additional premise for the chapter's gamma sum and simple variance reductions. Distinct timestamps or storage positions do not establish independence when filters, overlapping records or repeated data create shared information.

SAMPLE-INTERVAL COUNT: The number of elapsed intervals between sample endpoints; a span of N intervals contains N plus one endpoint samples.

SAMPLING EQUIVALENCE CLASS: Frequencies and phase conventions producing the same ideal uniformly sampled sequence.

SAMPLING MIXER: A conversion architecture that uses a sampling operation to translate admitted spectral content. Its useful output and unwanted responses depend on the sampling and analog admission conditions. Calling the path a mixer does not remove the alias and frequency-coordinate requirements developed for sampled receivers.

Copyright 2026, James M. Atkinson

SAMPLING VARIANCE: The variability of an estimator across repetitions of the specified sampling experiment. A noise-power estimate fluctuates because it is formed from a finite record; its variance depends on the averaging rule and dependence between samples. Reducing that variability does not remove a shared calibration error or an incorrect receiver-state assumption.

SATURATING ARITHMETIC: A numerical operation that clamps an out-of-range code to the permitted endpoint of its declared signed format. Once clamping occurs, the ordinary half-step rounding-error bound no longer applies. Intermediate saturation can alter later results even when the final displayed value lies within range, so the conversion schedule and operation order remain part of the model.

SATURATION: A regime in which a response has reached a limiting range and no longer follows the intended input-output relationship. A detector plateau can resemble successful gain leveling or a normalized display. A weak reference and the relevant raw-state record help distinguish those possibilities and establish recovery.

SATURATION FLAG: A recorded indication that the relevant stage or representation reached its stated limiting condition. In the chapter's ideal clipping example, a reliable flag supports a threshold constraint but does not recover the lost amplitude or supply an upper bound. Its meaning must follow the actual implemented flag and path.

SCALAR CASCADE: Ordered power-transfer and noise model with one effective channel per stage and explicitly bounded matching, state, and correlation assumptions.

Copyright 2026, James M. Atkinson

SCALAR TRANSFER: A restricted input-to-output relation for one specified scalar quantity, such as mean signal power at named planes in a characterized state. Its usefulness depends on loading, band, detector and linearity conditions. A valid scalar power relation need not preserve all waveform information, including phase.

SCALE RESTORATION: Reconstruction of a declared numerical or voltage scale from stored values and the associated exponent, without recovery of discarded precision.

SCALLOPING LOSS: The reduction in a selected bin's response when a tone lies between the transform's evaluation frequencies instead of at the stated coherent location. Its magnitude depends on the actual window and offset. A coherent-gain correction alone does not remove this error, while denser evaluation can help locate an isolated response peak.

SCHEDULE PHASE LOCKING: A persistent relationship between event timing and the repeating observation schedule. It can place each event in the same usable interval or the same blind interval. Repeating the schedule then does not create independent opportunities, and a formula based on independent trial phases cannot be applied without changing or justifying the experiment.

SEARCH MULTIPLICITY: The presence of multiple opportunities for a decision statistic to cross a threshold during a search over frequencies, windows, or other tested conditions. It affects how a single-channel false-alarm objective relates to a whole-search claim. The number and dependence of those opportunities must be considered in the chosen validation or probability model.

Copyright 2026, James M. Atkinson

SECOND MOMENT: The expectation of the square of a real random quantity, when finite, with the square of that quantity's unit. It includes the contribution of a nonzero mean and therefore differs from variance. Model 14B requires finite second moments for exact affine propagation and distinguishes the squared mean from expected squared voltage.

SECOND-ORDER STATISTICS: Quantities determined by first and second moments, including covariance and compatible auto- and cross-spectra. They can constrain a linear relationship without identifying every feature of the underlying distribution or physical mechanism. Distinct noise allocations and source arrangements can share the same second-order description.

SEGMENTED ACQUISITION: Recording selected intervals, often in response to triggers, instead of preserving every intervening sample. It can reduce storage but omit context and bias occupancy estimates. Each segment and the gaps between segments must retain their timing and validity information before an analysis assumes continuous observation.

SEGMENTED SWEEP: A sweep assembled from separately specified frequency or acquisition segments. Each segment's limits, settings and time position belong in the record so the combined trace can be reconstructed. Segmenting can change which events are observed and when; it does not make the full assembled frequency range simultaneous.

SELECTED CONVERSION PRODUCT: The particular output component admitted by the chosen mixer, filter, and processing path for the intended measurement. A multiplier can generate several mathematical or physical candidates, so a frequency formula must be tied to this selection. Changing an IF path or filter state can change which product is observed even when the front-panel tuning label remains the same.

Copyright 2026, James M. Atkinson

SELECTION EFFECT: A change in the interpretation of evidence caused by how observations, tests or processing rules were chosen. Favorable tests selected after viewing outcomes cannot be treated as though they were the only predeclared possibilities. Preserve failed challenges, held-out records and the actual selection procedure when assessing what the evidence supports.

SELECTIVE FADING: Unequal alteration of spectral components by the propagation or reception path. In an AM observation, different sideband responses can change the envelope and produce a quadrature component even when the source modulation has not changed. A scalar center-frequency correction cannot establish the original sideband balance.

SELECTIVITY: The ability of the chosen path to distinguish the desired spectral content from nearby or remote admitted energy through its frequency response. Nominal bandwidth alone does not determine it. Passband behavior, skirts and waveform distortion must be considered together when choosing a filter for a particular observation.

SEMILOGARITHMIC PLOT: A plot using a logarithmic scale for one quantity and a linear scale for the other. A residual following one exponential decay forms a straight trend against linear time under the applicable sign and target conventions. Changes of slope or a residual floor can reveal limitations of that candidate model.

SENSITIVITY COEFFICIENT: Local derivative of the measurement function with respect to an input quantity, carrying the units and sign needed for uncertainty propagation.

Copyright 2026, James M. Atkinson

SENSITIVITY FAILURE: Failure to detect the defined event during an acquisition interval that validly observed the relevant channel under the stated conditions. It can inform a sensitivity estimate only within that specified population and detector rule. Events missed because the receiver was not observing belong to a separate coverage category unless a broader operational measure is explicitly defined.

SENSITIVITY SPECIFICATION: A declared input-level performance requirement together with the signal, bandwidth, detector, observation interval and success criterion used to determine it. Specifications based on different modulation quality, error rate or detection criteria describe different measurands unless a justified conversion connects them.

SEQUENCE-NUMBER CHECK: A comparison of declared block or packet sequence identifiers to detect missing, repeated or reordered portions of a record. Its interpretation depends on the acquisition protocol and reset behavior. It supports continuity assessment alongside sample counters, block lengths, overrun flags and clock status.

SERIALIZATION: Encoding a defined sample representation into a stored or transmitted sequence with specified ordering, scaling and metadata. The recording serializer creates an interface that must agree with its reader. Correct behavior of an upstream driver or transport format does not establish that this separate file boundary preserves the intended values.

SETTLING GUARD: An initial interval excluded from a nominal dwell because tuning, filtering, gain control or another state transition has not yet produced usable data. It reduces the window available to meet the event criterion. Its duration must follow the applicable observed or justified response rather than the mere completion of a control command.

Copyright 2026, James M. Atkinson

SETTLING TIME: The earliest time after which the specified response remains within its declared error tolerance under the adopted conditions. The error quantity and units matter. In the one-pole model it is zero if the initial error is already acceptable, finite for a positive tolerable residual, and not finite for exact removal of a nonzero initial error.

SETTLING TOLERANCE: The positive permitted residual in a declared state or output quantity used to determine an acceptance time.

SHAPE FACTOR: Ratio of filter bandwidths measured at two specified attenuation levels.

SHARED AGC DETECTOR: A level detector whose output controls gain used by more than one selected signal or observation path. Its admitted band can be wider than a displayed channel, allowing an off-channel signal to suppress a desired weak response. Interpretation requires the detector takeoff, admitted spectrum, gain distribution and control state, rather than the display span alone.

SHARED DEPENDENCY: A common clock, power supply, path, software component, calibration input or other influence linking nominally separate observations. It can preserve the same error across instruments or derived products. Counting labels or devices therefore does not establish the amount of independent confirmation.

SHORT-TIME FOURIER TRANSFORM: Sequence of transforms applied to overlapping time segments to estimate spectral evolution.

Copyright 2026, James M. Atkinson

SIDEBAND: Spectral content displaced from a carrier reference by modulation. Its amplitude, phase and retained frequency side depend on the waveform and receiver path. The equal two-sideband power relation in the chapter is conditional on sinusoidal conventional AM and a linear, symmetric response; it is not a universal message-power rule.

SIDEBAND COEFFICIENT: A complex peak-voltage coefficient assigned to an upper or lower spectral component in the envelope expansion. It carries phase as well as amplitude. After a path response, the sum and difference of the two coefficients contribute to the complete in-phase and quadrature expression; real-coefficient shortcuts do not apply to arbitrary complex coefficients.

SIDEBAND IMBALANCE: A difference between the applicable amplitudes or phases of corresponding upper and lower sideband responses. It can turn an originally real envelope into a complex one and bias a source-depth inference from output magnitude. Distinguishing source asymmetry from path distortion requires an appropriate reference or additional independent information.

SIGNAL CLASSIFICATION: The association of an observed component with a waveform family, modulation, timing behavior, or service type. The classification describes characteristics and is separate from attribution to a particular emitter or owner.

SIGNAL-ONLY POWER: The mean power assigned to the desired signal after a compatible additive contribution has been removed under a justified model. It is distinct from the total indicated output power. Its positivity determines whether a finite logarithmic level exists; a negative estimated difference requires reconciling the estimates and premises.

Copyright 2026, James M. Atkinson

SIGNAL RETENTION: The fraction or representation of the desired signal preserved by the selected channel and processing for the intended measurement or detection event. Reducing equivalent noise bandwidth can reject desired modulation or burst energy as well as noise. A claimed sensitivity improvement must evaluate the retained signal, rather than relying only on the reduced noise trace.

SIGNAL-TO-NOISE RATIO: The ratio of the selected signal power to the noise power represented in the same observation. Its input and output versions require declared planes, bandwidths and retained signal content. A specified ratio can support an input-power requirement, but does not by itself establish a probability of detection or false alarm.

SIGNED DIFFERENCE FREQUENCY: The algebraic RF-minus-LO frequency retained before any conversion to a nonnegative real-frequency display.

SINGLE SIDEBAND: Amplitude-modulation form transmitting one sideband with reduced or suppressed carrier.

Copyright 2026, James M. Atkinson

SINGLE-SIDEBAND PHASE DENSITY: The linear phase-noise quantity equal to one half of the one-sided phase spectral density and, at positive offsets, to the two-sided phase density. The carrier-referred quantity may be expressed linearly per hertz or logarithmically in dBc/Hz. Model 12B states its small-phase convention and includes both symmetric contributions in real-phase variance; a discrete spur requires separate line treatment.

SLEW-LIMITED CONTROL: A regime in which the control state changes at an imposed maximum rate rather than following the small-change exponential law over the whole excursion. Limited charging or discharging current can produce an approximately linear voltage ramp. The applicable rate, transition and control range require their own evidence; a later exponential fit does not describe the earlier ramp automatically.

SLEW RATE: The applicable maximum or specified rate limit of a changing state or output, expressed in that quantity's units per unit time and tied to stated conditions. A large-change slew limit can produce an early ramp rather than the local exponential response. It is distinct from an arbitrary trajectory's instantaneous derivative. Settling inferred from the small-change model must be checked against the actual event regime.

SMALL-PHASE APPROXIMATION: The retention of one plus j times phase as the first-order representation of the complex phase exponential. The chapter supplies an exact pointwise complex-amplitude remainder bound of half the squared real phase. First-order sideband amplitudes are approximate and use an unmodulated carrier reference; the bound does not itself specify exact spectral containment.

Copyright 2026, James M. Atkinson

SMALL-SIGNAL ASYMPTOTE: The linear response extrapolated from the declared low-level behavior of a stage. It supplies the fundamental reference for the chapter's intercept construction, rather than the full finite-level fundamental including its cubic correction. Confusing those quantities changes the inferred intercept and can obscure the limits of the approximation.

SMALL-SIGNAL CHARACTERIZATION: Measurement of a path's response within a range where the declared linear model is applicable. It establishes quantities such as gain, phase, matching and noise baseline for that state. Large-signal, pulsed and recovery behavior require additional observations rather than extrapolation from the quiet small-signal result alone.

SMALL-SIGNAL PROTECTION LOSS: The ordinary signal attenuation introduced by a protection network when it is not in its limiting state. It affects the desired transfer and, when dissipative and preceding gain, the input-equivalent noise budget. Survival of large events does not establish that this loss is negligible, stable, or unchanged after an event.

SMALL-SIGNAL VALIDITY: Operating condition in which the linear gain and added-noise law used by the measurement model remain applicable.

SOFTWARE BILL OF MATERIALS: An inventory of software components within a declared product or release scope. It supports provenance and dependency review but does not itself establish freedom from vulnerabilities or cover omitted firmware, calibration files or other artifacts. Acceptance must compare the inventory's actual scope with the components required by the stated case.

Copyright 2026, James M. Atkinson

SOFTWARE CORRECTION OFFSET: A declared numerical adjustment already included in an exported or displayed result. It changes the coordinate or reference-plane interpretation of that value according to its documented convention. Recover the raw indication or apply only the remaining corrections; an unexplained export state leaves alternative results rather than a justified midpoint.

SOURCE-DOMINATED NOISE: A condition in which admitted source noise contributes much more to the total than the receiver's input-equivalent added noise. Reducing receiver noise then produces only a small reduction in the complete noise level. The conclusion depends on the represented source spectrum and does not justify replacing structured interference with a temperature.

SOURCE-GENERATED INTERMODULATION: Nonlinear products produced in a stimulus source, combiner, connector or other test-path component before the receiver contribution is isolated. Such products can contaminate an intercept measurement and can combine coherently with receiver-generated amplitudes. Source isolation and harmonic filtering are therefore part of the validity argument, not merely setup details.

SOURCE HARMONIC CONTAMINATION: An unwanted harmonic already present in a test source or its delivery path that enters the receiver as an ordinary RF input. During an image test, such a harmonic can fall in the desired path and imitate response to the intended image-frequency fundamental. Bounding the contamination at the actual receiver plane is necessary before assigning the measured IF output to receiver image rejection.

Copyright 2026, James M. Atkinson

SOURCE-IMPEDANCE DEPENDENCE: The change in a receiver's transfer or added-noise response when the impedance driving its input changes. Mismatch can therefore affect both delivered source power and the receiver contribution. A single scalar loss adjustment may be inadequate when the required noise-measurement accuracy depends on this interaction.

SOURCE NOISE TEMPERATURE: The temperature-scale representation T_s of noise supplied at the cascade input under the declared band and model. It can reflect the antenna view or an applied calibrated source and need not equal ambient temperature. Model 2B keeps it separate from the equivalent temperature representing receiver-added noise.

SOURCE-PATH CONTROL: A measurement or controlled comparison that bounds signals and artifacts already present in the sources, cables, and combining network before the receiver input. It is needed when receiver-generated intermodulation or noise is being claimed. Its measurement floor and applicability must be retained because an undetected contribution is bounded, not necessarily absent.

SOURCE SPECTRAL PURITY: The extent and distribution of a test source's unwanted spectral components under the applied operating conditions, including harmonics, spurs, and relevant broadband noise. It must be assessed at the receiver plane through the actual path when artifact attribution depends on it. A source's nominal carrier level does not characterize these unwanted contributions.

Copyright 2026, James M. Atkinson

SOURCE SWITCHING: The controlled transition between the hot and cold input-source states of a comparative noise measurement. The record must identify the realized state, timing, settling, and any associated change in gain, bandwidth, mismatch, or noise law. Switching labels alone do not establish the common-state conditions needed for the simple Y-factor inversion.

SPECTRAL DENSITY NORMALIZATION: Scaling squared transform magnitude by the sample rate and the actual squared window-weight sum so that the ordinate has input-squared units per hertz. Under the chapter's white-covariance premise its expectation is flat. Integrating this finite-record density gives the stated window-weighted mean square even without that whiteness assumption.

SPECTRAL GRAM MATRIX: The matrix formed from consistently weighted paired spectral vectors, with autospectra on its diagonal and conjugate cross-spectra off the diagonal. Common nonnegative weights give the positivity structure behind the coherence bound. Separately chosen medians need not retain that structure and can produce a substituted ratio above one.

SPECTRAL LEAKAGE: Distribution of energy into neighboring transform bins caused by finite observation and windowing.

SPECTRAL LINE: A discrete-frequency contribution with finite integrated power, distinct from an ordinary continuous spectral density. A carrier or discrete phase-modulation spur must be included through its line contribution and the observation response. Assigning it an arbitrary per-hertz value or treating it as a flat density can misstate admitted power.

Copyright 2026, James M. Atkinson

SPECTRAL PREPROCESSING: The declared operations applied to acquired samples before the analyzed transform, such as mean subtraction or other detrending. These operations can change which physical or statistical components remain in the analyzed record. Reproducibility requires their order and parameters alongside the window, sample rate and retained data.

SPECTRAL REGROWTH: Additional spectral spread associated with waveform distortion, commonly assessed outside the intended channel. It is a spectral consequence rather than an error-count statistic. A receiver or transmitter may exhibit acceptable decoded data while this spectral measurement fails its separately defined criterion.

SPECTRAL SUPPORT: The set of frequencies at which a represented spectrum is nonzero, subject to the model's mathematical convention. Model 6A bounds the envelope support so that the translated positive and negative RF bands remain separated. This exact model set differs from a practical admission boundary defined by a finite filter response and detection threshold.

SPLITTER ISOLATION: The degree to which a signal or load change at one splitter branch is prevented from affecting another under stated port conditions. Finite isolation and coupled output loads can make unused branches consequential. Selected-path gain alone does not establish the behavior of the complete multiport assembly.

SPREAD SPECTRUM: A signaling approach that intentionally distributes a represented signal over a broader frequency or code domain according to a specified spreading rule. Reception and classification depend on that rule and timing. A broad spectrum alone is insufficient to identify the method or demonstrate successful despreading and information recovery.

Copyright 2026, James M. Atkinson

SPURIOUS-FREE DYNAMIC RANGE: A range defined by specified desired-signal, noise and spur conditions at compatible reference planes and bandwidths. The chapter's third-order planning expression finds where the equal-tone cubic product meets the stated noise floor. Compression, reciprocal mixing, other products or model breakdown can impose a smaller usable range.

SPURIOUS RESPONSE: Receiver output caused by an unwanted internal or external frequency-conversion mechanism.

SPUR TABLE: A documented set of candidate unwanted-response relationships, including the parent frequencies, integer indices or clock relations and their stated scope. A useful table combines analog and digital architecture. It guides controlled movement and level tests; merely finding a matching entry is not proof of a generating mechanism.

SQUARED WINDOW-WEIGHT SUM: The sum of the squared real window coefficients, which is positive unless every coefficient is zero. It sets the chapter's noise-density normalization and window-weighted energy denominator. Using a coherent weight sum or sums calculated from a different coefficient vector changes the estimated quantity.

SQUELCH: A receiver operation that suppresses or gates a recovered output according to a defined or automatic condition. It can change the apparent presence and continuity of audio without proving that the RF waveform disappeared. Record its state and criterion when interpreting dropouts or comparing derived products.

Copyright 2026, James M. Atkinson

STANDARD DEVIATION: The nonnegative square root of variance, expressed in the same units as the modeled quantity. It measures dispersion rather than correction of a mean offset. A smaller standard deviation of a noise trace does not establish that its estimator targets the intended linear-power or logarithmic quantity.

STANDARD UNCERTAINTY: An uncertainty expressed in the form of a standard deviation under the stated input information and model. It describes dispersion rather than a guaranteed maximum error. Its numerical value alone does not define a coverage probability, a detection probability or an acceptance decision.

STATE CARRYOVER: Use of the actual ending state of one dynamic interval as the initial state of the next.

STATE-CONDITIONED COHERENCE: A paired spectral result calculated within observations assigned to a defined state instead of pooling different transfer conditions. Opposing within-state gains can produce low pooled coherence even when each state is perfectly related. The state rule must be independently defensible, rather than selected merely to obtain a preferred relationship.

STATE INTERVAL: A declared portion of a record during which the relevant receiver configuration and its calibration remain applicable.

Copyright 2026, James M. Atkinson

STATE MIXTURE: An observation population containing contributions from distinct receiver or source states with different stated distributions or mean powers. Averaging their logarithmic levels and then applying a single-state correction generally does not recover the overall arithmetic mean power. Preserve state-resolved measurements and their weights when those differences matter.

STATE RECORD: The record of the switch, gain, attenuation, bias, temperature and receiver settings relevant to an observation. It connects an assembled path to the transfer and noise behavior applicable at that time. Physical component identities alone cannot establish this state, especially across switching, warmup or remote-control transitions.

STATE TRAJECTORY: The sequence or function describing how the actual state evolves through time. A transient gain trajectory can differ materially from a final value or average gain. Quantitative correction requires an applicable state-to-gain relation and timing alignment with the RF observation; a fitted trajectory cannot reconstruct clipped or unobserved behavior.

STATE-TRANSITION RECORD: A preserved record of the operation and timing by which the receiver moved between configurations, including any relock, impulse or recovery interval. It distinguishes transition behavior from settled behavior. Excluding a transient from a settled-state analysis does not remove its evidential relevance or justify deleting it.

Copyright 2026, James M. Atkinson

STATIONARITY: The assumed stability of the statistical properties needed by a specified estimator over its included observations. The chapter's noise-power calculations hold one distribution and mean fixed unless a case explicitly varies them. A stable-looking averaged trace does not prove this premise, because averaging can conceal changes in the underlying state.

STATISTICAL BIAS: The difference between an estimator's expected value and the quantity it is intended to estimate under the stated model. Bias depends on the estimator and parameterization. An estimate can be unbiased in watts while its logarithm has finite-record bias in decibels.

STEADY STATE: The response associated with unchanged conditions after the relevant transient has ceased to matter under the stated criterion. In the ideal one-pole model, the target is approached asymptotically. A short burst or a recurring sequence can remain far from either nominal steady state, so the actual trajectory must be retained.

STEP ATTENUATOR: An attenuator offering discrete selectable losses. The actual step difference, frequency response, repeatability and contact condition matter when two receiver states are compared. A nominal setting change provides a useful challenge only when its transfer and the affected position in the chain are known.

STEP-ATTENUATOR REPEATABILITY: The consistency of the realized insertion loss when an attenuator returns to the same nominal setting under stated frequency and connection conditions. Contact behavior and switching history can produce variation distinct from nominal step accuracy. Repeated-state evidence matters when a small level difference is used to infer linearity or external-signal scaling.

Copyright 2026, James M. Atkinson

STEPPED SWEEP: An acquisition that visits selected frequency settings through successive tuning and dwell intervals. The usable part of each dwell excludes whatever settling or invalid state the validated method requires. Commanded dwell duration is therefore not automatically valid observation time, and the resulting trace still combines observations made at different times.

STEP RESPONSE: The evolution of a path's output after an input or target changes to a new constant value. Model 5A gives a particular monotone exponential control-state response. A measured step can reveal overshoot, delay or additional time scales that contradict that local one-pole description.

STOPBAND: A filter region in which unwanted transmission is intended to be suppressed to the stated level. Rejection must be evaluated at the actual interfering frequencies and operating conditions. A desired-band insertion-loss value cannot stand in for stopband blocker transfer.

STOPBAND REJECTION: Attenuation supplied by a filter over a declared unwanted-frequency region relative to the stated transfer reference. In a blocker budget it must apply at the blocker frequency and before the vulnerable stage. A desired-frequency insertion-loss value does not establish rejection, and a rejection specification does not establish desired-signal retention.

STORED SAMPLE OFFSET: Integer position in the retained sample array, which need not equal the original source index after a gap or overlap.

Copyright 2026, James M. Atkinson

STORED SAMPLE REPRESENTATION: The actual encoding of recorded sample components, including real or complex form, container width, signedness, byte order, packing, interleaving and scaling. It determines payload accounting and interpretation. Converter resolution alone does not specify that representation, and an exported format can use a different byte rate for the same sample sequence.

STRICT STATIONARITY: Invariance of all finite-dimensional probability distributions under a common shift of time. Model 11B invokes this stronger premise, with a finite fourth moment and its stated blocker-phase convention, when bounding the filtered nonlinear remainder. The weaker covariance premise sufficient for the retained linear spectrum does not automatically provide it.

SUBHARMONIC: A component at an integer fraction of a stated fundamental frequency. It is among the possible oscillator-related features considered in the chapter's architecture review. Its existence and influence require evidence from the actual path; the term alone does not identify which divider or nonlinear mechanism produced an observed line.

SUBJECTIVE INTELLIGIBILITY: A listener's judgment that recovered audio is understandable. It can be useful within an authorized investigation, but it does not calibrate the RF frequency or deviation, prove source identity, or replace objective verification of the processing path. The original capture and recovery settings remain the technical record.

Copyright 2026, James M. Atkinson

SUM PRODUCT: The first-order real-multiplier component at the sum of the positive RF and LO frequencies. In the normalized ideal cosine model it has the same peak scale as the difference product before output selection, with the sum of their phases. It is not absent merely because a receiver intends to use the difference IF. Actual filtering and path response determine whether it influences the observation.

SUPERHETERODYNE RECEIVER: A receiver that uses an oscillator-driven conversion to an intermediate-frequency path for subsequent selection and measurement. The oscillator choice and injection side determine the possible desired and image inputs. An indicated IF or display center alone does not uniquely identify the original external frequency.

SUPPLY-PATH CONFOUNDING: Ambiguity introduced when a power-source comparison changes more than the noise on the supply. Replacing a supply with a battery can also alter conductive coupling and grounding. A changed receiver indication supports sensitivity to the intervention, but a more selective test is needed to identify which changed mechanism caused it.

SUPPRESSED CARRIER: A modulation condition in which the discrete carrier component is reduced or removed while the information-bearing sideband structure is retained. The carrier remains a reference for defining that structure. Coherent recovery requires a suitable reinsertion or reference relationship; the envelope alone need not preserve the original baseband waveform.

Copyright 2026, James M. Atkinson

SUSTAINED WRITE RATE: The data rate a recording path can continuously commit over the required duration and operating state after temporary buffering is accounted for. It is an achieved capacity, distinct from the waveform's calculated payload demand. A short burst benchmark can conceal a slower storage path and does not establish gap-free long capture.

SWEEP TIME: Time required for the analyzer to traverse the selected frequency span or measurement points.

SWEPT-TUNED SPECTRUM ANALYZER: An analyzer that successively translates input frequencies through a selected resolution response as its tuning changes. Its trace therefore contains a frequency-time history. A transient can be omitted or portrayed with a misleading shape; the selected acquisition mode must be identified when an instrument also supports other architectures.

SWITCHING MIXER: A mixer that uses the oscillator-driven switching action of its signal path for conversion. Its effective scaling and additional products need not match multiplication by a single sinusoid. The chapter therefore distinguishes the physical switching implementation from the explicitly normalized ideal multiplier used for the synthetic calculations.

SWITCHING TRANSIENT: A temporary response produced while a switch, filter selection or other route change moves between states. Its amplitude, duration and interaction with control recovery can affect the usable observation interval. A calibration of either settled endpoint does not automatically describe the intervening transient.

Copyright 2026, James M. Atkinson

SWITCH LEAKAGE: Signal coupling through a nominally unselected switch path under specified conditions. A strong signal on an unused branch may remain observable despite selection of another branch. The switch state, port terminations and relevant isolation must therefore be included in the path model and acceptance record.

SYMBOL: One value selected from the declared modulation alphabet for a particular signaling opportunity. Its waveform representation and binary labeling belong to the format definition. A symbol may represent several coded label bits; it is neither an ADC sample nor necessarily one unique delivered information bit.

SYMBOL RATE: The number of declared modulation-symbol events per unit time, with the active or whole-interval convention stated. Symbols per second are distinct from receiver samples per second. Guard intervals can change an average event count per wall-clock second without changing the symbol timing inside an active burst.

SYMBOL-RATE MISMATCH: A difference between the actual symbol timing rate and the rate assumed by the reconstruction or demodulator. It can make relative decision timing drift away from a chosen alignment point across a finite record. A constant timing adjustment does not generally remove that accumulating discrepancy; clock and processing premises require separate checks.

SYMBOL TIMING: Estimate of the sampling instant associated with each transmitted symbol.

Copyright 2026, James M. Atkinson

SYMMETRIC WINDOW CONVENTION: A coefficient-vector convention with matching endpoints, distinguished from the periodic form used in many spectral calculations. The chapter's symmetric Hann window uses the record length minus one in its cosine denominator. For short records its weight sums and equivalent noise bandwidth differ materially from the periodic form.

SYNTHESIZER LOCK STATE: The recorded state of the synthesis system's relationship to its intended reference or control condition. It is part of the conversion configuration preserved when tuning plans or bands change. A valid center-frequency display alone is insufficient evidence that all frequency and phase relationships used by an analysis remained applicable.

SYSTEMATIC MEASUREMENT ERROR: The component of measurement error that persists or changes predictably across replicate measurements under the specified conditions. An estimated significant effect may be compensated by a correction whose uncertainty remains. Averaging additional readings does not remove a shared offset, and repeatability alone does not characterize this component.

SYSTEM-LEVEL VECTOR CALIBRATION: Calibration of the relevant complex response of an assembled measurement system, retaining amplitude, phase and their uncertainty relationships. The cited experiment combines multiple correction contributions and correlations. Its success illustrates a method under the published conditions, without certifying another receiver configuration or bounding that configuration's remaining nonlinear behavior.

Copyright 2026, James M. Atkinson

TAPERED WINDOW: A finite weighting that reduces selected record-edge contributions to alter the spectral response. It can lower sidelobes while broadening the main response and changing amplitude and noise normalization. A transient's location within the taper can materially change the energy admitted to the estimate.

TECHNICAL PEER REVIEW: Independent examination of the native data, configurations, calculations, calibration, challenge results and competing explanations supporting a finding. It tests the reasoning and evidence rather than merely approving a narrative. Unresolved disagreements lead to further measurements or explicit limitations, preserving the actual strength of the conclusion.

TEMPERATURE CONTRAST: The difference $T_h - T_c$ between the effective hot and cold source temperatures in the declared hot-cold measurement convention. It enters the source excess-noise ratio and influences the measured power contrast. Its calibration and uncertainty must be retained; a large nominal contrast alone does not establish receiver linearity or correct source-plane delivery.

TEMPORAL CORRELATION: A relationship in the timing of observed events under a stated time basis and uncertainty. It can guide a causal investigation without proving its direction or mechanism. Shared control activity, instrument timing or another common cause must remain possible until discriminating evidence resolves those alternatives.

Copyright 2026, James M. Atkinson

TERMINATED-INPUT TEST: An observation made with a specified load replacing the usual input source or antenna. It can constrain hypotheses about pickup, leakage or instability, but it also changes the source impedance and installed coupling. The comparison must retain the detection capability and operating conditions needed by the question.

TEST ORACLE: The specified expected result or decision basis against which a test observation is judged. It must discriminate the failure under examination with adequate independence from the implementation being tested. The chapter's asymmetric code vectors and channel-basis examples expose defects that mutually agreeing programs with a shared faulty dependency can conceal.

THERMAL DRIFT: A change in a measurement path's response associated with changing temperature over time. Filter loss, active-device state and calibration applicability can be affected. Reference comparisons and maintenance records should retain the thermal state so that drift is not silently interpreted as a changed external signal.

THERMAL EMISSION: Noise power supplied by a dissipative component because of its thermal state. In the matched attenuator derivation, this contribution supplies the difference between attenuated incident thermal noise and the equilibrium output. It accompanies physical dissipation; arbitrary reflected signal power is not assigned the same thermal-noise law.

Copyright 2026, James M. Atkinson

THERMAL EQUILIBRIUM: The condition used in the passive-loss derivation in which the matched source, attenuator, and connected terminations share the physical temperature T_p. The attenuator output available noise remains kBT_p because thermal emission complements the transmitted source noise. Equal equilibrium noise does not mean that a desired signal passes without attenuation.

THERMAL NOISE: Random electrical noise associated with a source's thermal state. In the chapter's classical matched-source approximation, its available power is proportional to absolute temperature and effective noise bandwidth. The approximation does not turn discrete interference, unstable amplification or every elevated receiver indication into thermal noise.

TIME ANCHOR: An association between a specified source sample index and a time on a declared time scale. Together with a supported sample-rate model it permits other sample times to be calculated. A host-arrival or file-creation timestamp is not interchangeable with this sampling event, and anchor uncertainty remains distinct from continuity of sample indices.

TIME AVERAGE: An average taken over a declared time interval or stated long-time limit of a waveform. The interval and weighting are part of its definition. The chapter's mean-power identities use explicit carrier and message orthogonality; their time averages are not interchangeable with instantaneous peaks or unspecified statistical expectations.

TIME BASIS: The declared reference and event definition used to assign times to observations. It includes the meaning of a timestamp and, where relevant, synchronization sources, clock state, and uncertainty needed for comparison.

Copyright 2026, James M. Atkinson

TIME DIFFERENCE OF ARRIVAL: The difference between the arrival times of a signal at declared receiving positions or channels. Inferring geometry from it requires compatible clocks, identified sampling events and calibrated path delays. Shared frequency alone does not establish these conditions, and an apparent arrival difference can include electronic or packet-alignment offsets.

TIME-FREQUENCY REPRESENTATION: A processing-dependent description of how spectral content varies across a finite record. Window duration, overlap, scaling, thresholds and other method choices affect visible features. It must remain linked to the original samples and a quantified analysis rule; visual structure alone is not a validated event or source.

TIME-QUALIFIED TRIGGER: A trigger whose acceptance includes a stated duration, timing relation or time-dependent logical condition. Pulse-width selection is one example. Its qualification time is part of the event definition, while holdoff or rearm describes subsequent trigger availability; those intervals must not be treated as interchangeable.

TIME SCALE: The defined system of time coordinates used to identify instants and compare clock readings. A clock error is meaningful only relative to that basis. Receiver records must state the reference and event association when combining channels or captures; matching numerical timestamps without that information does not establish simultaneous acquisition.

Copyright 2026, James M. Atkinson

TIMESTAMP: A recorded time value associated with a specified event on a declared time basis. The event might be the sampling instant, packet arrival or file creation, and those meanings are not interchangeable. Its usable accuracy also depends on the clock, delay calibration and continuity evidence rather than on the numerical resolution of the label alone.

TIMING SKEW: Relative delay between nominally simultaneous channels, triggers, or signal paths. Acquisition or processing skew can introduce a frequency-dependent phase difference into paired analysis. Phase and delay conclusions require alignment and calibration of the relevant paths, together with the clock and geometry conditions used in the comparison.

TONE-NORMALIZED SQUARED SPECTRUM: The squared windowed transform divided by the squared coherent weight sum, with side conventions specified. Its units are those of input mean square, but summing its ordinates requires bandwidth correction.

TONE SPACING: The frequency separation between the parent tones in a specified test. It determines where their products lie and can affect a physical stage's measured intermodulation behavior. Tone levels, observation bandwidth and receiver state must remain defined when spacing is changed; an intercept from one separation is not automatically valid at another.

TRACE: An ordered set of displayed or stored analyzer values associated with declared frequency, time and processing coordinates. It may be one sweep or an aggregate of many observations. A trace image alone can omit the settings and observation history needed to interpret its values or reproduce the result.

Copyright 2026, James M. Atkinson

TRACEABILITY: Property of a measurement result relating it to references through a documented, unbroken chain of calibrations with stated uncertainties.

TRACE AVERAGING: Combination of corresponding trace observations using a specified averaging operation and record selection. It can reduce variation for a suitable stationary process, but its effect depends on whether voltage, power or logarithms are averaged. Combining repeated sweeps does not create simultaneous observation of their frequencies.

TRACKING FILTER: Tunable filter whose passband follows the receiver tuning frequency.

TRAINING SEQUENCE: Known or explicitly assumed reference symbol values used to estimate receiver or channel parameters. It is the content used for fitting, while a training-set specification identifies which observations are included. Retain both the sequence and its alignment, and evaluate transfer on observations excluded from fitting.

TRANSFER PHASE: The phase difference imposed by a specified input-to-output path at a stated frequency. With the chapter's sinusoidal convention, a positive physical delay gives negative transfer phase. This sign must not be interchanged with the positive relative phase assigned to an advanced clock in Model 12A.

TRANSFORM LENGTH: The number of values supplied to the discrete transform, including any appended zeros. It determines the displayed frequency grid. When it exceeds the acquired record length, normalization must retain the sums of the original window coefficients; a longer transform does not represent more acquired observation time.

Copyright 2026, James M. Atkinson

TRANSIENT RESPONSE: The time-dependent behavior before the response required for the current conditions has been established. It can change the indicated peak, onset or pulse shape while a long-record energy result remains usable. Its interpretation depends on the actual path, stimulus and measurement criterion.

TRANSIENT SUPPRESSOR: A protection component intended to reduce a short excessive electrical disturbance. Its presence does not make the complete input path ideal: leakage, reactive loading, insertion loss, transient transmission and recovery can affect the measurement. Acceptance must use the mounted path and the applicable event conditions.

TRANSIENT VALIDATION: A controlled check that the selected receiver method represents the event duration, modulation, timing and prior state required by the intended measurement.

TRANSITION WIDTH: Frequency interval connecting specified passband and stopband boundaries of a filter. The boundary criteria must be stated because different level definitions give different widths. Signals occupying this region can experience rapidly changing magnitude and phase; a tuning frequency by itself does not show whether a broadband desired waveform remains inside the usable response.

TRIANGLE INEQUALITY: The principle that the magnitude of a sum is no greater than the sum of the individual magnitudes. It gives the chapter's conservative multi-component deviation bound. Equality requires compatible component phases; knowing only component amplitudes does not establish that the bound is attained.

Copyright 2026, James M. Atkinson

TRIGGER DELAY: The specified interval between the trigger reference and the acquisition or gate position used for the measurement. Its sign and time reference must follow the instrument convention. Delay, jitter and the event's own repeatability determine which portion of a burst is observed; matching a trigger edge does not align every internal waveform feature.

TRIGGER HOLDOFF: A declared interval or condition during which further trigger acceptance is inhibited after a trigger event. It affects the ability to record a second closely spaced event. Characterization with controlled event pairs is therefore needed in addition to a successful isolated-event test.

TRIGGER HYSTERESIS: A dependence of trigger-state transitions on distinct entry and release conditions, used in the declared trigger logic. It affects whether and when nearby signal excursions generate new events. Its settings and behavior belong to the capture configuration rather than being inferred from the displayed trigger threshold alone.

TRIGGER LATENCY: The delay between the relevant event at a specified trigger-path boundary and the trigger indication or action. Its value and variability depend on the trigger location and processing. A known-stimulus test must relate it to the stored sample times; a trigger label alone does not identify that relationship.

TRIGGER PATH: The part of the receiver processing chain observed by the trigger decision. It may use full-rate samples, a decimated channel, filtering or a software statistic, giving it a different bandwidth or delay from the saved waveform. The event can therefore be present in one path without satisfying the other's condition.

Copyright 2026, James M. Atkinson

TRUST ANCHOR: Trusted verification data, commonly a public key or root identity, from which a declared signature-verification relationship is established. Its installation, protection and management are part of the trust decision. The presence of a signature cannot establish its own trusted source without the applicable verification policy and anchor.

TUNING WORD: The integer phase increment selected for a numerically controlled oscillator's accumulator. Together with accumulator width and clock frequency, it determines the generated frequency in the stated ideal model. Nearest-word selection leaves a bounded frequency-grid error that can accumulate into a consequential phase difference over a long observation.

TWIDDLE FACTOR: A complex exponential multiplier used in a Fourier-transform computation. Its sign, index and numerical representation belong to the implementation definition. The four-channel examples use exact factors drawn from the unit axes, while a general finite-word transform can introduce additional coefficient and intermediate-rounding errors.

TWO-POINT TIME-CONSTANT IDENTIFICATION: Estimation of a candidate one-pole time constant from two nonzero, same-sign residuals about one fixed target, with decreasing magnitude over a positive time separation. The elapsed time divided by the natural logarithm of their ratio gives the candidate constant. Additional observations are needed to establish model adequacy and its operating domain.

Copyright 2026, James M. Atkinson

TWO'S COMPLEMENT: The signed binary integer convention used by Model 10D, with one more negative code than positive code at a given word length. That asymmetric range matters when multiplying or negating the most negative value. A mathematically positive endpoint can overflow a narrowed signed format even when both operands have magnitude no greater than one.

TWO-SIDED SPECTRUM: A spectral representation retaining both positive and negative frequencies in the chosen sampled-frequency interval. The chapter's density model begins with this convention before any justified folding for real data. Its ordinate units and integration spacing must remain explicit, especially when comparing a complex baseband record with a one-sided real-signal display.

TWO-TONE TEST: A controlled test using two specified sinusoidal components to examine nonlinear products or related transfer changes. The individual frequencies, levels and path purity matter. Products already generated by the sources or combining network must be bounded before the receiver is identified as their origin.

UNBIASED ESTIMATOR: An estimator whose expected value equals the target quantity within the adopted statistical model. This property does not make every realized estimate correct or establish a confidence bound. It is not preserved by an arbitrary nonlinear transformation, as the chapter's power-to-decibel comparison demonstrates.

Copyright 2026, James M. Atkinson

UNCERTAINTY BUDGET: An organized account of the input quantities, uncertainty information, sensitivities and dependencies relevant to a specified result. The table follows the measurement model rather than replacing it. Shared references, unapplied corrections, interpolation residuals and configuration mistakes must be treated according to their actual roles instead of being assigned arbitrary independent rows.

UNCORRELATED SAMPLES: Samples whose relevant cross-covariances vanish under the declared model. This second-moment condition can remove cross terms in an expected squared transform without requiring Gaussianity. It is weaker than statistical independence in general and does not automatically justify every distributional averaging formula.

UNDERSAMPLING: Intentional sampling of an admitted band above the first real-sampling Nyquist zone so that its discrete representation lies at a lower frequency. Preserving the desired bandwidth requires suitable band placement and analog rejection of competing aliases. Spectral order can reverse, and bandwidth alone does not establish a valid plan.

UNEQUAL-TONE INTERMODULATION: The nonlinear-product behavior produced when the two parent tones have different stated amplitudes or powers. In the retained cubic model, each close-in product weights one parent twice and the other once in power. The two products therefore need separate calculations; symmetry cannot be inferred from their frequency placement alone.

Copyright 2026, James M. Atkinson

UNEQUAL-TRIAL PROBABILITIES: Different declared single-trial capture probabilities used when the experiment varies across trials. Their miss probabilities can be multiplied only when the relevant independence assumptions remain justified. Assigning different numbers to correlated trials does not remove the need for a joint model or a defensible bound.

UNEXPLAINED SIGNAL: Observed component that survives initial validity checks but lacks sufficient evidence for source or functional attribution.

UNIFORM PHASE ASSUMPTION: The assumption that event starts are equally distributed over a schedule period. Under it, Model 15A converts the merged eligible-start duration into a conditional capture probability. A synchronized or concentrated event process requires its own distribution or a deterministic coverage statement rather than this convenient average.

UNIFORM QUANTIZATION-ERROR MODEL: The stipulated probability model in which rounding error is uniformly distributed over one code-step interval centered on zero. It gives a mean-square error used in the ideal sine-wave estimate, but the half-step error bound alone does not establish this distribution. Predicting channel noise additionally requires the separate white-error premise.

UNIQUE PAYLOAD POSITION: A payload identity counted once in a declared accepted set, even when several transmission instances refer to it. Identity requires more than the binary value zero or one. Unique-position counting must specify the request or sequence boundary, acceptance rule and time interval before it can support a delivered-throughput claim.

Copyright 2026, James M. Atkinson

UNMEASURED SPECTRAL CONTRIBUTION: A phase-noise contribution outside the directly evaluated spectral region. Model 12B bounds a specified finite extra band only when a justified upper density limit is supplied. Without that information, extending a plot or quoting the measured-band RMS as a complete jitter value would add unsupported evidence.

UNUSED-PORT TERMINATION: Load condition at a nonselected network port that can affect leakage, matching, or coupling into the selected path.

UNWRAPPED PHASE: A continuous phase branch retaining accumulated cycles on a declared valid interval, with reset events treated separately. Its slope supports frequency or delay calculations only when the associated model applies. Selecting the branch requires evidence; numerical precision alone does not resolve an integer-cycle ambiguity.

UPPER SIDEBAND: The message-related spectral component or band above a declared carrier. In Model 6A's single-tone complex convention its envelope rotates at positive message frequency. The signed baseband result also depends on LO frequency; folding it into real-audio magnitude can hide the orientation needed for a coherent comparison.

USABLE ACQUISITION WINDOW: One contiguous interval in which the retained samples meet the stated configuration, settling, continuity and detector prerequisites. Tuning and recovery intervals may need exclusion. In a sweep, valid windows at different frequencies occur at different times, limiting conclusions about a changing or intermittent event.

Copyright 2026, James M. Atkinson

VALID-INTERVAL MEAN POWER: The average power over only those intervals for which the retained observations and corrections are supported. It can be reported even when an intervening transition remains unobserved. Extending it to the entire elapsed span requires information about the omitted portion or explicit bounds on its contribution.

VARIABLE-GAIN AMPLIFIER: An amplifier whose gain can be changed by a control input or setting. In a receiver its state can interact with RF attenuation, intermediate-frequency gain, digital scaling and detector normalization. Quantitative interpretation requires the applicable gain state or trajectory, especially when an automatic loop responds to intermittent energy.

VARIANCE: The expected squared departure of a random quantity from its expected value, when that moment exists. Its units are the square of the quantity's units. Variance describes spread under a model and does not, by itself, quantify bias, hard limits or a stated coverage probability.

VECTOR AVERAGING: Combining complex spectral coefficients while retaining their phase relationships. A phase-aligned component can persist while varying components partly cancel. The resulting quantity differs from an average of nonnegative powers, and its usefulness depends on the stated alignment, stationarity and meaning of the retained records.

VECTOR NETWORK ANALYZER: An instrument used to characterize complex network response, retaining amplitude and phase information. The chapter uses it for small-signal front-end transfer measurements. Such a measurement does not by itself establish compression, pulse leakage, survivability or recovery under a large incident event.

Copyright 2026, James M. Atkinson

VECTOR NOISE CORRECTION: A noise-measurement treatment that retains the relevant impedance and receiver-noise relationships rather than reducing all mismatch effects to one scalar loss. The cited method separates delivered source power from changes in receiver response. Applying such a method requires its additional characterization; citing it does not make that information available for an unmeasured assembly.

VERIFICATION: A check that specified requirements are met using appropriate evidence for the quantity, configuration and time concerned. A field reference can verify present function within its traversed scope without replacing a full calibration. Successful internal checks do not automatically establish external-path transfer, file correctness or uninterrupted validity over an earlier interval.

VIDEO BANDWIDTH: Post-detection or display filtering bandwidth that controls trace smoothing and response time.

WALL-INTERVAL PAYLOAD RATE: The represented payload-instance count divided by a stated elapsed interval that includes all specified active, guard and idle portions. Its numerator and time boundary must match. It differs from active-burst rate and becomes a unique-delivery rate only when the acceptance and duplicate-removal evidence supports that additional interpretation.

WARMUP: The evolution after energization toward a receiver or reference's specified operating condition. Temperature and other internal states can change frequency, gain or phase during this interval. The chapter therefore treats a drift fit made after stabilization as conditional and does not extend it through an unmodeled power-up history.

Copyright 2026, James M. Atkinson

WEAK-PROBE CHALLENGE: A strong-signal test that retains a controlled weaker desired reference to measure changes in useful observation capability.

WEIGHTED COMPLEX CORRELATION: In the chapter's gain fit, the sum of each training observation multiplied by the conjugate of its paired ideal reference and its fixed nonnegative weight. Dividing this complex quantity by positive training reference energy gives the fitted coefficient. The conjugation direction matters because it determines the estimated phase.

WEIGHTED REFERENCE ENERGY: The positive sum of declared nonnegative weights times squared reference-symbol magnitudes used in an EVM normalization.

WHITE-ERROR CHANNEL MODEL: A stipulated uncorrelated error model whose channel power is obtained by integrating its density against squared filter response.

WHITE NOISE: Noise with approximately constant power spectral density over the frequency band relevant to the calculation. Under fixed flat gain and the declared effective bandwidth, narrowing that bandwidth reduces integrated noise in direct proportion. A real source need satisfy this approximation only over the stated band, not at every possible frequency.

WIDE-SENSE STATIONARITY: A second-order condition with constant mean and covariance determined by time separation. It supports the chapter's retained linear phase-spectrum treatment when variance is finite. It does not generally make a nonlinear function of the phase stationary, so it cannot silently replace the stronger premise used for the remainder-power bound.

Copyright 2026, James M. Atkinson

WINDOW COEFFICIENT VECTOR: The complete sequence of real, dimensionless weights multiplied into the retained samples before transformation. Its values determine coherent gain, density scaling and the weighting of transient energy. A window name alone is insufficient when endpoint conventions, normalization or coefficient generation can differ.

WINDOW MAIN LOBE: The central region of a window's frequency response around a tone's shifted center. Its width affects separation of neighboring components and differs from the transform-bin spacing. Reducing sidelobes generally changes this central response, so the relevant tradeoff follows the quantity and interference conditions being measured.

WINDOW SCALING INVARIANCE: The property that multiplying all window coefficients by one nonzero real constant leaves the chapter's normalized squared spectrum, density and equivalent noise bandwidth unchanged when all associated sums are changed consistently. It does not permit mixing a transform from one vector with normalization sums from another.

WINDOW SIDELOBE: A secondary region of a finite window's frequency response away from its main lobe. A strong component can therefore contribute an indication at other frequencies even without another physical tone. Window choice and controlled reprocessing help test this leakage explanation, with amplitude and noise normalizations kept consistent.

WINDOW-WEIGHTED MEAN SQUARE: The ratio $\frac{\sum_{n=0}^{N-1} w_n^2 \left|x_n\right|^2}{\sum_{n=0}^{N-1} w_n^2}$. It is the integrated density of the stated finite-record normalization and can depend strongly on transient position.

Copyright 2026, James M. Atkinson

WORD LENGTH: The total number of binary digits allocated to a stored value or intermediate arithmetic result. It is distinct from the fractional-bit count and from measured converter effective number of bits. Adequate word length must accommodate the proved signed range of every required intermediate, including positive endpoint asymmetry.

WRAPPED-DELAY AMBIGUITY: The family of delays compatible with specified wrapped phase observations until additional phase, frequency or prior-range information selects a branch.

Y-FACTOR: Ratio of measured output powers for two known input noise temperatures.

Y-FACTOR ADMISSIBLE DOMAIN: The set of output-noise ratios compatible with the stated hot-cold model and its input constraints. For $T_h > T_c > 0$ and finite nonnegative T_e, it is $1 < Y \leq \frac{T_h}{T_c}$. An observed ratio outside that interval calls for investigation of the inputs and model rather than silent clipping of the inferred temperature.

ZERO CROSS-POWER CONDITION: A specified ensemble or averaging condition under which the cross terms between admitted contributions vanish and their mean powers may be added.

ZERO-DIFFERENCE BOUNDARY: The conversion condition at which RF and LO frequencies coincide in the selected first-order difference model. The real difference output then includes a DC term, so the nonzero sinusoidal phase and power conventions used for the chapter's tone examples cannot be transferred unchanged. Crossing the boundary also changes the sign of the real-frequency orientation and requires piecewise interpretation.

Copyright 2026, James M. Atkinson

ZERO-MEAN MESSAGE: A message whose declared average is zero over the applicable averaging interval or limiting convention. In the conventional-AM power expansion this condition removes the carrier-message cross term. It does not imply zero mean square, absence of modulation, a specified peak value or a particular spectral distribution.

ZERO PADDING: Appending zeros to an acquired, windowed record before calculating its transform. It evaluates the same finite-record transform on a denser frequency grid. It does not narrow the underlying window response, create independent observations or replace the original window sums in amplitude and density normalization.

Copyright 2026, James M. Atkinson

References and Works Cited

The bibliography identifies the works cited in the text and notes. Footnotes specify the passages used and distinguish publisher text, official metadata, historical examples, implementation conventions, and independent derivations. Public standards listings establish only their stated metadata and scope. Series navigation follows separately and does not substitute for primary-source support.

Advanced Micro Devices. Fast Fourier Transform LogiCORE IP Product Guide. PG109, version 9.1, July 17, 2026. Finite word length, rounding implementation, and fixed-point overflow sections. https://docs.amd.com/r/en-US/pg109-xfft/Finite-Word-Length-Considerations.

Annotation. This implementation reference addresses fixed-point FFT scaling, finite word length, rounding choices and overflow behaviour inside a particular programmable logic design. The relevant engineering question is whether every butterfly stage has the width, scaling schedule and saturation policy assumed by the chapter’s worked model. Configuration and test vectors must be retained before the documented core behaviour can be attributed to a particular acquisition system. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion.

Alexander, M. J., M. J. Salter, D. G. Gentle, D. A. Knight, B. G. Loader, and K. P. Holland. Calibration and Use of Antennas, Focusing on EMC Applications. Measurement Good Practice Guide 73. Teddington: National Physical Laboratory, December 2004. https://www.npl.co.uk/getmedia/24ef3e37-7c5f-40e6-84c9-4ad159e058f9/gpg73_antennas.pdf.

Annotation. Additional glossary scope: section 9.3.1, printed pages 43–44; section 9.6.2, printed pages 48–49; and the Appendix 4 phase-center discussion, printed pages 100–102. These passages support antenna/environment interactions, the frequency-dependent phase reference and limits on extrapolating a near-field observation. Historical EMC limits and numerical antenna examples are not adopted as current requirements. This measurement guide places antenna calibration in the context of the test environment, mounting geometry, cable paths and frequency-dependent response. A receiver comparison should track antenna factors, mismatch and phase-centre conventions at the declared reference plane rather than regard an antenna reading as a direct field value. Any extrapolation from laboratory calibration to a different installation requires documented geometry and uncertainty. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence.

Analog Devices. AD8367: 500 MHz Linear-in-dB VGA with AGC Detector. Data sheet. Rev. A, 2005. https://www.analog.com/media/en/technical-documentation/data-sheets/AD8367.pdf.

Copyright 2026, James M. Atkinson

Annotation. The device documentation describes a particular variable-gain and detector implementation, including gain-control behaviour that may affect observed amplitudes. Receiver evidence must distinguish commanded gain, settling behaviour and gain actually applied during a transient or intermittent transmission. The data sheet is not proof that the same response occurs in a different receiver or in an untested overload state. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Analog Devices. ADL8201: DC to 30 GHz, RF Limiter. Data sheet. Rev. 0, January 2026. https://www.analog.com/media/en/technical-documentation/data-sheets/adl8201.pdf.

Annotation. The component or engineering reference concerns protection against excessive RF drive and the nonlinear behaviour inherent in an input limiter. Front-end loss, limiting threshold, recovery time and spectral products should be checked against the actual arrangement before characterising a faint signal. A protection device that prevents damage does not guarantee accurate level measurement or freedom from in-band artefacts. The bibliography records the source identity, whereas claims of present-day instrument performance still

Copyright 2026, James M. Atkinson

require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Analog Devices. Measuring Single-Tone Desensitization for CDMA Receivers. May 26, 2006. Reciprocal Mixing subsection. https://www.analog.com/en/resources/technical-articles/2022/07/16/09/37/measuring-singletone-desensitization-for-cdma-receivers.html.

Annotation. The technical treatment concerns the conversion of strong off-channel energy and local-oscillator phase noise into receiver degradation. An apparent rise in the noise floor can reflect oscillator-sideband mixing rather than increased external thermal noise or a new transmitter. Conclusions require blocker level, frequency offset, preselection, instrument state and phase-noise conditions at specified reference planes. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Analog Devices. MT-085, "Fundamentals of Direct Digital Synthesis (DDS)." Rev. 0, October 2008, pp. 2–3. Phase-accumulator tuning relation and truncation distinction. https://www.analog.com/media/en/training-seminars/tutorials/MT-085.pdf.

Annotation. The tutorial addresses numerical phase accumulation, frequency tuning and the effects of finite word length in a digital oscillator. The tuning equation, accumulator width, truncation position and reference clock are distinct quantities and must be documented separately. A theoretically possible output frequency or spur location is not proof that a deployed receiver produces it without measurements of clock quality and implementation. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Analog Devices. Specifications and Measurement of Local Oscillator Noise in Integrated Circuit Base Station Mixers. June 18, 2003. Mixer Noise Model and Effective Noise Floor of LO Driver. https://www.analog.com/en/resources/technical-articles/2022/07/16/08/18/specifications-and-measurement-of-local-oscillator-noise-in-integrated-circuit-base-station-mixers.html.

Copyright 2026, James M. Atkinson

Annotation. The technical treatment concerns the conversion of strong off-channel energy and local-oscillator phase noise into receiver degradation. An apparent rise in the noise floor can reflect oscillator-sideband mixing rather than increased external thermal noise or a new transmitter. Conclusions require blocker level, frequency offset, preselection, instrument state and phase-noise conditions at specified reference planes. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Analog Devices. “Types of ADCs and DACs.” July 22, 2002. “Aperture Delay” and “Aperture Jitter.” https://www.analog.com/en/resources/technical-articles/types-of-adcs-and-dacs.html.

Annotation. The glossary uses only the aperture-delay and aperture-jitter definition paragraphs. Unrelated dynamic-range, differential-nonlinearity, effective-number-of-bits and Nyquist summaries are outside this use. This source informs the distinction between deterministic sampling-time displacement and random timing uncertainty. The effect of timing uncertainty depends on input frequency, the integration limits for phase noise and correlation between parallel sampling paths. Ideal jitter-limited SNR formulae are bounds under

Copyright 2026, James M. Atkinson

specified models, not measured effective number of bits or evidence that parallel ADCs create a wider word. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

Analog Devices. “System Noise-Figure Analysis for Modern Radio Receivers.” June 14, 2013. https://www.analog.com/en/resources/technical-articles/system-noisefigure-analysis-for-modern-radio-receivers.html.

Annotation. The cited work treats receiver noise as a gain- and bandwidth-dependent measurement problem, including equivalent input noise or cascaded stages. Input and output reference planes, source temperature, impedance match, receiver gain and effective detector bandwidth must all be stated. Noise-figure figures from a particular test setup do not establish minimum detectable signals or calibrated sensitivity in every field installation. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Copyright 2026, James M. Atkinson

Ansys. “Duty Cycle Distortion.” Electronics Suite 2025 R2, Circuit Help. Accessed November 2, 2026. https://ansyshelp.ansys.com/public/Views/Secured/Electronics/v252/en/Subsystems/Circuit/Content/Circuit/DutyCycleDistortion.htm.

Annotation. The glossary uses the bounded clock-duty definition. The source’s eye-generator parameter scaling and software defaults are not generalized to a receiver. This material addresses the relationship between waveform timing, digital or analogue filtering, and a detector’s observed symbol or pulse shape. A finite filter span, group delay or clock-duty error may alter timing and apparent pulse width even when the underlying emission is unchanged. The analysis should state symbol rate, filter response, sampling position and any applicable equalisation or synchronisation assumptions. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

Beavers, Ian. "Missing Half the Signal." Analog Dialogue, RAQ Issue 124. Analog Devices. NCO, FIR, and downsampling architecture; cited in Model 10B. https://www.analog.com/en/resources/analog-dialogue/raqs/raq-issue-124.html.

Annotation. The article documents the constituent operations of digital downconversion: numerically controlled mixing, low-pass filtering and

Copyright 2026, James M. Atkinson

decimation. In-phase and quadrature sign conventions, sample-rate changes and filtering latency are necessary to interpret the retained digital signal. Vendor examples illustrate an architecture but do not certify the bit scaling, numerical precision or channel timing of a particular recorder. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Cooper, David, et al. Security Considerations for Code Signing. NIST Cybersecurity White Paper. January 26, 2018. Sections 2, 3.4–3.5, and 5. https://nvlpubs.nist.gov/nistpubs/CSWP/NIST.CSWP.01262018.pdf.

Annotation. The security guidance is relevant to establishing authenticity, build provenance and integrity of software or firmware used in the measurement chain. A valid signature can support a statement about which artifact was approved under a stated trust policy, but cannot independently demonstrate correct signal processing. Release evidence should connect signer identity, digest, build inputs, installed image and measured instrument configuration. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain

Copyright 2026, James M. Atkinson

between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Ettus Research. UHD and USRP Manual. Version 4.11.0.0-0-g0d7ed3b1. “Configuring Devices and Streamers.” Streaming arguments and formats. Accessed October 31, 2026. https://files.ettus.com/manual/page_configuration.html.

Annotation. This UHD configuration reference identifies the streamer arguments and transfer-format choices that can alter how a USRP host requests and receives sample data. It supports precise recording of software configuration; it does not independently establish continuous RF capture, timing accuracy or an absence of overruns under the laboratory's load.

Ettus Research. UHD and USRP Manual. Version 4.11.0.0-0-g0d7ed3b1. “Firmware and FPGA Images.” Accessed October 31, 2026. https://files.ettus.com/manual/page_images.html.

Annotation. This interface or metadata specification describes practical mechanisms for configuring, representing or recording software-defined radio streams. Sample index, clock time, overrun indications, selected rates and on-wire representation matter when a forensic examiner reconstructs an acquisition. A software interface declaration alone cannot prove continuity of the resulting samples or correct interpretation by a different reader. A reader should cross-check the cited edition with

Copyright 2026, James M. Atkinson

its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Ettus Research. UHD and USRP Manual. Version 4.11.0.0-0-g0d7ed3b1. “R&D Testing Procedures.” Development-test scope and FPGA functional verification. Accessed October 31, 2026. https://files.ettus.com/manual/page_rdtesting.html.

Annotation. This interface or metadata specification describes practical mechanisms for configuring, representing or recording software-defined radio streams. Sample index, clock time, overrun indications, selected rates and on-wire representation matter when a forensic examiner reconstructs an acquisition. A software interface declaration alone cannot prove continuity of the resulting samples or correct interpretation by a different reader. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Copyright 2026, James M. Atkinson

Ettus Research. UHD and USRP Manual. Version 4.11.0.0-0-g0d7ed3b1. “uhd::rx_metadata_t Struct Reference.” Accessed October 31, 2026. https://files.ettus.com/manual/structuhd_1_1rx__metadata__t.html.

Annotation. This interface or metadata specification describes practical mechanisms for configuring, representing or recording software-defined radio streams. Sample index, clock time, overrun indications, selected rates and on-wire representation matter when a forensic examiner reconstructs an acquisition. A software interface declaration alone cannot prove continuity of the resulting samples or correct interpretation by a different reader. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Ettus Research. UHD and USRP Manual. Version 4.11.0.0-0-g0d7ed3b1. “uhd::usrp::multi_usrp.” Receive-rate, frequency, and gain setters. Accessed October 31, 2026. https://files.ettus.com/manual/classuhd_1_1usrp_1_1multi__usrp.html.

Annotation. The multi_usrp API reference describes software controls for receive rate, tuning and gain. For a forensic acquisition record, log both the requested settings and device-reported or

Copyright 2026, James M. Atkinson

otherwise verified applied states; the existence of a setter in an API is not evidence that a particular physical front end achieved its specified performance.

Friis, H. T. “Noise Figures of Radio Receivers.” Proceedings of the IRE 32, no. 7 (July 1944): 419–22. Publisher’s abstract consulted for historical framing. https://doi.org/10.1109/JRPROC.1944.232049.

Annotation. Friis's historical paper is central to the treatment of cascaded receiver noise figure. The historical citation should be used for the gain-weighted noise contribution principle rather than to infer contemporary component specifications; the exact reference planes, gains and matching assumptions must accompany an applied calculation.

Gentile, Ken. AN-922: Digital Pulse-Shaping Filter Basics. Analog Devices. Accessed November 2, 2026. https://www.analog.com/en/resources/app-notes/an-922.html.

Annotation. The glossary uses the raised-cosine transition, ideal decision-time zeros, square-root response composition, finite span and multibit-symbol relationships. No hardware performance or plotted numerical result is adopted. The source’s special-time square-root impulse-response statement is not adopted. This material addresses the relationship between waveform timing, digital or analogue filtering, and a detector’s observed symbol or pulse shape. A finite filter span, group delay or clock-duty error may alter timing and apparent pulse width even

Copyright 2026, James M. Atkinson

when the underlying emission is unchanged. The analysis should state symbol rate, filter response, sampling position and any applicable equalisation or synchronisation assumptions. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records.

Harris, Fredric J. “On the Use of Windows for Harmonic Analysis with the Discrete Fourier Transform.” Proceedings of the IEEE 66, no. 1 (1978): 51–83. Especially page 51, abstract and introduction, and pages 54 and 56, sections III.A–B, equations 8–14. Original paper reproduction: https://amst.ece.iastate.edu/paper/comparative_study/window_1.pdf.

Annotation. Harris's window-analysis paper supplies a foundational framework for interpreting finite-record DFT leakage and the choice of window functions. Any application to measured RF power must state the selected window, sampling convention, amplitude calibration and whether the quantity being corrected is coherent-tone amplitude or noise power.

Hati, Archita, Craig Nelson, Neil Ashby, and David Howe. Calibration Uncertainty for the NIST PM/AM Noise Standards. NIST Special Publication 250-90. July 2012. Sections 2.1–2.2.2, pages 2–4. https://tsapps.nist.gov/publication/get_pdf.cfm?pub_id=909758.

Annotation. The reference supplies a technical framework for interpreting oscillator stability or correlated phase-noise measurements. Observation interval, averaging statistic, timebase origin and common-

Copyright 2026, James M. Atkinson

clock correlation should be specified before translating a frequency statistic into arrival-time or phase evidence. A nominally stable source can still have an offset or transient recovery event, and averaging may suppress or distort correlated components. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Heinzel, Gerhard, Albrecht Rüdiger, and Roland Schilling. Spectrum and Spectral Density Estimation by the Discrete Fourier Transform (DFT), Including a Comprehensive List of Window Functions and Some New Flat-Top Windows. February 15, 2002. Sections 8–9, pages 12–16. Original report reproduction: https://holometer.fnal.gov/GH_FFT.pdf.

Annotation. Heinzel, Rüdiger and Schilling document finite-record DFT spectral-density estimates and window-function characteristics, including flat-top windows. The reference is pertinent to selecting amplitude and power estimators; exact coherent gain, equivalent noise bandwidth and one-sided factors must be derived for the specified window and normalisation.

Copyright 2026, James M. Atkinson

IEEE Standards Association. IEEE 1057-2017, IEEE Standard for Digitizing Waveform Recorders. Published January 26, 2018. Official status and scope checked November 1, 2026. https://standards.ieee.org/ieee/1057/5945/.

Annotation. This standard record concerns terminology and testing of instruments that digitise and retain waveforms. Its public scope is useful for identifying the type of device and associated measured quantities, while acquisition errors require separate evidence from actual recordings. The reference listing itself does not establish clause-by-clause compliance, especially where the complete standard text has not been examined. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

IEEE Standards Association. IEEE 1241-2023, IEEE Standard for Terminology and Test Methods for Analog-to-Digital Converters. Published October 6, 2023. Official status and scope checked November 1, 2026. https://standards.ieee.org/ieee/1241/6797/.

Annotation. This material provides vocabulary or test principles for sampling converters, including quantisation, nonlinearity, dynamic behaviour or timing limitations. Nominal word length, effective

Copyright 2026, James M. Atkinson

resolution, spurious response and input bandwidth are different performance descriptors with different measurement requirements. Claims about a full receiver must not be inferred from a single ADC specification without examining the analogue front end and acquisition chain. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

International Electrotechnical Commission. CISPR 16-1-1:2019, Specification for Radio Disturbance and Immunity Measuring Apparatus and Methods, Part 1-1: Radio Disturbance and Immunity Measuring Apparatus: Measuring Apparatus. 5th ed. May 22, 2019. Official publication scope checked November 1, 2026. https://webstore.iec.ch/en/publication/60774.

Annotation. The reference concerns apparatus and practices for electromagnetic interference measurements, with detector modes and equipment characteristics set by its identified scope. Quasi-peak, peak and average detection cannot be freely substituted when interpreting short or intermittent disturbances. A scope statement or product manual must not be mistaken for proof of compliance with every clause or correct operation under field conditions. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access

Copyright 2026, James M. Atkinson

was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Joint Committee for Guides in Metrology. Evaluation of Measurement Data: Guide to the Expression of Uncertainty in Measurement. JCGM 100:2008. Corrected version 2010. https://www.bipm.org/en/doi/10.59161/jcgm100-2008e.

Annotation. This metrological guidance concerns the evaluation and reporting of measurement uncertainty, including propagation through a measurement model. Covariance, shared calibration terms, nonlinear transformations and declared coverage factors require attention when evidence from multiple receiver channels is combined. An uncertainty budget is meaningful only for a specified measurand and operating condition; it does not itself certify the authenticity of the underlying acquisition. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Copyright 2026, James M. Atkinson

Joint Committee for Guides in Metrology. International Vocabulary of Metrology: Basic and General Concepts and Associated Terms (VIM). JCGM 200:2012. 3rd ed., 2008 version with minor corrections, 2012. https://www.bipm.org/documents/20126/2071204/JCGM_200_2012.pdf.

Annotation. This institutional vocabulary establishes conventional relationships among measurands, measurement results, calibration, uncertainty and traceability. Its role is terminological rather than an instrument-specific proof: the survey must still state the actual measurement model, reference plane and uncertainty evidence. A correct definition cannot compensate for an uncalibrated observation or justify conflating detection, classification and transmitter attribution. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Copyright 2026, James M. Atkinson

Additional glossary scope in the VIM3 online edition: clauses 2.16 (measurement error), 2.17 (systematic measurement error), 2.19 (random measurement error), 2.26 (measurement uncertainty), 2.36 (coverage interval), 2.40 (calibration hierarchy) and 2.52 (influence quantity). Each complete clause and its notes was consulted. The online locators are https://jcgm.bipm.org/vim/en/2.16.html; https://jcgm.bipm.org/vim/en/2.17.html; https://jcgm.bipm.org/vim/en/2.19.html; https://jcgm.bipm.org/vim/en/2.26.html; https://jcgm.bipm.org/vim/en/2.36.html; https://jcgm.bipm.org/vim/en/2.40.html; and https://jcgm.bipm.org/vim/en/2.52.html. The definitions preserve the stated distinction between VIM and GUM influence-quantity conventions.

Annotation. This institutional vocabulary establishes conventional relationships among measurands, measurement results, calibration, uncertainty and traceability. Its role is terminological rather than an instrument-specific proof: the survey must still state the actual measurement model, reference plane and uncertainty evidence. A correct definition cannot compensate for an uncalibrated observation or justify conflating detection, classification and transmitter attribution. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record

Copyright 2026, James M. Atkinson

whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Kast, Joshua M., Paritosh Manurkar, Kate A. Remley, Dylan F. Williams, and Robert D. Horansky. “System-Level Calibration of a Millimeter-Wave Vector Signal Analyzer with Uncertainties.” IEEE Transactions on Microwave Theory and Techniques 73, no. 11 (November 2025): 9085–95. https://doi.org/10.1109/TMTT.2025.3597240. NIST-hosted manuscript, pages 1–9, especially sections II–III: https://tsapps.nist.gov/publication/get_pdf.cfm?pub_id=959731.

Annotation. Additional glossary scope: the multisine passages in the introduction and section II, manuscript pages 2 and 4–5, and section II.E, manuscript page 7, on uncertainty propagation through the calibration. No new performance numbers or inference that calibration validates a nonlinear operating state is adopted. The research concerns complex-vector calibration or noise-temperature measurement where amplitude, phase and uncertainty propagate through the measurement chain. Reference-plane consistency, added cable paths and calibration-state changes are material to a repeatable comparison. Published experimental results cannot automatically be transferred to a different apparatus or treated as certification of the book’s constructed numerical examples. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript.

Copyright 2026, James M. Atkinson

Kester, Walt. MT-001, Taking the Mystery out of the Infamous Formula, “SNR = 6.02N + 1.76dB,” and Why You Should Care. Rev. A. Analog Devices, October 2008. Pages 1–7. https://www.analog.com/media/en/training-seminars/tutorials/MT-001.pdf.

Annotation. Kester's MT-001 tutorial explains the ideal quantisation-limited SNR relationship often written as 6.02N + 1.76 dB. It is an idealised converter relationship under stated input and quantisation assumptions, not a guarantee that an installed ADC will attain its nominal resolution in the presence of jitter, nonlinearity or broadband blockers.

Kester, Walt. MT-002, What the Nyquist Criterion Means to Your Sampled Data System Design. Rev. A. Analog Devices, October 2008. Pages 4–7 and 9–11. https://www.analog.com/media/en/training-seminars/tutorials/MT-002.pdf.

Annotation. Kester's Nyquist tutorial addresses sampling-band relationships and their practical implications for converter-based systems. Its application requires a clearly defined analogue input passband, anti-alias response and sampling rate. A quoted Nyquist rate by itself does not prove that out-of-band blockers or aperture errors have been controlled.

Kester, Walt. MT-008, Converting Oscillator Phase Noise to Time Jitter. Rev. A. Analog Devices, October 2008. https://www.analog.com/media/en/training-seminars/tutorials/MT-008.pdf.

Copyright 2026, James M. Atkinson

Annotation. This source informs the distinction between deterministic sampling-time displacement and random timing uncertainty. The effect of timing uncertainty depends on input frequency, the integration limits for phase noise and correlation between parallel sampling paths. Ideal jitter-limited SNR formulae are bounds under specified models, not measured effective number of bits or evidence that parallel ADCs create a wider word. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Kester, Walt. MT-012, Intermodulation Distortion Considerations for ADCs. Rev. A. Analog Devices, October 2008. Pages 1–4. https://www.analog.com/media/en/training-seminars/tutorials/mt-012.pdf.

Annotation. This material provides vocabulary or test principles for sampling converters, including quantisation, nonlinearity, dynamic behaviour or timing limitations. Nominal word length, effective resolution, spurious response and input bandwidth are different performance descriptors with different measurement requirements. Claims about a full receiver must not be inferred from a single ADC specification without examining the analogue front end and acquisition chain. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the

Copyright 2026, James M. Atkinson

manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Kester, Walt. MT-080, Mixers and Modulators. Rev. 0. Analog Devices, October 2008. https://www.analog.com/media/en/training-seminars/tutorials/mt-080.pdf.

Annotation. Kester's mixers and modulators tutorial concerns practical frequency translation and the generation of sum, difference and unwanted mixing products. It supports explanation of idealised and practical mixer behaviour, but a specific installed spur level or image-rejection value requires a measurement under declared drive and termination conditions.

Keysight Technologies. “About Filters (Digital Demod).” 89600 VSA Help, 2026 Update 2.0. Accessed November 2, 2026. https://helpfiles.keysight.com/csg/89600B/Webhelp/Subsystems/digdemod/content/digdemod_about_filters.htm.

Annotation. The glossary uses the distinct measurement and reference filter roles, matched root-raised-cosine composition, roll-off and finite symbol span. No instrument default, edition-independent setting or product-performance claim is added. This measurement reference

Copyright 2026, James M. Atkinson

concerns digitally modulated signals and settings that affect an error-vector or constellation result. Error-vector normalisation, pulse-shaping filters, symbol timing and reference-signal construction must be known before results from two receivers can be compared. A proprietary default or measurement-guide illustration should not be treated as a universal numerical definition. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion.

Keysight Technologies. About Resolution Bandwidth. 89600 VSA Help. Opening definition and comparison of swept analyzers with the 89600 VSA. 2026 Update 2.0. Accessed November 1, 2026. https://helpfiles.keysight.com/csg/89600B/Webhelp/Subsystems/gui/content/rbw_about_rbw.htm.

Annotation. The 89600 VSA help entry describes resolution-bandwidth conventions in the identified software analysis context. Distinguish displayed RBW from equivalent noise bandwidth and from the observation time set by the underlying data record; do not transfer the instrument's software defaults to a swept-filter receiver without qualification.

Keysight Technologies. Digital Modulation in Communications Systems: An Introduction. Application note 5965-7160E. July 5, 2024. Pages 13–14, 38–39,

Copyright 2026, James M. Atkinson

and 41–43. https://www.keysight.com/us/en/assets/7018-09093/application-notes/5965-7160.pdf.

Annotation. This instructional source treats modulation, frequency translation or receiver signal-chain operation through explicit physical relationships. Image frequencies, sidebands, local-oscillator injection and intermediate-frequency filtering have to be checked against the receiver's actual topology. Ideal mixer identities do not establish that a real component is free of compression, leakage, spurs or path-dependent calibration errors. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Keysight Technologies. Keysight X-Series Signal Analyzers: N9069C Noise Figure Measurement Guide. Part N9069-90001. Edition 1, March 2016. https://www.keysight.com/us/en/assets/9018-04256/user-manuals/9018-04256.pdf.

Annotation. The N9069C measurement guide documents operational procedures for noise-figure measurements on the specified analyser family. It can support procedural descriptions and setting conventions, but the validity of a reported device noise figure

Copyright 2026, James M. Atkinson

additionally depends on calibration, source matching, temperature conditions and uncertainty evaluation.

Keysight Technologies. N9000B CXA Signal Analyzer Specification Guide. N9000-90035. Edition 6, May 2024. Page 56, note d. https://www.keysight.com.cn/cn/zh/assets/9018-04781/technical-specifications/9018-04781.pdf.

Annotation. This CXA specification guide is a source for model-specific, revision-specific instrument performance limits, including the qualifications associated with page 56, note d. Treat the published figures as conditional specifications; measurements or extrapolations beyond the stated configuration require separate evidence.

Keysight Technologies. Optimizing RF and Microwave Spectrum Analyzer Dynamic Range. Application note 5968-4545E. December 1, 2017. Pages 2 and 4–8. https://www.keysight.com/zz/en/assets/7018-06813/application-notes/5968-4545.pdf.

Annotation. The dynamic-range application note explains the trade-offs among analyser noise, distortion and operating level. These considerations guide gain and attenuation selection, but an asserted usable dynamic range is meaningful only at a stated reference plane, bandwidth, signal environment and allowable error criterion.

Copyright 2026, James M. Atkinson

Keysight Technologies. Spectrum and Signal Analyzer Measurements and Noise. Application note 5966-4008E. August 21, 2024. Pages 7–10. https://www.keysight.com/us/en/assets/7018-06765/application-notes/5966-4008.pdf.

Annotation. This bibliographic entry identifies a technical work concerned with the subject indicated by its stated title and described scope. For this volume, its relevance must be expressed through the exact equation, definition, test procedure or historical proposition to which the manuscript attaches the reference. A bibliographic listing is not a substitute for checking the relevant passage, its edition, its limiting conditions and the original measurement context. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion.

Keysight Technologies. Swept IMD and IM Spectrum Concepts. E5080B VNA Help. Tone Power Parameters, Intermodulation Distortion Parameters, and Intercept Point Parameters. Accessed November 1, 2026. https://helpfiles.keysight.com/csg/e5080b/Applications/Swept_IMD_and_IM_Spectrum_Concepts.htm.

Annotation. This vector-network-analyser documentation defines swept intermodulation and intercept-point parameter conventions. It is appropriate for explaining the meanings of the displayed metrics and tone powers, but any generalisation to another receiver

Copyright 2026, James M. Atkinson

requires compatible terminations, excitation levels and an independently verified linear operating region.

Keysight Technologies. Third Order Intermodulation Distortion Performance Test. N7875A help. Source isolation and source-harmonic filtering. Accessed November 1, 2026. https://helpfiles.keysight.com/calsoft/N7875A/Help/Content/Performance/TOI_PV.htm.

Annotation. This intermodulation test procedure concerns the isolation of sources and suppression of their harmonics during third-order distortion measurements. The procedure is relevant to separating distortion generated in the device under test from contamination introduced by test generators and combining networks; its numerical conclusions must be tied to the stated setup.

Keysight Technologies. “EVM (Custom IQ).” 89600 VSA Help. 2026 Update 2.0. Accessed November 1, 2026. https://helpfiles.keysight.com/csg/89600B/Webhelp/Subsystems/customIq/content/customiq_symtblerrdata_evm.htm.

Annotation. This measurement reference concerns digitally modulated signals and settings that affect an error-vector or constellation result. Error-vector normalisation, pulse-shaping filters, symbol timing and reference-signal construction must be known before results from two receivers can be compared. A proprietary default or measurement-guide

Copyright 2026, James M. Atkinson

illustration should not be treated as a universal numerical definition. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Keysight Technologies. “EVM Normalization Reference (Digital Demod).” 89600 VSA Help. 2026 Update 2.0. Accessed November 1, 2026. https://helpfiles.keysight.com/csg/89600B/Webhelp/Subsystems/digdemod/content/dlg_digdemod_comp_evmnormref.htm.

Annotation. This measurement reference concerns digitally modulated signals and settings that affect an error-vector or constellation result. Error-vector normalisation, pulse-shaping filters, symbol timing and reference-signal construction must be known before results from two receivers can be compared. A proprietary default or measurement-guide illustration should not be treated as a universal numerical definition. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be

Copyright 2026, James M. Atkinson

repeated with the new values rather than assumed to transfer automatically.

Keysight Technologies. “Spectrum Analyzer.” E505xA Help. “SA Setup Dialog,” detector and video-averaging entries. Accessed October 30, 2026. https://helpfiles.keysight.com/csg/e5055a/Applications/Spectrum_Analyzer.htm.

Annotation. The publication explains analyser operation and measurement settings governing spectral detection, resolution and transient capture. Resolution bandwidth, video filtering, detector mode and acquisition duty cycle can alter a displayed spectrum without changing the external transmitter. A manufacturer’s application note supports stated instrument behaviour but does not certify that a particular survey captured every possible short-duration event. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

MACOM. “Designing with Diodes: Protecting Sensitive Components.” September 2, 2022.

Copyright 2026, James M. Atkinson

https://www.macom.com/updates/articles/2022/designing-with-diodes-protecting.

Annotation. The component or engineering reference concerns protection against excessive RF drive and the nonlinear behaviour inherent in an input limiter. Front-end loss, limiting threshold, recovery time and spectral products should be checked against the actual arrangement before characterising a faint signal. A protection device that prevents damage does not guarantee accurate level measurement or freedom from in-band artefacts. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

MathWorks. “Channelizer.” DSP HDL Toolbox, R2026b documentation. Description and Preserve channel phase parameter. Accessed October 31, 2026. https://www.mathworks.com/help/dsphdl/ref/channelizer.html.

Annotation. This HDL channelizer reference concerns hardware implementation and the preservation of channel phase in the stated processing architecture. The cited interface and parameter description should be used to explain implementation choices, not

Copyright 2026, James M. Atkinson

to assume that an unspecified receiver preserves absolute phase, sample continuity or clock synchronisation.

MathWorks. “dsp.Channelizer.” R2026b documentation. Algorithms: polyphase implementation, maximally decimated channelizer, and non-maximally decimated or oversampled channelizer. Accessed October 31, 2026. https://www.mathworks.com/help/dsp/ref/dsp.channelizer-system-object.html.

Annotation. The dsp.Channelizer documentation distinguishes a polyphase channelizer from its oversampled and maximally decimated configurations. For receiver analysis, record the number of channels, decimation and overlap or oversampling convention before inferring channel bandwidth, sample timing or the continuity of reconstructed outputs.

MathWorks. “Fixed-Point Precision Rules for Avoiding Overflow in FIR Filters.” DSP System Toolbox. R2026b. Signed output intervals and full-precision accumulator settings. Accessed October 31, 2026. https://www.mathworks.com/help/dsp/ug/fixed-point-precision-rules-for-avoiding-overflow-in-fir-filters.html.

Annotation. This lecture or implementation document addresses multirate digital filtering, polyphase decomposition, channelisation and numerical representation. Phase conventions, finite impulse response length, startup state and decimation timing determine whether two computational forms are physically equivalent. Theory-level equivalence

Copyright 2026, James M. Atkinson

must be distinguished from software or FPGA execution whose internal rounding, truncation and control signals differ. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

MathWorks. “Perform Fixed-Point Arithmetic.” Fixed-Point Designer. R2026b. Multiplication, assignment, and explicit conversion rules. Accessed October 31, 2026. https://www.mathworks.com/help/fixedpoint/ug/perform-fixed-point-arithmetic.html.

Annotation. This lecture or implementation document addresses multirate digital filtering, polyphase decomposition, channelisation and numerical representation. Phase conventions, finite impulse response length, startup state and decimation timing determine whether two computational forms are physically equivalent. Theory-level equivalence must be distinguished from software or FPGA execution whose internal rounding, truncation and control signals differ. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. MIT OpenCourseWare. “Lecture 22: Modulated Filter Bank.” 6.341 Discrete-Time Signal Processing. OpenCourseWare 2006 notes for the Fall 2005 course, pp. 1–6. Modulated-bank and polyphase/DFT development; the causal convention in Model 10C is derived explicitly. https://ocw.mit.edu/courses/6-341-discrete-time-signal-processing-fall-2005/9bae63b4a7d9ac6bf534875e13c06ffd_lec22.pdf.

Annotation. This lecture or implementation document addresses multirate digital filtering, polyphase decomposition, channelisation and numerical representation. Phase conventions, finite impulse response length, startup state and decimation timing determine whether two computational forms are physically equivalent. Theory-level equivalence must be distinguished from software or FPGA execution whose internal rounding, truncation and control signals differ. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Copyright 2026, James M. Atkinson

National Institute of Standards and Technology. “Disciplined Oscillator (DO).” Computer Security Resource Center glossary, with NIST IR 8323 Rev. 1 source provenance. Accessed November 2, 2026. https://csrc.nist.gov/glossary/term/disciplined_oscillator_do.

Annotation. Used for reference steering only. The definition does not establish any specific receiver’s frequency, phase-noise, holdover or relock performance. The reference supplies a technical framework for interpreting oscillator stability or correlated phase-noise measurements. Observation interval, averaging statistic, timebase origin and common-clock correlation should be specified before translating a frequency statistic into arrival-time or phase evidence. A nominally stable source can still have an offset or transient recovery event, and averaging may suppress or distort correlated components. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

National Institute of Standards and Technology. “Frequency Stability.” Computer Security Resource Center glossary. Accessed November 2, 2026. https://csrc.nist.gov/glossary/term/frequency_stability.

Annotation. Used for interval dependence and the distinction between frequency stability and closeness to a frequency reference. A stable oscillator can retain an offset. The reference supplies a technical framework for interpreting oscillator stability or correlated phase-noise

Copyright 2026, James M. Atkinson

measurements. Observation interval, averaging statistic, timebase origin and common-clock correlation should be specified before translating a frequency statistic into arrival-time or phase evidence. A nominally stable source can still have an offset or transient recovery event, and averaging may suppress or distort correlated components. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion.

National Institute of Standards and Technology. NIST Digital Library of Mathematical Functions. Equations 5.9.16, 5.9.18, and 5.9.19. Accessed October 30, 2026. https://dlmf.nist.gov/5.9.

Annotation. The NIST Digital Library of Mathematical Functions provides authoritative identities at the particular cited equation numbers in Section 5.9. This entry should support only the mathematical transformations actually dependent on those identities. It is not, by itself, a calibration or validation source for the physical receiver models appearing elsewhere in the volume.

National Institute of Standards and Technology. NIST/SEMATECH e-Handbook of Statistical Methods. Section 2.1.2, "What Is a Check Standard?" Accessed November 1, 2026. https://www.itl.nist.gov/div898/handbook/mpc/section1/mpc12.htm

Copyright 2026, James M. Atkinson

Annotation. This methodological source addresses repeatable measurement comparisons, factor selection, interaction, replication or check-standard control. The relevant forensic application is to distinguish causal changes in a receiver from effects attributable to altered gain, antenna, clock or thermal conditions. Randomisation and documented calibration are important, but no statistical design automatically guarantees representative physical operating conditions. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

National Institute of Standards and Technology. NIST/SEMATECH e-Handbook of Statistical Methods. Section 5.2.1.2, "One Variable at a Time." Accessed November 1, 2026. https://www.itl.nist.gov/div898/handbook/pri/section2/pri212.htm

Annotation. This methodological source addresses repeatable measurement comparisons, factor selection, interaction, replication or check-standard control. The relevant forensic application is to distinguish causal changes in a receiver from effects attributable to altered gain, antenna, clock or thermal conditions. Randomisation and documented calibration are important, but no statistical design automatically

Nelson, Craig W., Archita Hati, and David A. Howe. “Phase Inversion and Collapse of the Cross-Spectral Function.” arXiv:1307.6605v1. July 24, 2013. Extended manuscript, pages 1–3. https://arxiv.org/pdf/1307.6605v1.

Annotation. Nelson, Hati and Howe examine phase inversion and collapse phenomena in cross-spectral processing. This reference is germane to the possibility that averaging complex cross-spectral quantities can conceal contributions; any inference about a real emitter requires calibration of both channels and explicit treatment of sign and phase conventions.

Niknejad, Ali M. Effect of Feedback on Distortion. EECS 142. University of California, Berkeley. Version dated March 30, 2025. Slides 9 and 27. https://rfic.eecs.berkeley.edu/courses/ee142/pdf/module16_distofb.pdf.

Annotation. This bibliographic entry identifies a technical work concerned with the subject indicated by its stated title and described scope. For this volume, its relevance must be expressed through the exact equation, definition, test procedure or historical proposition to which the manuscript attaches the reference. A bibliographic listing is not a substitute for checking the relevant passage, its edition, its limiting conditions and the original measurement context. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

Copyright 2026, James M. Atkinson

Perrott, Michael H. Lecture 8, Noise Figure, Impact of Amplifier Nonlinearities. 6.976 High Speed Communication Circuits and Systems. MIT OpenCourseWare, 2003. Slides 22–35. https://ocw.mit.edu/courses/6-976-high-speed-communication-circuits-and-systems-spring-2003/a3bae9358da0286076b42f98b9dafc20_lec8.pdf.

Annotation. Perrott's lecture material relates receiver noise figure to amplifier nonlinearity and RF-chain design. It can inform the conceptual comparison of noise and large-signal performance, but the presentation is instructional rather than a substitute for testing an installed receiver's noise temperature and intercept behaviour.

Randa, James P. Uncertainties in NIST Noise-Temperature Measurements. NIST Technical Note 1502. March 1998. https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf.

Annotation. Randa's NIST technical note addresses uncertainty associated with noise-temperature measurements. Its contribution is methodological: reported uncertainty must reflect the applicable measurement model and identified systematic and random terms. Do not transfer numerical uncertainties to an unrelated RF installation without reconstructing the relevant uncertainty budget.

Range Commanders Council. Telemetry Standards. IRIG Standard 106-05. Appendix A, “Frequency Considerations for Telemetry.” 2005. https://irig106.org/docs/106-05/appendixA.pdf.

Copyright 2026, James M. Atkinson

Annotation. The source describes relationships among modulation parameters, occupied spectrum and instrument observations. Approximate bandwidth rules depend on the signal model and the chosen significance or emission-mask criterion, rather than constituting exact occupied-band measurements. The chapter should distinguish an engineering estimate from calibrated detection and should state the assumed modulation and detector conventions. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Riley, W. J. Handbook of Frequency Stability Analysis. NIST Special Publication 1065. July 2008. https://nvlpubs.nist.gov/nistpubs/Legacy/SP/nistspecialpublication1065.pdf.

Annotation. Additional glossary scope: section 5.19, printed page 57, distinguishes internal aging from broader frequency drift. No illustrative fit coefficients or equipment results are adopted. The reference supplies a technical framework for interpreting oscillator stability or correlated phase-noise measurements. Observation interval, averaging statistic, timebase origin and common-clock correlation should be specified before translating a frequency statistic into arrival-time or phase evidence. A nominally stable source can still have an offset or transient

Copyright 2026, James M. Atkinson

recovery event, and averaging may suppress or distort correlated components. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

Rohde & Schwarz. R&S ESW EMI Test Receiver User Manual. 1177.6298.02. Version 18, 2025. https://scdn.rohde-schwarz.com/ur/pws/dl_downloads/pdm/cl_manuals/user_manual/1177_6298_01/ESW_UserManual_en_18.pdf.

Annotation. Additional glossary scope: printed pages 225–226 on quasi-peak temporal weighting and its distinction from RMS and sample detection. Model-specific timing and bandwidth defaults are not generalized, and this source use does not assert compliance by an unspecified receiver. The reference concerns apparatus and practices for electromagnetic interference measurements, with detector modes and equipment characteristics set by its identified scope. Quasi-peak, peak and average detection cannot be freely substituted when interpreting short or intermittent disturbances. A scope statement or product manual must not be mistaken for proof of compliance with every clause or correct operation under field conditions. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records.

equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

SciPy Community. “scipy.signal.coherence” and “scipy.signal.csd.” SciPy v1.18.0 reference documentation, definition, csd Notes, and average parameter. Accessed October 31, 2026. https://docs.scipy.org/doc/scipy/reference/generated/scipy.signal.coherence.html; https://docs.scipy.org/doc/scipy/reference/generated/scipy.signal.csd.html.

Annotation. The SciPy coherence and CSD references define their software estimators and the complex cross-spectrum convention. Coherence is a normalised, model-dependent statistical association between two records; it does not prove a common physical emitter. Claims based on numerical output should identify segmentation, overlap, averaging and the handling of complex conjugation.

SciPy Community. “scipy.signal.periodogram.” Official reference documentation, parameters and Notes. Accessed October 30, 2026. https://docs.scipy.org/doc/scipy/reference/generated/scipy.signal.periodogram.html.

Annotation. The publication concerns finite-record spectral estimators, window selection or the statistical relation between channels. Coherent gain, sum-of-squares normalisation, equivalent noise bandwidth, one-sided folding and averaging rule must match the reported spectrum

Copyright 2026, James M. Atkinson

quantity. A narrow display peak or elevated coherence is not by itself source attribution and should be interpreted alongside calibration and observation conditions. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

SciPy Community. “scipy.signal.windows.hann.” Official reference documentation, sym parameter and Notes. Accessed October 30, 2026. https://docs.scipy.org/doc/scipy/reference/generated/scipy.signal.windows.hann.html.

Annotation. The SciPy Hann-window reference distinguishes the symmetric and periodic definitions through its sym parameter. That distinction matters for the finite sum, coherent gain and equivalent noise bandwidth computed from a specified record length; the intended use must be documented rather than inferred from the common name 'Hann'.

SigMF Project. Signal Metadata Format Specification. Version 1.2.6. “Captures Array,” sample_start, datetime, and global_index. Accessed October 31, 2026. https://sigmf.org/.

Copyright 2026, James M. Atkinson

Annotation. The SigMF specification defines metadata constructs for locating capture segments and describing sample start positions, timestamps and indexing. These conventions assist interpretation and exchange of IQ recordings, but their correctness depends on the recorder populating them from trustworthy acquisition evidence rather than inferred file continuity.

SLSA. “Build: Verifying artifacts.” Specification version 1.2. “How to verify” and “Check expectations.” Accessed October 31, 2026. https://slsa.dev/spec/v1.2/verifying-artifacts.

Annotation. The security guidance is relevant to establishing authenticity, build provenance and integrity of software or firmware used in the measurement chain. A valid signature can support a statement about which artifact was approved under a stated trust policy, but cannot independently demonstrate correct signal processing. Release evidence should connect signer identity, digest, build inputs, installed image and measured instrument configuration. A reader should cross-check the cited edition with its chapter-level application and verify that the quoted scope is not broader than the accessible evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Souppaya, Murugiah, Karen Scarfone, and Donna Dodson. Secure Software Development Framework (SSDF) Version 1.1: Recommendations for Mitigating the Risk of Software Vulnerabilities. NIST SP 800-218. February 2022. Tasks PS.2.1 and PS.3.1–PS.3.2. https://doi.org/10.6028/NIST.SP.800-218.

Annotation. The security guidance is relevant to establishing authenticity, build provenance and integrity of software or firmware used in the measurement chain. A valid signature can support a statement about which artifact was approved under a stated trust policy, but cannot independently demonstrate correct signal processing. Release evidence should connect signer identity, digest, build inputs, installed image and measured instrument configuration. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Taylor, Barry N., and Chris E. Kuyatt. Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results. NIST Technical Note 1297. 1994 ed. https://www.nist.gov/pml/nist-technical-note-1297.

Annotation. This metrological guidance concerns the evaluation and reporting of measurement uncertainty, including propagation through a

Copyright 2026, James M. Atkinson

measurement model. Covariance, shared calibration terms, nonlinear transformations and declared coverage factors require attention when evidence from multiple receiver channels is combined. An uncertainty budget is meaningful only for a specified measurand and operating condition; it does not itself certify the authenticity of the underlying acquisition. The bibliography records the source identity, whereas claims of present-day instrument performance still require matching configuration and calibration evidence. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Tektronix. Fundamentals of Real-Time Spectrum Analysis. 37W-17249-4. August 2009. https://download.tek.com/document/37W_17249_4.pdf.

Annotation. Additional glossary scope: printed pages 32–34 on trigger mode, slope, source, external input, full-rate versus decimated trigger location, time qualification and frequency-mask comparison. The existing printed pages 17–18 transient-capture scope remains separately applicable. Historical options, numerical timing specifications and performance guarantees are not adopted as universal receiver capabilities. The publication explains analyser operation and measurement settings governing spectral detection, resolution and transient capture. Resolution bandwidth, video filtering, detector mode and acquisition duty cycle can alter a displayed spectrum without changing the external transmitter. A manufacturer’s application note

Copyright 2026, James M. Atkinson

supports stated instrument behaviour but does not certify that a particular survey captured every possible short-duration event. For the consolidated bibliography, the work supplies a traceable route to a particular technical method or definition used elsewhere in the manuscript.

United States Navy. Navy Electricity and Electronics Training Series, Module 12: Modulation. NAVEDTRA 14184. September 1998. Title and cited excerpts reproduced in SIGINTRADARTSCM.pdf, pages 7254, 7308–7310, and 7349–7354.

Annotation. This Navy training module supplies instructional terminology for modulation and sideband formation. It is a pedagogical foundation for interpreting receiver signals, not an independent validation of a contemporary electronic-surveillance measurement or a claim that a particular device behaves ideally.

United States Navy. Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles. NAVEDTRA 14189. September 1998. Title and receiver-architecture passages reproduced in SIGINTRADARTSCM.pdf, compilation pages 8345 and 8388–8392.

Annotation. This instructional source treats modulation, frequency translation or receiver signal-chain operation through explicit physical relationships. Image frequencies, sidebands, local-oscillator injection and intermediate-frequency filtering have to be checked against the receiver’s actual topology. Ideal mixer identities do not establish that a

Copyright 2026, James M. Atkinson

real component is free of compression, leakage, spurs or path-dependent calibration errors. This volume-level entry serves as a source locator; specific instrument results and measurements must be supported separately by their own test records. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Weatherspoon, Mark H., Lawrence P. Dunleavy, Ali Boudiaf, and James P. Randa. “Vector Corrected Noise Temperature Measurements.” 2002 IEEE MTT-S International Microwave Symposium Digest (2002): 2253–56. https://tsapps.nist.gov/publication/get_pdf.cfm?pub_id=954.

Annotation. Weatherspoon and co-authors present vector-corrected noise-temperature measurement methods, calling attention to complex transfer and mismatch relationships. Use the citation to motivate a vector correction model where applicable, not to claim that a scalar noise reading was automatically corrected for every source or receiver mismatch.

Series Navigation

The following companion-volume titles retain the series reading route. They are navigation references, not evidence that those manuscripts or their current editions were examined for the claims in this volume.

- S001-V009, Antenna Theory for TSCM and Technical Security.
- S001-V010, Survey Antennas, Probes, Fixtures, and Direction-Finding Apparatus.
- S001-V016, EMI, EMC, Shielding, Grounding, Bonding, and Power Integrity.
- S001-V020, Field Operations, Evidence Handling, Chain of Custody, and Litigation Support.
- S001-V024, Series Conventions, Standards, Units, and Citation Practice.
- S001-V038, Spectrum Governance, Frequency Allocation, Intercept Geometry, and RF Survey Doctrine.
- S001-V060, Electromagnetic Scattering, Boundary-Value Fields, Antenna-Medium Coupling, and FFT-Governed RF Inference.
- S001-V074, Monitoring-Receiver Deployment and Survey-Data Governance.
- S001-V087, Conductors, Cabling, Connectors, and Wiring Practice.
- S001-V093, Wave Propagation, Transmission Lines, and Antennas.
- S001-V094, Microwave Principles and Distributed Systems.
- S001-V099, Test, Measurement, and Diagnostic Equipment.
- S001-V100, Radio-Frequency Communications Principles.
- S001-V101, Radar Principles and Measurement.

Copyright 2026, James M. Atkinson

- S001-V104, Test Methods and Measurement Practice.
- S001-V110, SIGINT Collection Architecture, Radar Illumination, and Spectrum Exploitation for Defensive Technical Security.

Volume Subject Index

Each locator gives the opening page of the linked chapter, model, or section.

Absolute sample index: Chapter 10, Model 10E [page 5744]

Absolute-frequency cusp: Chapter 4 [page 1922]

Absolutely continuous phase: Chapter 6, Model 6B [page 3131]

Acceptance Case: Chapter 10, Framework 10F [page 5766]

Acceptance, Maintenance, and Lifecycle Control: Chapter 16 [page 9256]

Accumulator: Chapter 10, Signed formats and explicit conversion points [page 5725]

Acquisition interval: Chapter 1 [page 52]

Acquisition-conditioned metric: Chapter 7, Define the symbol experiment before fitting the constellation [page 3742]

Active symbol rate: Chapter 7, Model 7B [page 3768]

Actual state: Chapter 1 [page 52]

Adaptive control: Chapter 1 [page 52]

Additive white Gaussian noise: Chapter 7, Matched Filtering, Pulse Shaping, and Channel Effects [page 3741]

Additive-power model: Chapter 1, Model 1A [page 72]

Adjacent-channel power: Chapter 7, Error Vector Magnitude and Quality Metrics [page 3762]

Adjustment: Chapter 14, Attach calibration to a stated measurement result [page 8105]

Admissible result set: Chapter 7, Model 7B [page 3768]

Admitted analog band: Chapter 10, Sampling equivalence [page 5789]

Admitted blocker power: Chapter 11, Model 11B [page 6393]

Admitted RF band: Chapter 4 [page 1922]

Copyright 2026, James M. Atkinson

Affine measurement function: Chapter 14, Model 14B [page 8127]

Affine uncertainty propagation: Chapter 14, Model 14B [page 8127]

Aggregate input power: Chapter 3 [page 1247]

Aliasing: Chapter 10 [page 5678]

Alignment training set: Chapter 7, Model 7A [page 3744]

Amplitude Accuracy and Analyzer Self-Tests: Chapter 8 [page 4359]

Amplitude modulation: Chapter 6 [page 3106]

Amplitude Modulation and Envelope Detection: Chapter 6 [page 3106]

Amplitude Response and Linearity: Chapter 14 [page 8103]

Amplitude spectral density: Chapter 9, Noise density uses a different denominator [page 5033]

Analog Demodulator Verification: Chapter 6 [page 3106]

Analog modulation: Chapter 6, Carrier, Sidebands, and Modulation Evidence [page 3107]

Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals: Chapter 6 [page 3106]

Analog multiplier: Chapter 4, Model 4A [page 1924]

Analog-to-digital converter: Chapter 10, SDR Boundary and Partitioning [page 5679]

Analysis channelizer: Chapter 10, Model 10C [page 5703]

Analytic signal: Chapter 4 [page 1922]

Angular frequency: Chapter 6, Model 6B [page 3131]

Antenna factor: Chapter 13 [page 7535]

Antenna pattern: Chapter 13, Measurement Chain Ownership [page 7536]

Antenna terminal plane: Chapter 13, Define a complete path at named planes [page 7537]

Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration: Chapter 13 [page 7535]

Antennas and Field-to-Terminal Conversion: Chapter 13 [page 7535]

Copyright 2026, James M. Atkinson

Anti-alias filter: Chapter 10, Sampling, Aliasing, and Band Selection [page 5680]

Aperture delay: Chapter 12, Model 12A [page 6951]

Aperture jitter: Chapter 12, Clock Jitter and Sampling Uncertainty [page 6969]

Applicability Rationale: Chapter 10, Framework 10F [page 5766]

Architecture map: Chapter 16, Artifact Taxonomy and Competing Explanations [page 9257]

Arithmetic mean: Chapter 8, A stated statistical model [page 4431]

Arithmetic overflow: Chapter 10, Model 10D [page 5722]

Artifact: Chapter 1 [page 52]

Artifact record: Chapter 16, Write findings that preserve the strength and limit of each test [page 9278]

Artifact taxonomy: Chapter 16, Artifact Taxonomy and Competing Explanations [page 9257]

Artifact Taxonomy and Competing Explanations: Chapter 16 [page 9256]

Assembly record: Chapter 13; integrated treatment [page 7535]

Associativity: Chapter 10, Signed formats and explicit conversion points [page 5725]

Asymptotic limit: Chapter 2, Turn the cascade into bounded design requirements [page 675]

Attack time constant: Chapter 5 [page 2512]

Attenuator: Chapter 3, Gain Distribution and Attenuation [page 1256]

Attenuators, Filters, Splitters, and Switches: Chapter 13 [page 7535]

Attribution: Chapter 1 [page 52]

Autocovariance: Chapter 9, Noise density uses a different denominator [page 5033]

Automatic gain control: Chapter 5 [page 2512]

Automatic Gain Control and Hidden State: Chapter 5 [page 2512]

Autospectrum: Chapter 9, Define the ensemble before normalizing [page 5055]

Available noise power: Chapter 2 [page 643]

Copyright 2026, James M. Atkinson

Available source power: Chapter 4 [page 1922]

Average of logarithmic powers: Chapter 8, Noise averages, detector statistics, and the meaning of a decibel trace [page 4429]

Averaging and Statistical Stability: Chapter 9 [page 5024]

Band-limited phase variance: Chapter 12, Model 12B [page 6971]

Band-pass filter: Chapter 3, Front-End Purpose and Architecture [page 1248]

Bandwidth: Chapter 1 [page 52]

Baseband: Chapter 4, Model 4A [page 1924]

Bias current: Chapter 3, Measure protection in the small-signal and recovery states [page 1261]

Bias delivery: Chapter 13, External Preamplifiers, Bias, and Stability [page 7544]

Bias tee: Chapter 13 [page 7535]

Bin-centered tone: Chapter 9, Define the record before interpreting the display [page 5029]

Binary point scaling: Chapter 10, Model 10D [page 5722]

Bit: Chapter 7, Model 7B [page 3768]

Bit error rate: Chapter 7, Application 7A.9 [page 3760]

Bit rate: Chapter 7, Model 7B [page 3768]

Blanking: Chapter 6, Pulse, Radar, and Transient Reception [page 3147]

Blinding: Chapter 16, Challenge-Test Design [page 9258]

Blocker: Chapter 3, Find the first stage that can lose validity [page 1249]

Blocker offset: Chapter 11, Translate one blocker through the fluctuating oscillator [page 6396]

Blocker transfer: Chapter 3; integrated treatment [page 1247]

Blocker-source noise: Chapter 3 [page 1247]

Blocker-to-desired transfer ratio: Chapter 11, Application 11B.6 Move both blocker and desired reference planes [page 6408]

Copyright 2026, James M. Atkinson

Blocker-transfer verification: Chapter 13, Remote amplification requires electrical and installed checks [page 7545]

Blocking: Chapter 11 [page 6359]

Blocking and Reciprocal Mixing: Chapter 11 [page 6359]

Boltzmann constant: Chapter 2, Quantitative Model for Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal [page 659]

Buffer overflow: Chapter 10, Data Transport, Gaps, and Reproducible Recording [page 5743]

Build attestation: Chapter 10, Separate signed artifacts from operating configurations [page 5770]

Byte order: Chapter 10, Separate signed artifacts from operating configurations [page 5770]

Calibrated gain-control response: §5.4 [page 2519]

Calibrated noise source: Chapter 2, Y-Factor and Comparative Noise Measurements [page 656]

Calibration: Chapter 14, Calibration Model and Traceability [page 8104]

Calibration applicability: Chapter 1 [page 52]

Calibration certificate: Chapter 14, Calibration Model and Traceability [page 8104]

Calibration change control: Chapter 14, Calibration Lifecycle and Change Control [page 8125]

Calibration error envelope: Chapter 12, Model 12A [page 6951]

Calibration hierarchy: Chapter 14, Calibration Model and Traceability [page 8104]

Calibration interval: Chapter 12, Model 12A [page 6951]

Calibration Lifecycle and Change Control: Chapter 14 [page 8103]

Calibration Model and Traceability: Chapter 14 [page 8103]

Calibration scope: Chapter 14; integrated treatment [page 8103]

Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty: Chapter 14 [page 8103]

Candidate spur lattice: Chapter 4, Model 4A [page 1924]

Copyright 2026, James M. Atkinson

Capture effect: Chapter 6 [page 3106]

Capture feasibility: Chapter 15, Model 15A [page 8677]

Carrier: Chapter 6, Amplitude Modulation and Envelope Detection [page 3108]

Carrier acquisition: Chapter 7, Carrier and Timing Synchronization [page 3737]

Carrier and Timing Synchronization: Chapter 7 [page 3735]

Carrier phase: Chapter 4, Model 4A [page 1924]

Carrier phase ambiguity: Chapter 7, Application 7A.9 [page 3760]

Carrier power: Chapter 6 [page 3106]

Carrier reinsertion: Chapter 6 [page 3106]

Carrier storage in PIN limiters: §3.8 [page 1261]

Carrier synchronization: Chapter 7, Carrier and Timing Synchronization [page 3737]

Carrier tracking: Chapter 7, Carrier and Timing Synchronization [page 3737]

Carrier, Sidebands, and Modulation Evidence: Chapter 6 [page 3106]

Carson bandwidth estimate: Chapter 6, Model 6B [page 3131]

Cartesian product domain: Chapter 11, Application 11A.9 Propagate calibration bounds with their dependencies [page 6386]

Cascade noise temperature: Chapter 2; Model 2B [page 643]

Cascaded conversion branch: Chapter 4 [page 1922]

Cauchy–Schwarz inequality: Chapter 9, Energy closure and its limits [page 5036]

Causal relationship: Chapter 9, Cross-Spectra, Coherence, and Multichannel Analysis [page 5053]

Ceiling frame count: Chapter 7, Model 7B [page 3768]

Central moment: Chapter 14, Application 14B.10 [page 8141]

Challenge test: Chapter 16 [page 9256]

Copyright 2026, James M. Atkinson

Challenge-Test Design: Chapter 16 [page 9256]

Channel coding: Chapter 7, Model 7B [page 3768]

Channel grid: Chapter 10, Model 10C, Application 10C1 [page 5678]

Channel-power integration: Chapter 8, Resolution Bandwidth and Selectivity [page 4422]

Channel-swap test: Chapter 12, Multichannel Synchronization and Delay Calibration [page 6989]

Characteristic function: Chapter 12, Model 12B [page 6971]

Checksum: Chapter 7, Defensive Interpretation of Digital Signals [page 3763]

Circular buffer: Chapter 15, Trigger Types and Pretrigger Context [page 8695]

Circular complex Gaussian noise: Chapter 8, A stated statistical model [page 4431]

Clipping threshold: Chapter 1, Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse [page 91]

Clock Jitter and Sampling Uncertainty: Chapter 12 [page 6949]

Clock time error: Chapter 12, Model 12A [page 6951]

Closing guard: Chapter 15, Model 15A [page 8677]

Closing verification: Chapter 1 [page 52]

Coaxial transmission mode: Chapter 13, Common-Mode Current and Installed-Path Effects [page 7550]

Code rate: Chapter 7, Model 7B [page 3768]

Code signing: Chapter 10, Separate signed artifacts from operating configurations [page 5770]

Code-center test: Chapter 10, Quantization error model [page 5678]

Coded label bit: Chapter 7, Model 7B [page 3768]

Coefficient quantization: Chapter 10, Model 10D [page 5722]

Coherence: Chapter 9 [page 5024]

Coherence residual: Chapter 9, Paired spectral estimates [page 5024]

Measurement definition: Chapter 1, integrated treatment [page 52]

Measurement error: Chapter 14, Attach calibration to a stated measurement result [page 8105]

Measurement model: Chapter 14 [page 8103]

Measurement uncertainty: Chapter 14, Uncertainty Budgets and Decision Rules [page 8118]

Mechanism prediction: Chapter 16, Challenge-Test Design [page 9258]

Median: Chapter 9, Define the ensemble before normalizing [page 5055]

Memoryless nonlinearity: Chapter 11, Model 11A [page 6367]

Message mean square: Chapter 6 [page 3106]

Message normalization: Chapter 6 [page 3106]

Metadata, Time, and Site Context: Chapter 15 [page 8675]

Metric Validation and Held-Out Data: Chapter 7 [page 3735]

Minimization: Chapter 1 [page 52]

Minimum detectable signal: Chapter 2 [page 643]

Minimum preceding gain: Chapter 2 [page 643]

Minimum trial count: Chapter 15, Model 15A [page 8677]

Mismatch uncertainty: Chapter 14 [page 8103]

Mission Authority and Collection Boundaries: Chapter 1 [page 52]

Mixer: Chapter 4, Frequency Conversion as Multiplication [page 1923]

Copyright 2026, James M. Atkinson

Mixer de-embedding: Chapter 4 [page 1922]

Mixer level: Chapter 8, Swept Architecture and Frequency-Time Mapping [page 4416]

Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses: Chapter 4 [page 1922]

Modular wraparound: Chapter 10, Signed formats and explicit conversion points [page 5725]

Modulating message: Chapter 6, Model 6A [page 3112]

Modulation frequency: Chapter 6 [page 3106]

Modulation index: Chapter 6 [page 3106]

Monotone response: Chapter 5, Model 5A [page 2519]

Monte Carlo propagation: Chapter 14, Use covariance and model sensitivity deliberately [page 8119]

Multichannel Synchronization and Delay Calibration: Chapter 12 [page 6949]

Multipath: Chapter 6, Amplitude Modulation and Envelope Detection [page 3108]

Multiplier normalization: Chapter 4, Model 4A [page 1924]

Multisine: Chapter 14, System-Level Vector Calibration and Uncertainty [page 8145]

Mutual coupling: Chapter 13, Antennas and Field-to-Terminal Conversion [page 7539]

Native record: Chapter 1 [page 52]

Near field: Chapter 13, Antennas and Field-to-Terminal Conversion [page 7539]

Nearest even rounding: Chapter 10, Model 10D, Applications 10D7 and 10D10 [page 5678]

Negative control: Chapter 16, Challenge-Test Design [page 9258]

Negative finding: Chapter 1 [page 52]

Negative frequency: Chapter 4, Model 4A [page 1924]

Negative-peak detector: Chapter 8, Video Bandwidth, Averaging, and Detector Choice [page 4426]

Noise budget: Chapter 2, Model 2B [page 665]

Copyright 2026, James M. Atkinson

Noise factor: Chapter 2 [page 643]

Noise figure: Chapter 2 [page 643]

Noise Figure and Noise Temperature: Chapter 2 [page 643]

Noise Figure and System Sensitivity Calibration: Chapter 14 [page 8103]

Noise floor: Chapter 2, Thermal Noise as a Bandwidth-Dependent Quantity [page 644]

Noise marker: Chapter 8, Noise averages, detector statistics, and the meaning of a decibel trace [page 4429]

Noise parameters: Chapter 13, Treat connections and unused branches as part of the network [page 7548]

Noise power spectral density: Chapter 8, Ten worked applications [page 4437]

Noise rise allowance: Chapter 11, Model 11B [page 6393]

Noise temperature: Chapter 2 [page 643]

Noise-limited sensitivity: Chapter 2 [page 643]

Noise-marker correction: Chapter 8, Noise averages, detector statistics, and the meaning of a decibel trace [page 4429]

Noise-only validation: Chapter 2 [page 643]

Nominal slot grid: Chapter 7, Model 7B [page 3768]

Nonalternating residual: Chapter 5 [page 2512]

Nondispersive delay: Chapter 12, Model 12A [page 6951]

Nonlinear memory: Chapter 11, Measure compression without confusing it with control action [page 6365]

Nonlinear order: Chapter 11, Intermodulation and Intercept Metrics [page 6366]

Nonlinear remainder: Chapter 14, Use covariance and model sensitivity deliberately [page 8119]

Copyright 2026, James M. Atkinson

Nonzero coefficient support: Chapter 10, A continuity condition for finite filtering and decimation [page 5747]

Normalized filter power response: Chapter 11, Integrate the channel that actually produces the reported value [page 6398]

Normalized response error: Chapter 16, Reconcile evidence without assigning unsupported probabilities [page 9276]

Notch filter: Chapter 3 [page 1247]

Null space: Chapter 10, Application 10C9 Critical sampling can retain a complete blind residue [page 5719]

Numerical stability: Chapter 5 [page 2512]

Numerically controlled oscillator: Chapter 10 [page 5678]

Nyquist bin: Chapter 9, Noise density uses a different denominator [page 5033]

Nyquist interval: Chapter 9, Discrete Records and Spectral Estimates [page 5025]

Nyquist zone: Chapter 10, Sampling equivalence, admissible bands, and receiver interpretation [page 5789]

Observation: Chapter 1 [page 52]

Observation limit: Chapter 16, Localize an artifact by changing the stage that could create it [page 9260]

Observation, Classification, Attribution, and Content Recovery: Chapter 1 [page 52]

Observed-time fraction: Chapter 1, Application 1A.10. Separate a valid corrected level from an unobserved transition interval [page 97]

Occupied bandwidth: Chapter 7, Matched Filtering, Pulse Shaping, and Channel Effects [page 3741]

Off-bin tone: Chapter 9, Spectral Leakage and Window Selection [page 5027]

Offset integration band: Chapter 12, Model 12B [page 6971]

One-decibel compression point: Chapter 11, Compression and Gain Change [page 6363]

Copyright 2026, James M. Atkinson

One-sided spectrum: Chapter 9, Noise density uses a different denominator [page 5033]

Open-circuit voltage: Chapter 13, Keep field conversion separate from terminal power [page 7542]

Operating domain: Chapter 1 [page 52]

Operational Decision Discipline: Chapter 1 [page 52]

Operational Sensitivity Verification: Chapter 2 [page 643]

Opposite-sideband leakage: Chapter 6 [page 3106]

Optical isolation comparison: Chapter 13, Common-Mode Current and Installed-Path Effects [page 7550]

Orthogonal frequency-division multiplexing: Chapter 7, Constellations and Symbol Representation [page 3736]

Orthogonality: Chapter 6, Model 6A [page 3112]

Oscillator aging: Chapter 12, Frequency Reference and Tuning Accuracy [page 6950]

Out-of-band signal: Chapter 3, Front-End Purpose and Architecture [page 1248]

Output intercept level: Chapter 11, Construct the intercept from the linear asymptote [page 6373]

Output-added noise: Chapter 2 [page 643]

Overfitting: Chapter 7, Matched Filtering, Pulse Shaping, and Channel Effects [page 3741]

Overlap-corrected throughput: Chapter 7, Model 7B [page 3768]

Overload: Chapter 3, Front-End Purpose and Architecture [page 1248]

Oversampled channelizer: Chapter 10, Model 10C, Applications 10C5, 10C8, and 10C10 [page 5678]

Overshoot: Chapter 5, Model 5A [page 2519]

Packet error rate: Chapter 7, Define the symbol experiment before fitting the constellation [page 3742]

Packet fragmentation: Chapter 10, Source indices, stored offsets, and time anchors [page 5745]

Paired spectral estimate: Chapter 9, Paired spectral estimates [page 5024]

Pairwise power correlation: Chapter 8, Power averaging before the logarithm [page 4434]

Parent-frequency perturbation: Chapter 4 [page 1922]

Parseval identity: Chapter 9, Energy closure and its limits [page 5036]

Passband: Chapter 3, Preselection and Filter State [page 1251]

Passband phase distortion: Chapter 3 [page 1247]

Passband ripple: Chapter 3; Chapter 5 [page 2512]

Passive path loss: Chapter 1 [page 52]

Passive-loss allowance: Chapter 2 [page 643]

Path correction: Chapter 13 [page 7535]

Payload byte rate: Chapter 15, Bind sample continuity, storage accounting and derived results [page 8707]

Payload instance: Chapter 7, Model 7B [page 3768]

Payload-bit fraction: Chapter 7, Model 7B [page 3768]

Peak amplitude: Chapter 4, Model 4A [page 1924]

Peak envelope power: Chapter 6, Model 6A [page 3112]

Peak input power: Chapter 3 [page 1247]

Peak-envelope-to-average-power ratio: Chapter 6, Model 6A [page 3112]

Peak-to-RMS conversion: Chapter 4 [page 1922]

Peak-voltage envelope: Chapter 6, Model 6A [page 3112]

Per-tone power: Chapter 11, Model 11A [page 6367]

Percentile: Chapter 9, Averaging and Statistical Stability [page 5052]

Periodic reduction: Chapter 15, Model 15A [page 8677]

Periodic window convention: Chapter 9, DFT normalization [page 5028]

Copyright 2026, James M. Atkinson

Periodogram: Chapter 9, Noise density uses a different denominator [page 5033]

Phase accumulator: Chapter 10, Application 10B8 Tuning resolution and accumulated phase error [page 5699]

Phase center: Chapter 13, Keep field conversion separate from terminal power [page 7542]

Phase covariance: Chapter 12, Model 12B [page 6971]

Phase excursion: Chapter 6, Model 6B [page 3131]

Phase modulation: Chapter 6 [page 3106]

Phase noise: Chapter 12 [page 6949]

Phase Noise and Close-In Observation: Chapter 12 [page 6949]

Phase remainder bound: Chapter 11, Model 11B [page 6393]

Phase reset: Chapter 6 [page 3106]

Phase reversal and record conjugation: §4.5 [page 1932]

Phase sensitivity: Chapter 6, Model 6B [page 3131]

Phase truncation: Chapter 10, Application 10B8 Tuning resolution and accumulated phase error [page 5699]

Phase-increment alias class: Chapter 6, Model 6B [page 3131]

Phase-increment variance: Chapter 12, Model 12B [page 6971]

Phase-locked loop: Chapter 6, Single Sideband and Coherent Reception [page 3110]

Phase-shift keying: Chapter 7, Constellations and Symbol Representation [page 3736]

Physical temperature: Chapter 2, Model 2B [page 665]

Pilot reference: Chapter 6, Single Sideband and Coherent Reception [page 3110]

PIN diode: Chapter 3, Input Protection and Recovery [page 1260]

Point-observation limit: Chapter 15, Model 15A [page 8677]

Pointwise bound: Chapter 6, Model 6B [page 3131]

Spurious response: Chapter 4 [page 1922]

Spurious-free dynamic range: Chapter 11, Dynamic Range Is a Family of Conditions [page 6360]

Squared window-weight sum: Chapter 9, Define the record before interpreting the display [page 5029]

Squelch: Chapter 6 [page 3106]

Standard deviation: Chapter 8, Power averaging before the logarithm [page 4434]

Standard uncertainty: Chapter 14, Uncertainty Budgets and Decision Rules [page 8118]

State carryover: Chapter 5, Model 5A [page 2519]

State interval: Chapter 1, integrated treatment [page 52]

State mixture: Chapter 8, A stated statistical model [page 4431]

State record: Chapter 13, Define a complete path at named planes [page 7537]

State trajectory: Chapter 5, Model 5A [page 2519]

Copyright 2026, James M. Atkinson

State-conditioned coherence: Chapter 9, Ten worked applications of Equation 18 and its paired-spectrum realization [page 5060]

State-transition record: Chapter 16, Preserve comparable observation capability [page 9266]

Stationarity: Chapter 8, A stated statistical model [page 4431]

Statistical bias: Chapter 8, A stated statistical model [page 4431]

Steady state: Chapter 5, Model 5A [page 2519]

Step attenuator: Chapter 3, Gain Distribution and Attenuation [page 1256]

Step response: Chapter 5, Choose an IF path for the quantity being measured [page 2518]

Step-attenuator repeatability: Chapter 3 [page 1247]

Stepped sweep: Chapter 8, Swept Architecture and Frequency-Time Mapping [page 4416]

Stopband: Chapter 3, Preselection and Filter State [page 1251]

Stopband rejection: Chapter 3 [page 1247]

Stored sample offset: Chapter 10, Model 10E [page 5744]

Stored sample representation: Chapter 15, Wideband Recording and Data Integrity [page 8702]

Strict stationarity: Chapter 11, Application 11B.10 Bound the omitted phase term in the selected channel [page 6415]

Subharmonic: Chapter 4, Local-Oscillator Purity and Leakage [page 1942]

Subjective intelligibility: Chapter 6, Single Sideband and Coherent Reception [page 3110]

Sum product: Chapter 4 [page 1922]

Superheterodyne receiver: Chapter 4, Frequency Conversion as Multiplication [page 1923]

Supply-path confounding: Chapter 13, Remote amplification requires electrical and installed checks [page 7545]

Suppressed carrier: Chapter 6, Amplitude Modulation and Envelope Detection [page 3108]

Sustained write rate: Chapter 15, Wideband Recording and Data Integrity [page 8702]

Copyright 2026, James M. Atkinson

Sweep Method Acceptance: Chapter 8 [page 4359]

Sweep time: Chapter 8 [page 4359]

Sweep Time, Triggering, and Transient Signals: Chapter 8 [page 4359]

Swept Architecture and Frequency-Time Mapping: Chapter 8 [page 4359]

Swept-tuned spectrum analyzer: Chapter 8, Swept Architecture and Frequency-Time Mapping [page 4416]

Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity: Chapter 8 [page 4359]

Switch leakage: Chapter 13, Attenuators, Filters, Splitters, and Switches [page 7547]

Switching mixer: Chapter 4, Frequency Conversion as Multiplication [page 1923]

Switching transient: Chapter 3, Preselection and Filter State [page 1251]

Symbol: Chapter 7, Constellations and Symbol Representation [page 3736]

Symbol rate: Chapter 7, Quantitative Model for Digital Modulation Reception, Synchronization, EVM, and Error Metrics [page 3767]

Symbol timing: Chapter 7 [page 3735]

Symbol, coding and payload rate accounting: Chapter 7 model [page 3735]

Symbol-rate mismatch: Chapter 7, Carrier and Timing Synchronization [page 3737]

Symmetric window convention: Chapter 9, Energy closure and its limits [page 5036]

Synthesizer lock state: Chapter 4, Conversion Gain, Loss, and Calibration [page 1948]

System-level vector calibration: Chapter 14, System-Level Vector Calibration and Uncertainty [page 8145]

Systematic measurement error: Chapter 14, Use covariance and model sensitivity deliberately [page 8119]

Tapered window: Chapter 9, Spectral Leakage and Window Selection [page 5027]

Technical peer review: Chapter 16, Program Governance and Peer Review [page 9281]

Copyright 2026, James M. Atkinson

Temperature contrast: Chapter 2 [page 643]

Temporal correlation: Chapter 16, Integration with Direction, Wireline, Optical, and Physical Evidence [page 9274]

Terminated-input test: Chapter 13, External Preamplifiers, Bias, and Stability [page 7544]

Test oracle: Chapter 10, Choose evidence that can discriminate the required behavior [page 5773]

Thermal drift: Chapter 3, Preselection and Filter State [page 1251]

Thermal emission: Chapter 2, Derive passive loss from thermal equilibrium [page 670]

Thermal equilibrium: Chapter 2 [page 643]

Thermal noise: Chapter 2, Thermal Noise as a Bandwidth-Dependent Quantity [page 644]

Thermal Noise as a Bandwidth-Dependent Quantity: Chapter 2 [page 643]

Time anchor: Chapter 10, Source indices, stored offsets, and time anchors [page 5745]

Time average: Chapter 6, Model 6A [page 3112]

Time basis: Chapter 1 [page 52]

Time difference of arrival: Chapter 12, Multichannel Synchronization and Delay Calibration [page 6989]

Time scale: Chapter 12, Model 12A [page 6951]

Time-Frequency and Nonstationary Methods: Chapter 9 [page 5024]

Time-frequency representation: Chapter 9, Time-Frequency and Nonstationary Methods [page 5071]

Time-qualified trigger: Chapter 15, Trigger Types and Pretrigger Context [page 8695]

Timestamp: Chapter 12, Frequency Reference and Tuning Accuracy [page 6950]

Timing skew: Chapter 12; Chapter 5 [page 2512]

Tone spacing: Chapter 11, Intermodulation and Intercept Metrics [page 6366]

Tone-normalized squared spectrum: Chapter 9, DFT normalization [page 5028]

Trace: Chapter 8, Swept Architecture and Frequency-Time Mapping [page 4416]

Copyright 2026, James M. Atkinson

Trace averaging: Chapter 8, Video Bandwidth, Averaging, and Detector Choice [page 4426]

Traceability: Chapter 14 [page 8103]

Tracking filter: Chapter 3 [page 1247]

Training sequence: Chapter 7, Define the symbol experiment before fitting the constellation [page 3742]

Transfer phase: Chapter 12, Model 12A [page 6951]

Transform length: Chapter 9, Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation [page 5073]

Transient response: Chapter 5, Filter Shape, Selectivity, and Time Response [page 2514]

Transient suppressor: Chapter 3, Input Protection and Recovery [page 1260]

Transient validation: Chapter 8, integrated treatment [page 4359]

Transition width: Chapter 3 [page 1247]

Triangle inequality: Chapter 6, Application 6A.10 [page 3127]

Trigger delay: Chapter 8, Sweep Time, Triggering, and Transient Signals [page 4441]

Trigger holdoff: Chapter 15, Verify the trigger at its actual signal-path location [page 8697]

Trigger hysteresis: Chapter 15, Trigger Types and Pretrigger Context [page 8695]

Trigger latency: Chapter 15, Trigger Types and Pretrigger Context [page 8695]

Trigger path: Chapter 15, Trigger Types and Pretrigger Context [page 8695]

Trigger Types and Pretrigger Context: Chapter 15 [page 8675]

Triggering, Burst Capture, Recording, Metadata, and Reproducibility: Chapter 15 [page 8675]

Trust anchor: Chapter 10, Separate signed artifacts from operating configurations [page 5770]

Tuning word: Chapter 10, Application 10B8 Tuning resolution and accumulated phase error [page 5699]

Twiddle factor: Chapter 10, Causal polyphase grouping and the transform convention [page 5707]

Copyright 2026, James M. Atkinson

Two-point time-constant identification: Chapter 5 [page 2512]

Two-sided spectrum: Chapter 9, Noise density uses a different denominator [page 5033]

Two-tone test: Chapter 3, An acceptance sequence that separates competing failures [page 1266]

Two's complement: Chapter 10, Signed formats and explicit conversion points [page 5725]

Unbiased estimator: Chapter 8, A stated statistical model [page 4431]

Uncertainty and Environmental Noise: Chapter 2 [page 643]

Uncertainty budget: Chapter 14, Uncertainty Budgets and Decision Rules [page 8118]

Uncertainty Budgets and Decision Rules: Chapter 14 [page 8103]

Uncorrelated samples: Chapter 9, Noise density uses a different denominator [page 5033]

Undersampling: Chapter 10, Sampling, Aliasing, and Band Selection [page 5680]

Unequal-tone intermodulation: Chapter 11, Derive the retained spectral amplitudes [page 6370]

Unequal-trial probabilities: Chapter 15, Model 15A [page 8677]

Unexplained signal: Chapter 16 [page 9256]

Uniform phase assumption: Chapter 15, Model 15A [page 8677]

Uniform quantization-error model: Chapter 10, Quantization margin and channel bandwidth [page 5804]

Unique payload position: Chapter 7, Model 7B [page 3768]

Unmeasured spectral contribution: Chapter 12, Model 12B [page 6971]

Unused-port termination: Chapter 13; integrated treatment [page 7535]

Unwrapped phase: Chapter 6, Model 6B; Chapter 5 [page 2512]

Upper sideband: Chapter 6 [page 3106]

Usable acquisition window: Chapter 15, Model 15A [page 8677]

Valid-interval mean power: Chapter 1, Model 1A [page 72]

Variable-gain amplifier: Chapter 3, Gain Distribution and Attenuation [page 1256]

Copyright 2026, James M. Atkinson

Variance: Chapter 8, A stated statistical model [page 4431]

Vector averaging: Chapter 9, Averaging and Statistical Stability [page 5052]

Vector network analyzer: Chapter 3, Measure protection in the small-signal and recovery states [page 1261]

Vector noise correction: Chapter 13, Treat connections and unused branches as part of the network [page 7548]

Verification: Chapter 14, Calibration Model and Traceability [page 8104]

Verification and Maintenance Controls: Chapter 3 [page 1247]

Video bandwidth: Chapter 5; Chapter 8 [page 4359]

Video Bandwidth, Averaging, and Detector Choice: Chapter 8 [page 4359]

Wall-interval payload rate: Chapter 7, Model 7B [page 3768]

Warmup: Chapter 12, Model 12A [page 6951]

Weak-probe challenge: Chapter 11, integrated treatment [page 6359]

Weighted complex correlation: Chapter 7, Model 7A [page 3744]

Weighted reference energy: Chapter 7, Model 7A [page 3744]

White noise: Chapter 2, Power, bandwidth, and the reference plane [page 645]

White-error channel model: Chapter 10, Quantization error model [page 5678]

Wide-sense stationarity: Chapter 11, Define the phase spectrum before converting decibels [page 6394]

Wideband Recording and Data Integrity: Chapter 15 [page 8675]

Window coefficient vector: Chapter 9, Define the record before interpreting the display [page 5029]

Window main lobe: Chapter 9, Spectral Leakage and Window Selection [page 5027]

Window scaling invariance: Chapter 9, Energy closure and its limits [page 5036]

Window sidelobe: Chapter 9, Spectral Leakage and Window Selection [page 5027]

Copyright 2026, James M. Atkinson

Window-weighted mean square: Chapter 9, DFT normalization [page 5028]

Word length: Chapter 10, Signed formats and explicit conversion points [page 5725]

Wrapped-delay ambiguity: Chapter 12, Model 12A [page 6951]

Y-factor: Chapter 2 [page 643]

Y-factor admissible domain: Chapter 2 [page 643]

Y-Factor and Comparative Noise Measurements: Chapter 2 [page 643]

Zero cross-power condition: Chapter 11, Model 11B [page 6393]

Zero padding: Chapter 9, Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation [page 5073]

Zero-difference boundary: Chapter 4 [page 1922]

Zero-mean message: Chapter 6 [page 3106]
